The *Journal of Applied Physics* (ISSN: 0021-8979) is published semimonthly by the American Institute of Physics, 500 Sunnyside Blvd., Woodbury, NY 11797-2999. Second-class postage paid at Woodbury, NY, and additional mailing offices. POSTMASTER: Send address changes to *Journal of Applied Physics*, AIP, 500 Sunnyside Blvd., Woodbury, NY 11797-2999.

© 1994 by the American Institute of Physics.

The *Journal of Applied Physics* is the American Institute of Physics' (AIP) archival journal for significant new results in applied physics. The journal publishes articles that emphasize understanding of the physics underlying modern technology. There are two issues per month. The subject coverage includes, but is not limited to, experimental or theoretical physics applied to all aspects of materials: for example, charge and mass transport, superconductivity, magnetism; surfaces, interfaces, thin films, crystal lattice defects; electrical, optical, magnetic, and structural properties; processing; ion implantation. Materials covered include semiconductors, superconductors, metals and alloys, amorphous materials, and oxides. Other important topics are: electrical, optical, and magnetic devices; optics and lasers; nonlinear optics; electrical discharges; acoustics. The Proceedings of the Annual Conference on Magnetism and Magnetic Materials is a regular feature. *Applied Physics Reviews* is a series of occasional review articles on similar subjects.

Submit manuscripts (3 copies) to Editor, *Journal of Applied Physics,* Argonne National Laboratory, Bldg. 203, Room R-127, 9700 South Cass Avenue, P.O. Box 8296, Argonne, IL 60439-8296.

Subscription Prices* (1994)	U.S.A. & Poss.	Can., Mex., Central & S. Amer. & Caribbean	Foreign Surface Mail	Air Freight — Europe, Asia, Africa & Oceania	Optional Air Freight — Europe, Asia, Africa & Oceania
Members†	$190	$270	$270	-----	$380
Nonmembers	$1655	$1735	-----	$1945‡	-----

*The journal is available on microfiche at $190 per year to members and $1655 per year at the nonmember rate.
†AIP Member and Affiliated Societies. ‡Includes air freight service.

Back-Number Prices: 1994 single copies: $80. Prior to 1994 single copies: $24 for members; $80 for nonmembers. Prices for conference supplements available on request.

Subscription, renewals, and address changes should be addressed to *AIP Circulation and Fulfillment Division (CFD), 500 Sunnyside Blvd., Woodbury, NY 11797-2999.* Allow at least six weeks advance notice. For address changes please send both old and new addresses and, if possible, include a mailing label from a recent issue.

Claims, Single Copy Replacement and Back Volumes: Missing issue requests will be honored only if received within six months of publication date (nine months for Australia and Asia). Single copies of a journal may be ordered and back volumes are available in print or microform. Members—contact AIP Member Services at (516) 576-2288; (800) 344-6901. Nonmember subscribers—contact AIP Subscriber Services at (516) 576-2270; (800) 344-6902.

Page Charge and Reprint Billing: Contact: AIP Publication Page Charge and Reprints—CFD, 500 Sunnyside Blvd., Woodbury, NY 11797-2999; (516) 576-2234; (800) 576-6909.

Copying Fees: Copying of articles beyond that permitted by the Fair Use provisions (Sections 107 and 108) of the U.S. Copyright Law requires payment of fees. The code at the bottom of the first page of each article gives the fee for each copy of the article. Fees should be paid through the *Copyright Clearance Center (CCC), 222 Rosewood Drive, Danvers, MA 01923.* Persons desiring to photocopy materials for classroom use should contact CCC's Academic Permissions Service.

The item-fee code for this publication is 0021-8979/94 $6.00.

Permission For Other Use: Permission is granted to quote from the journal with the customary acknowledgment of the source. To reprint a figure, table, or other excerpt requires in addition the consent of one of the original authors and notification to AIP. Reproduction for advertising or promotional purposes, or republication in any form, is permitted only under license from AIP, which will normally require that the permission of one of the authors also be obtained. Direct inquiries to: Office of Rights and Permissions, American Institute of Physics, 500 Sunnyside Blvd., Woodbury, NY 11797-2999.

Document Delivery: For information on obtaining copies of individual articles, contact AIP Circulation and Fulfillment Division, 500 Sunnyside Blvd., Woodbury, NY 11797-2999; phone: (516) 576-2277; (800) 344-6908; fax: (516) 394-9704; E-mail: elecprod@pinet.aip.org.

Online Availability: Abstracts of journal articles published by the AIP and its Member Societies are available in bibliographic databases on major online hosts. The abstracts are also available in the SPIN database via the AIP online service, PINET (Physics Information Network). PINET also offers Advance Abstracts, a current awareness service with abstracts of research papers up to three months prior to their publication in AIP or Member Society Journals. Call (800) 874-6383 or (516) 576-2262 for further information.

PREFACE

The 6th Joint MMM-INTERMAG Conference was held in the Albuquerque Convention Center, June 20–23, 1994. Continuing a practice inaugurated at the 1993 MMM Conference in Minneapolis, the conference was preceded by a Sunday afternoon tutorial session sponsored by the Education Committee of the IEEE Magnetics Society. This accommodates particularly those attendees staying over the Saturday night before the conference. This year's topic was "Magnetic Multilayers: Fundamental Issues to Applications." The tutorial was particularly timely and played to a standing-room-only audience.

In addition to the usual invited papers, there were eight invited symposia; there were three on topics relating to magnetic and magneto-optic recording, and one each on magnetic microscopy, magnetic aftereffect, giant magnetoresistance, magneto-impedance, and neutron scattering studies of vortex structures in superconductors. There was also an evening panel discussion on units in magnetism. The session was lively, but failed to reach closure.

The conference was a marked success. It was larger than any previous Joint Conference. It was also generally agreed that the program, facilities, and environment were excellent. It was attended by 1227 participants. A total of 1444 abstracts were submitted from 36 countries. Of these, 497 originated in the U.S., 178 were from Japan, 155 from Russia, and 119 were from China (PRC and ROC), accounting for 66% of submissions. The program committee accepted 1048 abstracts (73%) for presentation.

Once again we are publishing, in this volume of the Journal of Applied Physics and in the associated volume of the IEEE Transactions on Magnetics, fully refereed papers based upon the conference presentations. The Transactions volume includes 368 contributed papers and 11 invited papers and constitutes the INTERMAG Proceedings for 1994; the Journal volume includes 280 contributed papers and 47 Invited papers and constitutes the MMM Proceedings for 1994. As usual, all fully paid registrants at the conference receive both volumes. Subscribers to either periodical will receive only the corresponding volume with their subscription. Both volumes contain the complete Table of Contents.

The conference reception at the "Los Amigos Round-Up Ranch" was sold out. Despite heavy rain that kept all activities indoors, this reception was a great success, with perhaps more thorough mingling of attendees than would have occurred in good weather.

Finally, I would like to thank the dedicated and talented volunteers on the Steering Committee and the very professional team of Courtesy Associates personnel for an exceptional job.

Stanley H. Charap
General Chairman
6th Joint MMM-INTERMAG Conference
Carnegie Mellon University
Pittsburgh, Pennsylvania, U.S.A.

 Table of Contents for the Papers Appearing in the *IEEE Transactions on Magnetics*

Hard Magnets: Nitrides, Films, and Ferrites

6035	High field magnetization measurements of Sm_2Fe_{17}, $Sm_2Fe_{17}C_x$, and $Sm_2Fe_{17}C_xH_{5-x}$	O. Isnard, S. Miraglia, M. Guillot, D. Fruchart, K. H. J. Buschow
6038	X-ray structural studies of nitrogen diffusion in Dy_2Fe_{17}	Er. Girt, Z. Altounian, X. Chen, Ming Mao, D. H. Ryan, M. Sutton, J. M. Cadogan
6041	Atomic diffusion mechanism and diffusivity of nitrogen into Sm_2Fe_{17}	Chris N. Christodoulou, Norikazu Komada
6044	Effect of nitrogen on the properties of hard magnets	M. Melamud, L. H. Bennett, R. E. Watson
6047	Theoretical analysis of the spin-density distributions in $Y_2Fe_{17}N_3$ and $Y_2Fe_{17}C_3$	W. Y. Ching, Ming-Zhu Huang, Xue-Fu Zhong
6050	Study on the effect of the previous hydrogenation of the nitride formation of a Sm_2Fe_{17}(4 at. % Nb) alloy	H. W. Kwon, I. R. Harris
6053	The effects of hydrogen disproportionation, desorption, and recombination on the structure and magnetic properties of $Sm_2Fe_{17}N_x$ and $NdFe_{10}Mo_2N_x$ compounds	Jun Yang, Shengzhi Dong, Weihua Mao, Ping Xuan, Yingchang Yang
6056	Phase formation in melt-spun Nd-Fe-Mo-Ti alloys	F. E. Pinkerton, C. D. Fuerst, J. F. Herbst
6059	In-plane magnetized YIG substrates self-biased by SmCo based sputtered film coatings	F. J. Cadieu, H. Hegde, E. Schloemann, H. J. Van Hook
6062	Transverse susceptibility and magnetic anisotropy of CoTi-doped barium hexaferrite single crystals	G. Zimmermann, K. A. Hempel
6065	Preparation of high-coercivity fine barium ferrite powder	W. A. Kaczmarek, B. W. Ninham
6068	Nitriding studies of aligned high anisotropy $ThMn_{12}$-type $NdFe_{11}Co_{1-y}Mo_yN$ film samples (abstract)	A. Navarathna, P. Samarasekara, H. Hegde, R. Rani, F. J. Cadieu

Magnetic Anisotropy in Thin Films and Multilayers

6069	Theoretical predictions of interface anisotropy in the presence of interdiffusion (invited)	J. M. MacLaren, R. H. Victora
6075	Magnetic anisotropy of metal/Co/metal and metal/Co/insulator sandwiches	Michael H. Wiedmann Brad N. Engel, Charles M. Falco
6078	Effect of submonolayer coverage on magnetic anisotropy of ultrathin cobalt films M/Co/Au(111) with M=Au, Cu Pd	P. Beauvillain, A. Bounouh, C. Chappert, R. Mégy, S. Ould-Mahfoud, J. P. Renard, P. Veillet, D. Weller, J. Corno
6081	Effects of Ar-ion implantation and annealing on structural and magnetic properties of Co/Pd multilayers	John Q. Xiao, K. Liu, C. L. Chien, L. F. Schelp, J. E. Schmidt
6084	Sputtering pressure effects and temperature-dependent magnetism of Co/Pd multilayers	S. Y. Jeong, Z. S. Shan, P. He, J. X. Shen, Y. B. Zhang, J. A. Woollam, D. J. Sellmyer
6087	Magnetoelastic effect in Co/Pd multilayer films	Young-Suk Kim, Sung-Chul Shin
6090	Interface processing in multilayer films	R. J. Pollard, M. J. Wilson, P. J. Grundy
6093	Anomalous interface magnetism in ultrathin Co films with in-plane anisotropy	F. O. Schumann, M. E. Buckley, J. A. C. Bland

(Continued)

6096 FMR studies of magnetic properties of Co and Fe thin films on Al_2O_3 and MgO substrates — Yu. V. Goryunov, G. G. Khaliullin, I. A. Garifullin, L. R. Tagirov, F. Schreiber, P. Bödeker, K. Z. Bröhl, Ch. Morawe, Th. Mühge, H. Zabel

6099 The relationship between the microstructure and magnetic properties of sputtered Co/Pt multilayer films (abstract) — Y. H. Kim, Amanda K. Petford-Long, J. P. Jakubovics

6100 Identification of magnetoelastic and magnetocrystalline anisotropy contributions in ultrathin epitaxial Co(110) films (abstract) — J. Fassbender, Ch. Mathieu, B. Hillebrands, G. Güntherodt, R. Jungblut, M. T. Johnson

Coupling and Transport in Unusual Systems

6101 Nature of half-metallic ferromagnets: Transport studies — J. S. Moodera, D. M. Mootoo

6104 Magnetoresistance and magnetic properties of NiFe/oxide/Co junctions prepared by magnetron sputtering — T. S. Plaskett, P. P. Freitas, N. P. Barradas, M. F. da Silva, J. C. Soares

6107 Changes in resistivity behavior of metallic glass $Fe_{70}Ni_{12}B_{16}Si_2$ due to molybdenum substitution for nickel — A. K. Bhatnagar, B. Seshu, K. D. D. Rathnayaka, D. G. Naugle

6110 Anisotropic magnetism and resistivity of an $Al_{70}Ni_{15}Co_{15}$ decagonal quasicrystal — J. T. Markert, J. L. Cobb, W. D. Bruton, A. K. Bhatnagar, D. G. Naugle, A. R. Kortan

6113 Mössbauer effect investigation of the pentagonal approximant phase in the Fe-Nb system — R. A. Dunlap, J. Kyriakidis, M. Yewondwossen

6116 Short period oscillations in the Kerr effect of 4*d*- and 5*d*-transition metal wedges on Co films (invited) (abstract) — A. Carl, D. Weller

6117 Magnetoresistance of CuNiCo ternary alloys (abstract) — R. S. Beach, D. Rao, A. E. Berkowitz

Kondo, Mixed Valence, and Heavy Fermions I

6118 Enhancement of the localized behavior in $CeNi_{0.8}Pt_{0.2}$ Kondo compound replacing Ce by magnetic ions (Pr,Nd) — J. C. Gómez Sal, J. A. Blanco, J. I. Espeso, J. Rodríguez Fernández, D. Gignoux

6121 Low-temperature phase diagram of YbBiPt — R. Movshovich, A. Lacerda, P. C. Canfield, J. D. Thompson, Z. Fisk

6124 Quadrupolar effects in $PrCu_2Si_2$ — R. Osborn, E. A. Goremychkin

6127 Mixed valence in a generalized Hubbard model — A. N. Kocharian, G. R. Reich

6130 Consequences of competing hybridization for magnetic ordering in correlated-electron lattices — Carlos Sanchez-Castro, Bernard R. Cooper, Kevin S. Bedell

6133 Antiferromagnetic order in superconducting UPt_3: An x-ray magnetic scattering study (invited) — E. D. Isaacs, P. Zschack, A. P. Ramirez, C. S. Oglesby, E. Bucher

6137 Non-Fermi liquid ground states in strongly correlated *f*-electron materials (invited) (abstract) — M. B. Maple

6137 Magneto-oscillatory phenomena in highly correlated metals (invited) (abstract) — S. R. Julian, G. J. McMullan, C. Pfleiderer, F. S. Tautz, G. G. Lonzarich

Novel Hard Magnets

6138 New rare-earth intermetallic phases $R_3(Fe,M)_{29}X_n$: (R=Ce, Pr, Nd, Sm, Gd; M=Ti, V, Cr, Mn: and X=H, N, C) (invited) — J. M. Cadogan, Hong-Shuo Li, A. Margarian, J. B. Dunlop, D. H. Ryan, S. J. Collocott, R. L. Davis

6144 Structural and magnetic properties of $R_3(Fe,T)_{29}$ compounds — C. D. Fuerst, F. E. Pinkerton, J. F. Herbst

6147 Magnetic and crystal structure of the novel compound $Nd_3Fe_{29-x}Ti_x$ — Z. Hu, W. B. Yelon

6150 Magnetic properties of interstitially modified $Nd_3(Fe,Ti)_{29}X_y$ compounds (X=H, C, and N) — D. H. Ryan, J. M. Cadogan, A. Margarian, J. B. Dunlop

(Continued)

6153 Phase equilibria in the Fe-rich corner of the Nd-Fe-Ti ternary alloy system at 1100 °C — A. Margarian, J. B. Dunlop, R. K. Day, W. Kalceff

6156 Magnetic properties of $Sm_2Fe_{14-x}Co_xSi_2$-based quasiternary compounds — F.-M. Yang, W. Gong, G. C. Hadjipanayis

6159 Mössbauer study of permanent-magnet :naterials: $Sm_2Fe_{17-x}Al_x$ compounds — I. A. Al-Omari, S. S. Jaswal, A. S. Fernando, D. J. Sellmyer

6162 Neutron diffraction and magnetic studies of $Nd_2Fe_{17-x-z}Al_xSi_z$ — Z. Hu, W. B. Yelon

6165 New magnetic material based on $SmCo_4B$ — Hideaki Ido, Osamu Nashima, Takehiro Takahashi, Kiwamu Oda, Kiyohiro Sugiyama

Macroscopic Quantum Tunneling/Spin Glasses

6168 Dissipation in macroscopic quantum tunneling and coherence in magnetic particles (invited) — Anupam Garg

6174 Evidence for quantum mesoscopic tunneling in rare-earth layers — M. J. O'Shea, P. Perera

6177 Bloch states of a Bloch wall — Hans-Benjamin Braun, Daniel Loss

6180 Magnetic properties of cubic $R_xY_{1-x}Al_2$ (R=Dy, Tb) intermetallic random anisotropy magnets (invited) — A. del Moral, J. I. Arnaudas, C. de la Fuente, M. Ciria, E. Joven, P. M. Gehring

6186 Correlation decay in low-dimensional spin glasses — A. N. Kocharian, A. S. Sogomonian

6189 Relaxation and spin correlations in ^{119}Sn-doped a-$Fe_{90}Sc_{10}$ — D. Wiarda, D. H. Ryan

6192 Field-dependent susceptibility aging in CuMn spin glasses — P. W. Fenimore, M. B. Weissman

6195 Quantum tunneling in magnetic particles (invited) (abstract) — D. P. DiVincenzo

6196 Remanent magnetization of AgMn spin glasses (abstract) — Emily Engle, E. Dan Dahlberg

6197 Calculated field cooled and zero field cooled magnetizations of the three-dimensional Ising spin glass using Monte Carlo hard-spin mean-field theory (abstract) — Edwin A. Ames, Susan R. McKay

Symposium on Magneto-Impedance

6198 Giant magneto-imoedance and magneto-inductive effects in amorphous alloys (invited) — L. V. Panina, K. Mohri, K. Bushida, M. Noda

6204 Very large magneto-impedance in amorphous soft ferromagnetic wires (invited) — K. V. Rao, F. B. Humphrev, J. L. Costa-Krämer

6209 Sensitive field- and frequency-dependent impedance spectra of amorphous FeCoSiB wire and ribbon (invited) — R. S. Beach, A. E. Berkowitz

Kondo, Mixed Valence, and Heavy Fermions II

6214 Heavy fermion behavior of U_2T_2X compounds — L. Havela, V. Sechovský, P. Svoboda, M. Diviš, H. Nakotte, K. Prokeš, F. R. de Boer, A. Purwanto, R. A. Robinson, A. Seret, J. M. Winand, J. Rebizant. J. C. Spirlet, M. Richter, H. Eschrig

6217 Incommensurate antiferromagnetic phase in UNiGe — V. Sechovský, L. Havela, P. Svoboda, A. Purwanto, Allen C. Larson, R. A. Robinson, K. Prokeš, H. Nakotte, F. R. de Boer, H. Maletta

6220 Magnetic susceptibility and electronic specific heat of Anderson lattice with finite f-band width — Sunil Panwar, Ishwar Singh

6223 Electrical resistivity and thermoelectric power of heavy fermions and mixed-valence systems — Sunil Panwar, Ishwar Singh

(Continued)

6226	Understanding the great range of magnetic ordering behavior in correlated *f*-electron systems	Q. G. Sheng, B. R. Cooper
6229	Discovery of τ=2/9 iock-in in holmium	D. A. Tindall, C. P. Adams, M. O. Steinitz, T. M. Holden

$R_2FE_{14}B$ Hard Magnets and Applications

6232	Die-upset Nd-Fe-Co-B magnets from blends of dissimilar ribbons	C. D. Fuerst, E. G. Brewer
6235	Evidence for reversal by nucleation in RE-Fe-B die-upset magnets	L. Henderson Lewis, Y. Zhu, D. O. Welch
6238	Microstructure and magnetic properties of mechanically alloyed anisotropic Nd-Fe-B	J. Wecker, H. Cerva, C. Kuhrt, K. Schnitzke, L. Schultz
6241	Preparation and transmission electron microscope investigation of sintered $Nd_{15.4}Fe_{75.7}B_{6.7}Cu_{1.3}Nb_{0.9}$ magnets	Johannes Bernardi, Josef Fidler
6244	Fe-Nd-C-based ingot permanent magnets by solid-state transformation	M. Leonowicz, H. A. Davies, S. Wojciechowski
6247	Generation of highly uniform fields with permanent magnets (invited)	M. G. Abele
6253	Fabrication of multipolar magnetic field sources	H. A. Leupold, G. F. McLane
6256	Kinetic studies on solid-HDDR processes in Nd-Fe-B-type alloys	O. Gutfleisch, M. Verdier, I. R. Harris
6259	Study of desorbed hydrogen-decrepitated anisotropic Nd-Fe-B powder using x-ray diffraction	G. P. Meisner, V. Panchanathan
6262	The electrochemical hydrogenation of NdFeB sintered alloys	Kuo En Chang, Garry W. Warren
6265	Relation of remanence and coercivity of Nd,(Dy)-Fe,(Co)-B sintered permanent magnets to crystallite orientation	A. S. Kim, F. E. Camp, H. H. Stadelmaier
6268	Comparison of magnetic methods for the determination of texture of permanent magnets	G. Asti, R. Cabassi, F. Bolzoni, S. Wirth, D. Eckert, P. A. P. Wendhausen, K.-H. Müller
6271	Magnetic-field orientation and coercivity	Brandon Edwards, D. I. Paul

Magnetic Multilayer Coupling

6274	Magnetic structures and interactions in Ho/Y, Ho/Lu, and Ho/Er superlattices (invited)	R. A. Cowley, D. F. McMorrow, A. Simpson, D. Jehan, P. Swaddling, R. C. C. Ward, M. R. Wells
6278	Epitaxial ferromagnetic MnAs thin films grown by molecular-beam epitaxy on GaAs: Structure and magnetic properties	M. Tanaka, J. P. Harbison, M. C. Park, Y. S. Park, T. Shin, G. M. Rothberg
6281	Co/CoAl magnetic superlattices on GaAs	J. De Boeck, C. Bruynseraede, H. Bender, A. Van Esch, W. Van Roy, G. Borghs
6284	Investigations of the interplay between crystalline and magnetic ordering in Fe_3O_4/NiO superlattices	D. M. Lind, J. A. Borchers, R. W. Erwin, J. F. Ankner, E. Lochner, K. A. Shaw, R. C. DiBari, W. Portwine, P. Stoyonov, S. D. Berry
6287	Magnetic characterization of epitaxial $Y_5Fe_6O_{12}/Bi_3Fe_5O_{12}$ and $Y_5Fe_3O_{12}/Eu_1Bi_2Fe_5O_{12}$ heterostructures grown by pulsed laser deposition	B. M. Simion, R. Ramesh, V. G. Keramidas, G. Thomas, E. Marinero, R. L. Pfeffer
6290	Interlayer correlations and helical spin ordering in MnTe/CdTe multilayers (abstract)	V. Nunez, T. M. Giebultowicz, W. Faschinger, G. Bauer, H. Sitter, J. K. Furdyna
6291	Interlayer coupling in antiferromagnetic EuTe/PbTe superlattices (abstract)	T. M. Giebultowicz, V. Nunez, G. Springholz, G. Bauer, J. Chen, M. C. Dresselhaus, J. K. Furdyna
6292	Heat capacity measurements of antiferromagnetic CoO/NiCoO superlattices (abstract)	E. N. Abarra, K. Takano, F. Hellman, A. E. Berkowitz

(Continued)

6293 Exchange coupling, interface structure, and perpendicular magnetic anisotropy in Tb/Fe multilayers (abstract) — J. Tappert, J. Jungermann, B. Scholz, R. A. Brand, W. Keune

6294 Interfacial contributions to magnetic anisotropy in metal/semiconductor systems (abstract) — B. T. Jonker, H. Abad, J. J. Krebs

Fine Particles

6295 The magnetization density profile of a grain boundary in nickel (invited) — M. R. Fitzsimmons, A. Röll, E. Burkel, K. E. Sikafus, M. A. Nastasi, G. S. Smith, R. Pynn

6301 Magnetic and magnetocaloric properties of melt-spun Gd_xAg_{100-x} alloys — C. D. Fuerst, J. F. Herbst, R. K. Mishra, R. D. McMichael

6304 Thickness dependence of the magnetic and electrical properties of $Fe:SiO_2$ nanocomposite films — S. S. Malhotra, Y. Liu, J. X. Shen, S. H. Liou, D. J. Sellmyer

6307 Calculation of magnetic moments in Ho_2C_3 nanocrystals — S. A. Majetich, J. O. Artman, C. Tanaka, M. E. McHenry

6310 Kramers's rate theory, broken symmetries, and magnetization reversal (invited) — Hans-Benjamin Braun

6316 Magnetic properties of nanophase cobalt particles synthesized in inversed micelles — J. P. Chen, C. M. Sorensen, K. J. Klabunde, G. C. Hadjipanayis

6319 Magnetic and structural properties of vapor-deposited Fe-Co alloy particles — S. Gangopadhyay, Y. Yang, G. C. Hadjipanayis, V. Papaefthymiou, C. M. Sorensen, K. J. Klabunde

6322 Extended x-ray-absorption fine-structure studies of heat-treated fcc-$Fe_{50}Cu_{50}$ powders processed via high-energy ball milling — P. Crespo, A. Hernando, A. Garcia Escorial, K. M. Kemner, V. G. Harris

6325 Structure analysis of coprecipitated $ZnFe_2O_4$ by extended x-ray-absorption fine structure — B. Jeyadevan, K. Tohji, K. Nakatsuka

6328 Magnetic anisotropy of small clusters and very thin transition-metal films — H. Dreyssé, J. Dorantes-Dávila, Š. Pick, G. M. Pastor

6331 Structure and magnetic properties of $Nd_2Fe_{14}B$ fine particles produced by spark erosion (abstract) — H. Wan, A. E. Berkowitz

Macroscopic Quantum Tunneling

6332 Thermal equilibrium noise with $1/f$ spectrum in a ferromagnetic alloy: Anomalous temperature dependence — S. Vitale, A. Cavalleri, M. Cerdonio, A. Maraner, G. A. Prodi

6335 Experimental observation of magnetostochastic resonance — A. N. Grigorenko, P. I. Nikitin, A. N. Slavin, P. Y. Zhou

Critical Phenomena, Spin Glasses, and Frustrated Magnets

6338 Critical magnetic susceptibility of gadolinium — R. A. Dunlap, N. M. Fujiki, P. Hargraves, D. J. W. Geldart

6341 Monte Carlo simulation of Ising models with dipole interaction — U. Nowak, A. Hucht

6344 Magnetic phase diagrams of $NdRu_2Si_2$ and $TbRu_2Si_2$ compounds — M. Salgueiro da Silva, J. B. Sousa, B. Chevalier, J. Etourneau

6347 Study of critical properties of the Potts model by the modified variational cumulant expansion method — N. G. Fazleev, Hao Che, J. L. Fry, D. L. Lin

6350 Phase transition in a system of interacting triads — H. T. Diep, D. Loison

6353 Critical behavior of the random Potts model — B. M. Khasanov, S. I. Belov, D. A. Tayurskii

6356 Influence of exchange bond disorder on the magnetic properties of $(Pd_{1-x}Fe_x)_{95}Mn_5$ near T_c — Z. Wang, X. Qi, H. P. Kunkel, Gwyn Williams

6359 Magnetic transitions at high fields in $(Fe,Mn)_3Si$ alloys — H. J. Al-Kanani, J. G. Booth, J. W. Cable, J. A. Fernandez-Baca

6362 Critical behavior of the two-dimensional easy-plane ferromagnet — Alessandro Cuccoli, Valerio Tognetti, Paola Verrucchi, Ruggero Vaia

6365	Magnetic anomaly in insulator-conductor composite materials near the percolation threshold	L. V. Panina, A. S. Antonov, A. K. Sarychev, V. P. Paramonov, E. V. Timasheva, A. N. Lagarikov
6368	Time dependence effects in disordered systems	K. O'Grady, M. El-Hilo, R. W. Chantrell
6371	Magnetization of amorphous $Fe_{0.82}B_{0.18}$ and $Fe_{0.90}Zr_{0.10}$ compounds with additions of Tb	S. J. Clegg, J. H. Purdy, R. D. Greenough, F. Jerems
6374	Magnetic ordering in the three-dimensional site frustrated Heisenberg model	Morten Nielsen, D. H. Ryan, Hong Guo, Martin Zuckermann
6377	Mössbauer measurements of spin correlations in a-$(Fe,Ni)_{90}Zr_9Sn$	D. Wiarda, D. H. Ryan
6380	Study of the spin glass transition of amorphous FeZr alloys using small angle neutron scattering	K. Mergia, S. Messoloras, G. Nicolaides, D. Niarchos, R. J. Stewart
6383	Study of magnetohistory effects in $YFe_{12-x}Mo_x$ (x=1.5–3.0)	Yi-Zhong Wang, Bo-Ping Hu, Gui-Chuan Liu, Lin Song, Kai-Ying Wang, Ji-Fan Hu, Wu-Yan Lai

Symposium on Slow Relaxation/Magnetic Aftereffect

6386	Magnetic viscosity, fluctuation fields, and activation energies (invited)	R. Street, S. D. Brown
6391	Analysis and interpretation of time dependent magnetic phenomena (invited)	L. Folks, R. Street
6396	Ubiquitous nonexponential decay: The effect of long-range couplings? (invited)	E. Dan Dahlberg, D. K. Lottis, R. M. White, M. Matson, E. Engle
6401	Mesoscopic model for the primary response of magnetic materials (invited)	R. V. Chamberlin
6407	Models of slow relaxation in particulate and thin film materials (invited)	R. W. Chantrell, A. Lyberatos, M. El-Hilo, K. O'Grady
6413	Time dependence of switching fields in magnetic recording media (invited)	M. P. Sharrock

Ultrathin Films and Overlayers

6419	Magnetic and structural instabilities of ultrathin Fe(100) wedges (invited)	S. D. Bader, Dongqi Li, Z. Q. Qiu
6425	Magnetic and structural instabilities of ferromagnetic and antiferromagnetic Fe/Cu(100)	Dongqi Li, M. Freitag, J. Pearson, Z. Q. Qiu, S. D. Bader
6428	Impurity hyperfine fields in metastable body centered cubic Co	J. Dekoster, B. Swinnen, M. Rots, G. Langouche, E. Jedryka
6431	Ferromagnetism and growth of Ru monolayers on C(0001) substrates	G. Steierl, R. Pfandzelter, C. Rau
6434	Spin reorientation transition in Ni films on Cu(100)	S. Z. Wu, G. J. Mankey, F. Huang, R. F. Willis
6437	Magnetization-related transport anomalies in metal/ferromagnetic insulator heterostructures	G. M. Roesler, Jr., M. E. Filipkowski, P. R. Broussard, M. S. Osofsky, Y. U. Idzerda
6440	Lorentz electron microscopy studies of magnetization reversal processes in epitaxial Fe(001) films	E. Gu, J. A. C. Bland, C. Daboo, M. Gester, L. M. Brown, R. Ploessl, J. N. Chapman
6443	Magnetic response of ultrathin Fe on MgO: A polarized neutron reflectometry study	S. Adenwalla, Yongsup Park, G. P. Felcher, M. Teitelman
6446	Roughness dependent magnetic hysteresis of a few monolayer thick Fe films on Au(001)	Y.-L. He, G.-C. Wang
6449	Fluctuation effects in ultrathin films	S. T. Chui
6452	Magnetic studies of fcc Co films grown on diamond (abstract)	J. A. Wolf, J. J. Krebs, Y. U. Idzerda, G. A. Prinz

(Continued)

6452 A Monte Carlo study of the temperature dependence of magnetic order on ferromagnetic and antiferromagnetic surfaces: Implications for spin-polarized photoelectron diffraction (abstract) — F. Zhang, S. Thevuthasan, R. T. Scalettar, R. R. P. Singh, C. S. Fadley

X-ray Magneto-optics

6453 X-ray magnetic circular dichroism in the near and extended absorption edge structure (invited) — G. Schütz, P. Fischer, K. Attenkofer, M. Knülle, D. Ahlers, S. Stähler, C. Detlefs, H. Ebert, F. M. F. de Groot

6459 Discussion of the magnetic dichroism in the x-ray resonance scattering — Peter Rennert

6462 Experimental investigation of dichroism sum rules for V, Cr, Mn, Fe, Co, and Ni: Influence of diffuse magnetism — W. L. O'Brien, B. P. Tonner, G. R. Harp, S. S. P. Parkin

6465 Spin-specific photoelectron diffraction using magnetic x-ray circular dichroism — J. G. Tobin, G. D. Waddill, X. Guo, S. Y. Tong

6468 Enhanced magnetic moment and magnetic ordering in MnNi and MnCu surface alloys — W. L. O'Brien, B. P. Tonner

6471 Observation of x-ray magnetic circular dichroism at the Rh $M_{2,3}$ edge in Co-Rh alloys — G. R. Harp, S. S. P. Parkin, W. L. O'Brien, B. P. Tonner

6474 Circular magnetic x-ray dichroism for rare earths — H. König, Xindong Wang, B. N. Harmon, P. Carra

6477 Circular dichroism in core-level photoemission from nonmagnetic and magnetic systems: A photoelectron diffraction viewpoint (abstract) — A. P. Kaduwela, H. Xiao, S. Thevuthasan, C. Westphal, M. A. Van Hove, C. S. Fadley

6477 Elemental determination of the magnetic moment vector (abstract) — H.-J. Lin, G. Meigs, C. T. Chen, Y. U. Idzerda, G. A. Prinz, G. H. Ho

Coupled Multilayers, Thin Films, and GMR

6478 Hybrid NiFeCo-Ag/Cu multilayers: Giant magnetoresistance, structure, and magnetic studies — J. D. Jarratt, J. A. Barnard

6481 Giant magnetoresistance in NiFe-Ag granular alloys — F. Badía, A. Labarta, X. Batlle, M. L. Watson

6484 Anisotropic giant magnetoresistance induced by magnetoannealing in Fe-Ag granular films — J. G. Na, C. T. Yu, X. G. Zhao, W. Y. Lai, H. L. Luo, J. G. Zhao

6487 Influence of microstructure on magnetoresistance of FeAg granular films — Chengtao Yu, Ye Yang, Yuqing Zhou, Shuxiang Li, Wuyan Lai, Zhenxi Wang

6490 Magnetic properties of FeSi-SiO_2 granular films — Z. S. Jiang, X. Ge, J. T. Ji, H. Sang, G. Guo, Y. W. Du, S. Y. Zhang

6493 Hysteresis of binary clusters — Ivo Klik, Jyh-Shinn Yang, Ching-Ray Chang

6496 Some specific features of fine Fe and Fe-Ni particles — Yu. V. Baldokhin, P. Ya. Kolotyrkin, Yu. I. Petrov, E. A. Shafranovsky

6499 Magnetoresistance of the magnetically ordered icosahedral quasicrystals Al-Pd-Mn-B — M. H. Yewondwossen, S. P. Ritcey, Z. J. Yang, R. A. Dunlap

6501 Electrical transport in amorphous Fe-Mn-Zr alloys — V. Srinivas, A. K. Nigam, G. Chandra, D. W. Lawther, M. Yewondwossen, R. A. Dunlap

6504 Field dependence of nuclear magnetic resonance in molecular beam epitaxy grown Co(111)/Cu multilayers — T. Thomson, H. Kubo, J. S. Lord, P. C. Riedi, M. J. Walker

6507 Dependence of giant magnetoresistance in Co/Cu multilayers on the thickness of the Co layers — A. M. Shukh, D. H. Shin, H. Hoffmann

6510 Vertical inhomogeneity of the magnetization reversal in antiferromagnetically coupled Co/Cu multilayers at the first maximum — R. Mattheis, W. Andrä, L. Fritzsch, J. Langer, S. Schmidt

6513 Magnetic and structural studies of sputtered Co/Cu multilayer films — J. D. Kim, Amanda K. Petford-Long, J. P. Jakubovics, J. E. Evetts, R. Somekh

6610	Magnetic states of magnetic multilayers at different fields	P. A. Schroeder, S.-F. Lee, P. Holody, R. Loloee, Q. Yang, W. P. Pratt, Jr., J. Bass
6613	Investigation of the magnetic structures in giant magnetoresistive multilayer films by electron microscopy	L. J. Heyderman, J. N. Chapman, S. S. P. Parkin
6616	Distribution of current in spin valves (abstract)	Bruce A. Gurney, Virgil S. Speriosu, Harry Lefakis, Dennis R. Wilhoit
6616	A comparison of the giant magnetoresistance and anisotropic magnetoresistance in Co/Cu sandwich films (abstract)	B. H. Miller, E. Youjun Chen, Mark Tondra, E. Dan Dahlberg
6617	Enhanced magnetoresistance in chromium doped Fe/Cr multilayers (abstract)	Noa M. Rensing, Bruce M. Clemens
6617	Low field giant magnetoresistance and oscillatory interlayer exchange coupling in polycrystalline and (111)-oriented permalloy/Au multilayers (abstract)	S. S. P. Parkin, T. A. Rabedeau, R. F. C. Farrow, R. Marks
6618	Giant magnetoresistance at low fields in $[(Ni_xFe_{1-x})_yAg_{1-y}]$/Ag multilayers prepared by molecular beam epitaxy (abstract)	R. F. C. Farrow, R. F. Marks, A. Cebollada, M. F. Toney, D. Dobbertin, R. Beyers, S. S. P. Parkin, T. A. Rabedeau
6619	Effects of domains on magnetoresistance (abstract)	Shufeng Zhang, Peter M. Levy

$Fe_{16}N_2$: Giant Moment or Not (Panel Discussion)

6620	The synthesis, structure, and characterization of α''-$Fe_{16}N_2$ (invited)	K. H. Jack
6626	Magnetism of α''-$Fe_{16}N_2$ (invited)	Robert M. Metzger, Xiaohua Bao, Massimo Carbucicchio
6632	The magnetization of bulk $\alpha''Fe_{16}N_2$ (invited)	J. M. D. Coey

(Continued)

6637	Magnetic and Mössbauer studies of single-crystal $Fe_{16}N_2$ and Fe-N martensite films epitaxially grown by molecular beam epitaxy (invited)	Yutaka Sugita, Hiromasa Takahashi, Matahiro Komuro, Katsuya Mitsuoka, Akimasa Sakuma
6642	Magnetic moment of α''-$Fe_{16}N_2$ films (invited)	Migaku Takahashi, H. Shoji, H. Takahashi, H. Nashi, T. Wakiyama, M. Doi, M. Matsui
6648	Enhanced Fe moment in nitrogen martensite and $Fe_{16}N_2$ (invited)	W. E. Wallace, M. Q. Huang
6653	Enhancement of the formation of $Fe_{16}N_2$ on Fe films by Co additions (invited)	Yoshiharu Inoue, Shigeto Takebayashi, Toshio Mukai

Preparation and Physics of Artificially Structured Magnets

6656	Properties and measurement of scanning tunneling microscope fabricated ferromagnetic particle arrays (invited)	A. D. Kent, S. von Molnár, S. Gider, D. D. Awschalom
6661	Magnetic properties of amorphous nanocolumns created by heavy ion irradiation of paramagnetic YCo_2 thin films (invited)	D. Givord, J. P. Nozières, M. Ghidini, B. Gervais, Y. Otani
6667	Magnetic wire and box arrays (invited)	Atsushi Maeda, Minoru Kume, Takashi Ogura, Kazuhiko Kuroki, Takashi Yamada, Madoka Nishikawa, Yasoo Harada
6671	Ferromagnetic filaments fabrication in porous Si matrix (invited)	Sergey A. Gusev, Natalia A. Korotkova, Dmitry B. Rozenstein, Andrey A. Fraerman
6673	Single-domain magnetic pillar array of 35 nm diameter and 65 Gbits/in.^{2} density for ultrahigh density quantum magnetic storage	Stephen Y. Chou, Mark S. Wei, Peter R. Krauss, Paul B. Fischer
6676	Magnetic properties of nanostructured thin films of transition metal obtained by low energy cluster beam deposition	V. Dupuis, J. P. Perez, J. Tuaillon, V. Paillard, P. Mélinon, A. Perez, B. Barbara, L. Thomas, S. Fayeulle, J. M. Gay
6679	Size effects on switching field of isolated and interactive arrays of nanoscale single-domain Ni bars fabricated using electron-beam nanolithography	Mark S. Wei, Stephen Y. Chou

Itinerant Magnetism and Electronic Structure I

6682	Itinerant electron metamagnetism and related phenomena in Co-based intermetallic compounds (invited)	T. Goto, H. Aruga Katori, T. Sakakibara, H. Mitamura, K. Fukamichi, K. Murata
6688	Local and nonlocal density functional studies of FeCr	David J. Singh
6691	Temperature-dependent electronic structure and ferromagnetism of bcc iron	W. Nolting, A. Vega
6694	Theory for itinerant electrons in noncollinear and incommensurate structured magnets (invited)	J. Kübler, L. M. Sandratskii, M. Uhl
6700	Verwey transition in magnetite: Mean-field solution of the three-band model	S. K. Mishra, Z. Zhang, S. Satpathy
6703	Wannier states in magnetite	Trao Her, Carel Boekema
6705	Orbital ordering and magneto-optical effects in CeSb	V. P. Antropov, B. N. Harmon, A. I. Liechtenstein

Hard Magnets I

6708	Magnetic properties of $Sm_2(Fe,V)_{17}N_y$ coarse powder	Shunji Suzuki, Shinya Suzuki, Masahito Kawasaki
6711	Mössbauer study of $R_2Fe_{17}C_x$ (R=Tb,Dy) as-quenched intermetallics compounds	Hua-Yang Gong, Bao-Gen Shen, Lin-Shu Kong, Lei Cao, Wen-Shan Zhan, Zhao-Hua Cheng, Fang-Wei Wang

(Continued)

6714	Magnetic properties of $Tm_2Fe_{17}C_x$ ($0 \leq x \leq 2.8$) compounds prepared by melt spinning	Bao-Gen Shen, Lin-Shu Kong, Lei Cao, Hua-Yang Gong, Fang-Wei Wang, Zhao-Hua Cheng, Jian-Gao Zhao
6717	Kerr microscopy observation of carbon diffusion profiles in $Sm_2Fe_{17}C_x$	J. Zawadzki, P. A. P. Wendhausen, B. Gebel, A. Handstein, D. Eckert, K.-H. Müller
6720	Neutron-diffraction study on the structure of $Nd(TiFe)_{12}N_x$ and $Nd(TiFeCo)_{12}N_x$ alloys	Shu-Ming Pan, Hong Chen, Zu-Xiong Xu, Ru-Zhang Ma, Ji-Lian Yang, Bai-Sheng Zhang, De-Yan Xue, Qiang Ni
6722	Synthesis and magnetic properties of $PrFe_{12-x}Mo_x$ and $PrFe_{12-x}Mo_xN_y$ ($0.5 \leq x \leq 1.0$; $y \approx 1$)	O. Kalogirou, V. Psycharis, L. Saettas, D. Niarchos
6725	Study of permanent magnetic properties of the 1-12 nitrides with Nd and Pr	Ying-Chang Yang, Qi Pan, Ben-Pai Cheng, Xiao-Dong Zhang, Zun-Xiao Liu, Yun-Xi Sun, Sen-Ling Ge
6728	Structural and magnetic properties of $Ce(Fe,M)_{12}N_x$ interstitial compounds, M=Ti, V, Cr, and Mo	Qi Pan, Zun-Xiao Liu, Ying-Chang Yang
6731	Neutron-diffraction and Mössbauer effect study of the $Tb_2Fe_{17-x}Al_x$ solid solutions	G. K. Marasinghe, S. Mishra, O. A. Pringle, Gary J. Long, Z. Hu, W. B. Yelon, F. Grandjean, D. P. Middleton, K. H. J. Buschow
6734	Structure and magnetic anisotropy of $Sm_2Fe_{17-x}Al_xC$ ($x=2$–8) compounds prepared by arc melting	Zhao-Hua Cheng, Bao-Gen Shen, Jun-Xian Zhang, Fang-Wei Wang, Hua-Yang Gong, Wen-Shan Zhan, Jian-Gao Zhao
6737	Uniaxial magnetic anisotropy in Fe-rich 2:17 compounds with *sp* substitutions	R. A. Dunlap, Z. Wang, M. Foldeaki
6740	Magnetic properties of $R_2Fe_{17-x}Ga_x$ compounds (R=Y, Ho)	J. L. Wang, R. W. Zhao, N. Tang, W. Z. Li, Y. H. Gao, F. M. Yang, F. R. de Boer
6743	Magnetic properties of $Sm_2(Fe_{1-x}Ga_x)_{17}$ ($x=0-0.5$) compounds and their nitrides	W.-Z. Li, N. Tang, J.-L. Wang, Fuming Yang, Y. W. Zeng, J. J. Zhu, F. R. de Boer
6746	Structure and magnetic properties of arc-melted $Sm_2(Fe_{1-x}Co_x)_{14}Ga_3C_2$ compounds	Bao-gen Shen, Lin-shu Kong, Fang-wei Wang, Lei Cao, Bing Liang, Zhao-hua Cheng, Hua-yang Gong, Hui-qun Guo, Wen-shan Zhan
6749	Neutron diffraction and Mössbauer effect study of the structure of $DySi_xFe_{11-x}CoN$ alloys	Shu-ming Pan, Hong Chen, Den-ke Liu, Zu-xiong Xu, Ru-zhang Ma, Ji-lian Yang, Bai-sheng Zhang, De-yan Xue, Qiang Ni
6751	A full electron LMTO-ASA study of electronic band structure and magnetic properties for $RFe_{11}TiN_x$ (R=Y, Nd, Sm; $x=0,1$)	W. Y. Hu, J. Z. Zhang, Q. Q. Zheng, C. Y. Pan
6754	Magnetic properties and molecular field theory analysis of $RFe_{10}Mo_2$ alloys	Xie Xu, S. A. Shaheen
6757	Magnetic alignment in powder magnet processing	S. Liu
6760	Sputter synthesis of $TbCu_7$ type Sm(CoFeCuZr) films with controlled easy axis orientation	H. Hegde, P. Samarasekara, R. Rani, A. Navarathna, K. Tracy, F. J. Cadieu
6763	Metastable $Nd_2(Fe_{1-x}Co_x)_{23}B_3$ ($0 \leq x \leq 1.0$) compounds with the 2:23:3-type structure	Bao-gen Shen, Bo Zhang, Fang-wei Wang, Jun-xian Zhang, Bing Liang, Wen-shan Zhan, Hui-qun Guo, Jian-gao Zhao
6766	Magnetic properties of $(Nd_{0.9}R_{0.1})_5Fe_{17}$ with R=Sm, Gd, and Y	Cong-Xiao Liu, Yun-Xi Sun, Zun-Xiao Liu, Chin Lin

(Continued)

6769	New permanent magnetic MnBiDy alloy films	Fang Ruiyi, Fang Qingqing, Zhang Sheng, Peng Chubing, Dai Daosheng

Symposium on Neutron Scattering Studies of Vortex Structures in Superconductors

6772	Neutron scattering studies of the vortex lattice in niobium and 123 superconductors (invited)	N. Rosov, J. W. Lynn, T. E. Grigereit
6778	Vortex structures in $YBa_2Cu_3O_7$ (invited)	B. Keimer, J. W. Lynn, R. W. Erwin, F. Dogan, W. Y. Shih, I. A. Aksay
6784	Small-angle neutron scattering study of the flux-line lattice in a single crystal of $Bi_{2.15}Sr_{1.9}CaCu_2O_{8+x}$ (invited)	M. Yethiraj, H. A. Mook, E. M. Forgan, R. Cubitt, M. T. Wylie, D. M. Paul, S. L. Lee, J. Ricketts, P. H. Kes, K. Mortensen
6788	Neutron diffraction from the vortex lattice in the heavy fermion superconductor UPt_3 (invited) (abstract)	R. N. Kleiman, G. Aeppli, D. J. Bishop, C. Broholm, E. Bucher, N. Stüchelli, U. Yaron, K. N. Clausen, B. Howard, K. Mortensen, J. S. Pedersen
6789	Small angle neutron scattering from the vortex lattice in 2*H*-$NbSe_2$ (invited) (abstract)	P. L. Gammel, U. Yaron, D. A. Huse, R. N. Kleiman, R. Batlogg, C. S. Oglesby, E. Bucher, D. J. Bishop, T. E. Mason, K. Mortensen

Giant Magnetoresistance in Granular Magnetic Systems

6790	Giant magnetoresistance in sputtered Cr-Fe heterogeneous alloy films	K. Takanashi, T. Sugawara, K. Hono, H. Fujimori
6793	Origin of giant magnetoresistance effect in granular thin films	Atsushi Maeda, Minoru Kume, Satoru Oikawa, Kazuhiko Kuroki
6796	Evolution of structure and magnetoresistance in granular Ni(Fe,Co)/Ag multilayers: Dependence on magnetic layer thickness	X. Bian, X. Meng, J. O. Ström-Olsen, Z. Altounian, W. B. Muir, M. Sutton, R. W. Cochrane
6799	Magnetoresistance in (Fe–Co)/Ag films	A. Tsoukatos, D. V. Dimitrov, A. S. Murthy, G. C. Hadjipanayis
6802	Interaction effects and magnetic ordering in GMR alloys	S. J. Greaves, M. El-Hilo, K. O'Grady, M. Watson
6805	Magnetic structure of the spin valve interface	D. M. C. Nicholson, W. H. Butler, X.-G. Zhang, J. M. MacLaren, B. A. Gurney, V. S. Speriosu
6808	Theory of transport in inhomogeneous systems and application to magnetic multilayer systems	W. H. Butler, X.-G. Zhang, D. M. C. Nicholson, J. M. MacLaren
6811	The effect of interactions on GMR in granular solids	M. El-Hilo, K. O'Grady, R. W. Chantrell
6814	Giant magnetoresistance in spinodally decomposed Cu–Ni–Fe films	L. H. Chen, S. Jin, T. H. Tiefel, T. C. Wu
6817	Relaxation of magnetoresistance and magnetization in granular $Cu_{90}Co_{10}$ obtained from rapidly quenched ribbons	P. Allia, C. Beatrice, M. Knobel, P. Tiberto, F. Vinai
6820	Magnetic and magnetotransport properties of granular $Cu_{85}Fe_{15}$ prepared by mechanical alloying	Siddharth S. Saxena, Jinke Tang, Young-Sook Lee, Charles J. O'Connor
6823	Granular giant magnetoresistive materials and their ferromagnetic resonances (abstract)	M. Rubinstein, B. N. Das, N. C. Koon, D. B. Chrisey, J. Horwitz
6824	Magnetoresistance of granular Cu-(Co,Fe) and Cu-Co-B (abstract)	R. v. Helmolt, J. Wecker, K. Samwer

Hard Magnets II

6825	Evolution of recombination in a solid HDDR processed $Nd_{14}Fe_{79}B_7$ alloy	N. Martinez, D. G. R. Jones, O. Gutfleisch, D. Lavielle, D. Peré, I. R. Harris

(Continued)

6828	Effects of HDDR treatment conditions on magnetic properties of Nd-Fe-B anisotropic powders	H. Nakamura, R. Suefuji, S. Sugimoto, M. Okada, M. Homma
6831	The use of polytetrafluoroethylene in the production of high-density bonded Nd-Fe-B magnets	C. Tattam, A. J. Williams, J. N. Hay, I. R. Harris, S. F. Tedstone, M. M. Ashraf
6834	Evidence of domain-wall pinning in W-doped (NdDy)(FeCo)B sintered magnets	T. Y. Chu, T. S. Chin, C. H. Lin, J. M. Yao
6837	Magnetic properties of rare-earth compounds of the $RCo_{10}Mo_2$ type	D. C. Zeng, N. Tang, T. Zhao, Z. G. Zhao, K. H. J. Buschow, F. R. de Boer
6840	Magnetic hardening by crystallization of amorphous precursors using very high heating rates	C. de Julián, J. M. González, C. Morón
6843	Magnetic phase diagrams of YCo_4B-based components	Z. G. Zhao, R. de Boer, K. H. J. Buschow, Y. P. Ge, J. Y. Wang
6846	A systematic study on stability of flux in Nd-Fe-B magnets consolidated by direct joule heating	H. Fukunaga, H. Tomita, M. Wada, F. Yamashita, T. Toshimura
6849	Studies of Mössbauer spectrum on $Sm_2(Fe,Ga)_{17}C_{1.5}$ alloy	Hong Chen, Zu-xiong Xu, Ru-zhang Ma, Shu-ming Pan, Bao-gen Shen, De-yan Xue, Qiang Ni
6851	Low-temperature behavior of thermopower in rare-earth iron borides $R_2Fe_{14}B$ (R=Nd, Sm, Gd, Tb, Dy, Ho, Er)	R. P. Pinto, M. E. Braga, M. M. Amado, J. B. Sousa, K. H. J. Buschow
6853	Effects of field orientation on field uniformity in permanent magnet structures	J. H. Jensen, M. G. Abele
6856	Lightweight, distortion-free access to interiors of strong magnetic field sources	H. A. Leupold, E. Potenziani, II, A. S. Tilak
6859	Laminar construction of spheroidal field sources with distortion-free access	H. A. Leupold, A. S. Tilak, E. Potenziani, II
6862	Effect of magnetization profiles on the torque of magnetic coupling	Der-Ray Huang, Gwo-Ji Chiou, Yeong-Der Yao, Shyh-Jier Wang
6865	A magnetic coupling without parasitic force for measuring devices	Jean-Paul Yonnet, Jérôme Delamare
6868	Accurate determination of permanent magnet motor parameters by digital torque angle measurement	M. A. Rahman, Ping Zhou
6871	A three-material passive *dI/dt* limiter	S. J. Young, F. P. Dawson, A. Konrad
6874	An extended magnet in a passive *dI/dt* limiter	S. J. Young, F. P. Dawson, A. Konrad
6877	Effects of additives on magnetic properties of sheet Sr-Ba ferrite magnets	Young Jei Oh, In Bo Shim, Hyung Jin Jung, Jae Yun Park, Seung Iel Park, Young Rang Um, Young Jong Lee, Seung Wha Lee, Chul Sung Kim

Spin Waves and Other Excitations

6880	Critical scattering of electromagnetic waves on spin fluctuations in nonsaturated magnetic films under acoustic pump	I. E. Dikshtein, R. G. Kryshtal, A. V. Medved
6883	Light scattering from spin waves in MnF_2	M. G. Cottam, V. P. Gnezdilov, H. J. Labbé, D. J. Lockwood
6886	Controlling high frequency chaos in circular YIG films	D. W. Peterman, M. Ye, P. E. Wigen
6889	Study of spin wave resonance in a superconductor with paramagnetic impurities	I. A. Garifullin, Yu. V. Goryunov, G. G. Khaliullin
6892	Two-magnon absorption in Nd_2CuO_4	V. L. Sobolev, Yu. G. Pashkevich, H. L. Huang, I. M. Vitebskii, V. A. Blinkin

(Continued)

6895 Surface precession solitons (surface "Magnetic drops") in uniaxial magnetics (abstract) — Yurij Bespyatykh, Igor Dikshtein, Sergey Nikitov

6895 Nonlinear self-localized surface spin waves in ferromagnets (abstract) — Alan Boardman, Yurij Bespyatykh, Igor Dikshtein, Sergey Nikitov

6896 Spin wave dispersion in ferromagnetic nickel (abstract) — J. M. Rejcek, J. L. Fry, N. G. Fazleev

6897 Ferromagnetic resonance and Brillouin light scattering from epitaxial Fe_xSi_{1-x} films on Si(111) (abstract) — M. Mendik, Z. Frait, H. von Känel, N. Onda

Hyperfine Field, Mössbauer Effect, and NMR

6898 Nuclear secondary echo in ferromagnets caused by quadrupole and Suhl–Nakamura interactions — V. I. Tsifrinovich

6900 A Mössbauer effect study on the acicular cobalt ferrite particles — J. G. Na, D. H. Han, J. G. Zhao, H. L. Luo

6903 X-ray photoelectron spectroscopy and Mössbauer study of $Ho(Fe_{1-x}Mn_x)_2$ compounds — Y. J. Tang, Y. B. Feng, H. L. Luo, S. M. Pan

6906 Hyperfine fields of mercury in single-crystalline cobalt — J. G. Marques, J. G. Correia, A. A. Melo, J. C. Soares, E. Alves, M. F. da Silva

6909 Simulation of nuclear magnetic resonance spin echoes using the Bloch equation: Influence of magnetic field inhomogeneities — J. A. Nyenhuis, O. P. Yee

6912 Correlation of magneto-volume effects and local properties of the Fe_2Ti-laves phase (abstract) — J. Pelloth, R. A. Brand, W. Keune

Symposium on Giant Magnetoresistance in Compounds

6913 Giant magnetoresistance effects in intermetallic compounds (invited) — V. Sechovský, L. Havela, K. Prokeš, H. Nakotte, F. R. de Boer, E. Brück

6919 Giant magnetoresistance related transport properties in multilayers and bulk materials (invited) — H. Sato, H. Henmi, Y. Kobayashi, Y. Aoki, H. Yamamoto, T. Shinjo, V. Sechovsky

6925 Intrinsic giant magnetoresistance of mixed valence La-A-Mn oxide (A=Ca,Sr,Ba) (invited) — R. von Helmolt, J. Wecker, K. Samwer, L. Haupt, K. Bärner

6929 Colossal magnetoresistance in La-Ca-Mn-O ferromagnetic thin films (invited) — S. Jin, M. McCormack, T. H. Tiefel, R. Ramesh

6934 Giant magnetoresistance in *f*-electron systems (invited) (abstract) — Tadao Kasuya, Takashi Suzuki

Superconductivity I

6935 Theory of spin dynamics in the metallic cuprates (invited) — Qimiao Si, Yuyao Zha, K. Levin

6941 Hydrostatic pressure on $HgBa_2CaCu_2O_{6+\delta}$ and $HgBa_2Ca_2Cu_3O_{8+\delta}$ — F. Chen, L. Gao, R. L. Meng, Y. Y. Xue, C. W. Chu

6944 Magnetoconductivity of $Bi_2Sr_2Ca_{1-x}Y_xCu_2O_{8+\delta}$ in fluctuation regime — C. P. Dhard, S. N. Bhatia, P. V. P. S. S. Sastry, J. V. Yakhmi, A. K. Nigam

6947 Straightened voltage effect in high-T_c superconductors — A. Grishin, J. Niska, B. Loberg, H. Weber

6950 Long-time magnetic relaxation measurements on a quench melt growth YBCO superconductor — L. H. Bennett, L. J. Swartzendruber, M. J. Turchinskaya, J. E. Blendell, J. M. Habib, H. M. Seyoum

6953 Surface barriers and two-dimensional-collective pinning in single crystal $Nd_{1.85}Ce_{0.15}CuO_{4-\delta}$ superconductors — F. Zuo, S. Khizroev, Xiuguang Jiang, J. L. Peng, R. L. Greene

6956 On vector generalization of the critical state model for superconducting hysteresis — I. D. Mayergoyz

6959 Proximity effect in MBE-grown superconducting/spin-glass multilayers — Carlos W. Wilks, Brad N. Engel, Charles M. Falco

(Continued)

6962 Heterodyne microwave mixing in a superconducting $YBa_2Cu_3O_{7-x}$ coplanar waveguide circuit containing a single engineered grain boundary junction — R. G. Seed, C. Vittoria, A. Widom

6965 Superconducting $YBa_2Cu_3O_{7-x}/Y_4Ba_3O_9$ multilayers: Field independent critical current and dimensional crossover (abstract) — Jun-Hao Xu, A. M. Grishin, K. V. Rao

6965 Schematic frictional model for interacting vortices in an isotropic superconducting plate (abstract) — J. S. Kouvel, S. J. Park

Magnetic Multilayer Coupling II

6966 Spin-polarized photoemission from quantum well and interface states (invited) — C. Carbone, E. Vescovo, R. Klăsges, W. Eberhardt, O. Rader, W. Gudat

6972 Recent progress in the theory of interlayer exchange coupling (invited) — P. Bruno

6977 Exchange anisotropy in films, and the problem of inverted hysteresis loops — Amikam Aharoni

6980 Ruderman–Kittel–Kasuya–Yosida polarizations in inhomogeneous media — W. Baltensperger, J. S. Helman

6983 Spin reversal in Co/Au(111)/Co trilayers — V. Grolier, J. Ferré, M. Galtier, M. Mulloy

6986 Effect of coupling on magnetic properties of uniaxial anisotropy NiFeCo/TaN/NiFeCo sandwich thin films — T. Yeh, L. Berg, B. Witcraft, J. Falenschek, J. Yue

6989 Antiferromagnetic versus ferromagnetic coupling in Fe/Cr(107) and Cr/Fe(107) — A. Vega, H. Dreyssé, C. Demangeat, A. Chouairi, L. C. Balbás

6992 Influence of Cr growth on exchange coupling in Fe/Cr/Fe(100) (invited) (abstract) — Joseph A. Stroscio, D. T. Pierce, J. Unguris, R. J. Celotta

6993 Exchange magnetic coupling through nonmagnetic insulator spacers (abstract) — Shufeng Zhang

Magnetostriction I

6994 Fabrication of magnetostrictive actuators using rare-earth (Tb,Sm)-Fe thin films (invited) — T. Honda, K. I. Arai, M. Yamaguchi

7000 Preparation and applications of magnetostrictive thin films — E. Quandt, B. Gerlach, K. Seemann

7003 Magnetostriction in TbDyFe thin films — P. J. Grundy, D. G. Lord, P. I. Williams

7006 Application of the ratio d/χ to the investigation of magnetization processes in giant-magnetostrictive materials — A. R. Piercy, S. C. Busbridge, D. Kendall

7009 Magnetization, Young's moduli, and magnetostriction of rare-earth–iron eutectic alloys with $R=Tb_{0.6}Dy_{0.4}$ — A. E. Clark, M. Wun-Fogle, J. P. Teter, J. B. Restorff, S. F. Cheng

7012 Theory of magnetostriction with application to Terfenol-D — R. D. James, D. Kinderlehrer

7015 Recent developments in modeling of the stress derivative of magnetization in ferromagnetic materials — D. C. Jiles, M. K. Devine

7018 Magnetization and magnetostriction curves from micromagnetics — Antonio DeSimone

7021 Magnetostriction of melt-spun Dy-Fe-B alloys — S. H. Lim, T. H. Noh, I. K. Kang, S. R. Kim, S. R. Lee

7024 Magnetic properties and magnetostriction in grain-oriented $(Tb_xDy_{1-x})(Fe_{1-y}Mn_y)_{1.95}$ compounds — .. Kobayashi, I. Sasaki, T. Funayama, M. Sahashi

7027 Stress effect on the magnetization of Dy in the $Dy/DyFe_2$ eutectic — J. P. Teter, S. F. Cheng, J. R. Cullen

7030 Direct measurements of magnetostrictive process in amorphous wires using a scanning tunneling microscope (abstract) — J. L. Costa, J. Nogués, K. V. Rao

7031 Tunable bistability from magnetostriction (abstract) — A. S. Arrott, J.-G. Lee

(Continued)

Itinerant Magnetism and Electronic Structure II

7032	Influence of Stoner-type excitations on the formation of magnetization and magnetic order in disordered metal-metalloid alloys	A. K. Arzhnikov, L. V. Dobysheva, E. P. Yelsukov
7034	Magnetic susceptibility studies in Gd_2CuO_4 below 300 K	J. Mira, J. Castro, J. Rivas, D. Baldomir, C. Vázquez-Vázquez, J. Mahía, A. López-Quintela, D. Fiorani, R. Caciuffo, D. Rinaldi, T. Jones, S. B. Oseroff
7037	Cluster model studies on the electronic and magnetic properties of $LaCo_{13}$ and $La(Fe_xAl_{1-x})_{13}$ alloys	G. W. Zhang, X. G. Gong, Q. Q. Zheng, J. G. Zhao
7040	Structure, transport and thermal properties of UCoGa	A. Purwanto, R. A. Robinson, K. Prokeš, H. Nakotte, F. R. de Boer, L. Havela, V. Sechovský, N. C. Tuan, Y. Kergadallan, J. C. Spirlet, J. Rebizant
7043	The effect of Mn on the magnetic properties of YFe_2	Jian-Wang Cai, Yuan-Bing Feng, He-Lie Luo, Zhi Zeng, Qing-Qi Zheng
7046	Effects of Al substitution in Nd_2Fe_{17} studied by first-principles calculations	Ming-Zhu Huang, W. Y. Ching
7049	Magnetic and crystallographic order in α-manganese	A. C. Lawson, Allen C. Larson, M. C. Aronson, S. Johnson, Z. Fisk, P. C. Canfield, J. D. Thompson, R. B. Von Dreele
7052	Magnetic field dependence of T_c of EuB_6 (abstract)	A. Lacerda, T. Graf, J. L. Sarrao, M. F. Hundley, D. Mandrus, J. D. Thompson, Z. Fisk

Nanocomposite Magnets

7053	Two- and three-dimensional calculation of remanence enhancement of rare-earth based composite magnets (invited)	T. Schrefl, R. Fischer, J. Fidler, H. Kronmüller
7059	Aligned two-phase magnets: Permanent magnetism of the future? (invited)	R. Skomski
7065	Nanocomposite $R_2Fe_{14}B$/Fe exchange coupled magnets	L. Withanawasam, A. S. Murphy, G. C. Hadjipanayis, R. F. Krause
7068	Influence of nitrogen content on coercivity in remanence-enhanced mechanically alloyed Sm-Fe-N	K. O'Donnell, C. Kuhrt, J. M. D. Coey
7071	Coercivity of Ti-modified (α-Fe)-$Nd_2Fe_{14}B$ nanocrystalline alloys	J. M. Yao, T. S. Chin, S. K. Chen
7074	Magnetization processes in remanence enhanced materials (invited) (abstract)	R. Street, P. Allen, J. Ding, E. Feutrill, L. Folks, P. A. I. Smith, R. C. Woodward

Magnetic Multilayer Coupling III

7075	Magnetic order and spin-flop transition in Co-Re multilayers	Z. Tun, W. J. L. Buyers, I. P. Swainson, M. Sutton, R. W. Cochrane
7078	Interlayer exchange coupling versus ferromagnetic layer thickness in asymmetric Co/Ru/Co trilayer films	L. Zhou, Z. Zhang, P. E. Wigen, K. Ounadjela
7081	Magnetic layer thickness dependence of the interlayer exchange coupling in (001) Co/Cu/Co	P. J. H. Bloemen, M. T. H. van de Vorst, M. T Johnson, R. Coehoorn, W. J. M. de Jonge
7084	Cumulative interface roughness and magnetization in antiferromagnetically coupled NiCo/Cu multilayers	X. Meng, X. Bian, R. Abdouche, W. B. Muir, J. O. Ström-Olsen, Z. Altounian, M. Sutton
7087	Coercivity and magnetization process versus dipolar coupling in $Ni_{80}Fe_{20}$/Cu/Co/Cu spin valves	R. Kergoat, J. Miltat, T. Valet, R. Jerome

(Continued)

7090	Observation of large biquadratic coupling of FeCo through Mn (invited) (abstract)	M. E. Filipkowski, C. J. Gutierrez, J. J. Krebs, G. A. Prinz
7091	Magnetic dipole mechanism for biquadratic interlayer coupling (abstract)	S. Demokritov, E. Tsymbal, P. Grünberg, W. Zinn, Ivan K. Schuller
7092	Polarized neutron reflectivity studies of biquadratic coupling in [Fe/Cr] (100) and [Fe/Al] (100) superlattices and films (invited) (abstract)	J. F. Ankner, A. Schreyer H. Zabel, J. A. Borchers, C. F. Majkrzak, M. Schäfer, J. A. Wolf, P. Grünberg, M. E. Filipkowski, C. J. Gutierrez, J. J. Krebs, G. A. Prinz

Critical Phenomena

7093	Monte Carlo histogram calculation of the critical exponents of an $Fe_xMg_{1-x}Cl_2$ Ising model (invited)	Laura Hernández, H. T. Diep
7099	Simultaneous surface and bulk magnetic properties investigations by using simultaneous gamma, x-rays and conversion electron Mössbauer spectroscopy: Method and experimental results	A. S. Kamzin, L. A. Grigor'ev, A. F. Ioffe
7102	Magnetic properties of Fe_xCu_{1-x} granular alloy films	Peng Chubing, Chen Haiying, Li Guozhong, Dai Daosheng
7105	New possibilities offered by high resolution Fourier transform spectroscopy in studying magnetic phase transitions	M. N. Popova
7108	How does mean-field theory work in magnetic multilayer systems?	Xiao Hu, Yoshiyuki Kawazoe
7111	Magnetic properties of the one-dimensional Heisenberg compounds (3-X-anilinium)$_8$[CuCl$_6$]Cl$_4$; X=Br, I	Gayatri Vyas, Leonard W. ter Haar
7114	Comparison of two-dimensional Heisenberg and two-dimensional *XY* model behaviors in Pd(1.2 at. % Fe) films	J. D. McKinley
7117	The effects of frustrated biquadratic interactions on the phase diagrams and criticality of the Blume–Emery–Griffiths model (abstract)	Daniel P. Snowman, Susan P. McKay
7117	Magnetic phase transitions in $CsEr(MoO_4)_2$ and $KDy(MoO_4)_2$-chain-layered Ising compounds (abstract)	E. N. Khats'ko, A. S. Cherny

Superconductivity II

7118	Na-doping effect on the magnetic properties of the YBCO ceramics	T. Nurgaliev, S. Miteva, I. Nedkov, A. Veneva, M. Taslakov
7121	Properties of polycrystalline samples of $Nd_{2-x}Ce_xCuO_{4-y}$ obtained from a sol-gel precursor	V. B. Barbeta, R. F. Jardim, L. Ben-Dor, M. B. Maple
7124	Magnetic ordering of Pr in $Pb_2Sr_2PrCu_3O_8$	W. T. Hsieh, W-H. Li, K. C. Lee, J. W. Lynn, J. H. Shieh, H. C. Ku
7127	Annealing temperature and O_2 partial pressure dependence of T_c in $HgBa_2CuO_{4+\delta}$	Q. Xiong, Y. Cao, F. Chen, Y. Y. Xue, C. W. Chu
7130	Penetration of electromagnetic fields into superconductors with gradual resistive transition	I. D. Mayergoyz
7133	Study of the frequency and low-field dependence of ac susceptibility in YBaCuO	M. Zazo, L. Torres, J. Iñiguez, C. de Francisco, J. M. Muñoz
7136	Effects of Ga doping on the magnetic ordering of Pr in $PrBa_2Cu_3O_7$	W-H. Li, C. J. Jou, S. T. Shyr, K. C. Lee, J. W. Lynn, H. L. Tsay, H. D. Yang
7139	Galvanomagnetic properties of quasi-one-dimensional superconductors	K. Yu. Arutyunov, N. P. Danilova, A. A. Nikolaeva
7142	Remanent magnetization of layered and isotropic superconductors (abstract)	Yu. V. Bugoslavsky, A. A. Minakov, S. I. Vasyurin
7143	Two types of additional maxima in magnetization curves of layered superconductors (abstract)	Yu. V. Bugoslavsky, A. A. Minakov
7143	"Effective radius" of the 4*f* electrons in $REBa_2Cu_3O_7$, RE=Dy, Ho, Er (abstract)	Yu. A. Koksharov, P. K. Silaev
7144	Helicoidal, magnetic vortex in a current-carrying superconductor in a longitudinal magnetic field: New exact solution (abstract)	Yuri A. Genenko

(Continued)

Magnetostriction II

7145 Ga substitution effect on magnetic and magnetostrictive properties of $TbFe_2$ compounds — Y. J. Tang, Y. B. Feng, H. L. Luo, S. M. Pan

7148 Comparison of the dynamic magnetomechanical properties of $Tb_{0.27}Dy_{0.73}Fe_2$ and $Tb_{0.30}Dy_{0.70}Fe_2$ — D. Kendall, A. R. Piercy

7151 Anisotropy in twinned terfenol-D crystals — D. G. Lord, D. Harvey

7154 Device oriented magnetoelastic properties of $Tb_xDy_{1-x}Fe_{1.95}$ (x=0.27, 0.3) at elevated temperatures — K. Prajapati, R. D. Greenough, A. G. Jenner

7157 Influence of hydrogen on the magnetic properties of Terfenol-D — L. Ruiz de Angulo, J. S. Abell, I. R. Harris

7160 Control of Terfenol-D under load — A. G. Jenner, R. D. Greenough, D. Allwood, A. J. Wilkinson

7163 Pressure dependencies of magnetostrictive strain and d coefficient in Terfenol-D after thermal or magnetic annealing — N. Galloway, R. D. Greenough, A. G. I. Jenner, M. P. Schulze

7166 Effect of bias magnetic field on the magnetostrictive vibration of amorphous ribbons — Naoshi Asuke, Tatsuru Namikawa, Yohtaro Yamazaki

IEEE TRANSACTIONS ON

MAGNETICS

NOVEMBER 1994 VOLUME 30 NUMBER 6 IEMGAQ (ISSN 0018-9464)

A PUBLICATION OF THE IEEE MAGNETICS SOCIETY

PART I OF TWO PARTS

Sixth Joint Magnetism and Magnetic Materials—International Magnetics Conference Albuquerque, New Mexico, June 20–23, 1994

Journal of Applied Physics Table of Contents 3774
IEEE Magnetics Society 1994 3791
Conference Organization 3793
Contributors 3794
Preface 3795
Introduction 3796

Symposium on Advanced Magnetic Recording

Outlook for Maintaining Areal Density Growth Rate in Magnetic Recording—*E. Grochowski and D. Thompson* 3797
Design, Fabrication and Testing of Spin-Valve Read Heads for High Density Recording—*C. Tsang, R. Fontana, T. Lin, D. Heim, V. Speriosu, B. Gurney and M. Williams* 3801
Advanced Read Channels for Magnetic Disk Drives—*T. Howell, W. Abbott and K. Fisher* 3807

GMR and Spin Valve Sensors for Magnetic Recording

Application of Giant Magnetoresistive Elements in Thin Film Tape Heads—*W. Folkerts, J. Kools, T. Rijks, R. Coehoorn, M. De Nooijer, G. Somers, J. Ruigrok, and L. Postma* 3813
High Sensitivity, GMR, 1 Micron Wide, End-on, Ganged, Read Head Sensors—*E. Chen, A. Pohm, J. Daughton, J. Brown and W. Black* 3816
Magnetoresistance of Symmetric Spin Valve Structures—*T. Anthony, J. Brug, and S. Zhang* 3819
Micromagnetics of GMR Multilayer Sensors at High Current Densities—*N. Smith* 3822
Size and Self-Field Effects in Giant Magnetoresistive Thin Film Devices—*R. Cross, S. Russek, and S. Sanders, M. Parker, J. Barnard, and S. Hossain* 3825
High Frequency Permeability Measurements On $Ni_{76}Fe_{10}Co_{14}$/Cu Giant Magnetoresistive Multilayers—*W. Doyle, H. Fujiwara, S. Hossain, A. Matsuzono, and M. Parker* 3828
Unshielded Spin-Valve Sensors Exchange-Biased by Thin TbCo Layers—*J. Leal, N. Oliveira, L. Rodrigues, A. Sousa, and P. Freitas* 3831
Magnetoresistance Studies of NiCoO Exchange Biased Spin-valve Structures—*C-L. Lin, J. Sivertsen, and J. Judy* 3834
Highly Sensitive Giant Magnetoresistance in NiFe/(Ni/Fe/Cu)n/NiFe Thin Films—*A. Kouchiyama, T. Miyauchi, and K. Watanabe* 3837

Magnetoresistive Thin Film Recording Heads

Flux-Guided MR Head for Very Low Flying Height—*T. Koshikawa, Y. Ohtsuka, Y. Ikegawa, H. Tanaka, J. Toda, and Y. Mizoshita* 3840
Performance Characteristics of a 4-Terminal Vertical Magnetoresistive/Inductive Head—*T. Shibata, N. Saito, H. Narisawa, Y. Soda, and T. Sekiya* 3843
Electrical Characteristics of a 500 Mb/in^2 Slanted Contact MR Head—*J. Fernandez-de-Castro, P. George and R. Machelski* 3846
Exchange Biasing Schemes for MR Disk Heads—*S. Yuan* 3849
Comparative Experimental Study of Exchange Biased Symmetric and Antisymmetric Dual Magnetoresistive Heads—*I. Trindade and M. Kryder* 3852

Stability and Biasing Characteristics of a Permanent Magnet Biased SAL/MR Device—*S. Liao, T. Torng, and T. Kobayashi* 3855
Numerical Analysis of Sensitivity Distribution for MR Strips Stabilized by Permanent Magnet Films—*K. Kikuchi, T. Kobayashi, T. Kawai, and A. Sakuma* 3858
Study of SAL-Biased MR Heads with Patterned Permanent Magnet Bias—*Y. Guo, J-G. Zhu, and S. Liao* 3861
Design and Fabrication of Unshielded Dual-Element Horizontal MR Heads—*J. Guzman, K. Mountfield, M. Kryder, R. Bojko, and R.E. Jones, Jr.* 3864
Simulation of Micromagnetic and Magnetoresistive Response in a Shielded Permalloy Strip—*T. Koehler* 3867

Inductive Thin Film Recording Heads
Writing Performance of Narrow Gap Heads Made with Sputtered Laminated FeN Materials on 3800 Oe Coercivity Media—*H. Hu, L. Vo, T. Nguyen, N. Robertson, M. Re, and C. Jahnes* 3870
Modeling of Narrow Track Thin Film Write Head Fields—*M. Kryder and W-Y. Lai* 3873
Performance Evaluation of Different Pole Geometries in Thin Film Heads—*S. Batra, A. Torabi, M. Mallary, S. Ramaswamy, and S. Marshall* 3876
The Effect of Rise Time and Field Gradient on Nonlinear Bit Shift in Thin Film Heads—*A. Torabi, M. Mallary, and S. Marshall* 3879
Write Induced Track Misregistration Due to Magnetic Center Shifts in Thin Film Inductive Heads—*M. Salo, Y. Tang, and T. Gallagher* 3882
Inductance Fluctuation, Domain Instability and Popcorn Noise in Thin Film Heads—*F. Liu and M. Kryder* 3885
Stress Effects of Water Sorption in Cure Baked Photoresist Underlayers on the Magnetic Easy Axis of Permalloy Film Overlayers—*P. Kasiraj, C. Moylan, and R. Fontana* 3888
Off-Track Capability of a Pole Trimmed Thin Film Head—*K. Fukuda, M. Sakai, N. Yamanaka, A. Iijima, and M. Matsuzaki* 3891
An Improvement of Thin Film Inductive Heads—*Y. Sakurai, T. Ishiguro, K. Katagiri, T. Kuriyama, and Y. Ichinose* 3894
Perpendicular Contact Recording Head with High Moment Laminated FeAlN/NiFe Pole Tips—*S. Wang, E. Louis, J. Wolfson, R. Anderson and M. Kryder* 3897
Multi-Track Submicron-Width Recording with a Novel Integrated Single Pole Head in Perpendicular Magnetic Recording—*H. Muraoka and Y. Nakamura* 3900

Magnetic Recording Heads
A Thin Film Head for HD-VCRs—*H. Ohmori, T. Yamamoto, M. Shoji, Y. Sugiyama, K. Hayashi, and M. Hayakawa* 3903
Low Inductance Double-Sided Metal-in-Gap Nano Composite Slider Using Fe-Ta-N Magnetic Film System for 250 Mb/in^2 Recording—*R. Goto, T. Kawai, M. Yamazaki, F. Tsuneda, S. Suwabe, I. Sakaguchi, and A. Iwama* 3909
Effects of Nitrogen Content on the Microstructure and Magnetic Properties of FeTaN Films—*J-C. Lin, L-J. Chen, and C-J. Chen* 3912
Microstructure and Magnetic Properties of FeTaN Films—*E. Haftek and J. Barnard* 3915
Electrochemical Corrosion Study of High Moment Thin Film Head Materials—*S. Gangopadhyay, V. Inturi, J. Barnard, M. Parker, H. Saffarian, and G. Warren* 3918
Stress, Microstructure and Materials Reliability of Sputter-Deposited Fe-N Films—*P. Narayan and Y. Kim* 3921
FeSiN Films for a Narrow Track Head—*M. Kadono, T. Yamamoto, M. Michijima, M. Kyoho, T. Matsuda, and T. Muramatsu* 3924
X-ray Diffraction and Magnetic Properties of Rapid Thermal Annealed Sendust Films—*M. Ullah, K. Coffey, M. Parker, and J. Howard* 3927
Thick and Stress-Free Sendust Films on Silicon for Recording Heads Cores—*J. Daval, B. Bechevet, J. Arroyo, B. Valon, M-F. Armand, and H. Joisten* 3930
Correlation between Noise-After-Write and Magnetic Domain Structure Conversions in Thin-Film Heads by Electron Microscopy—*K. Kobayashi* 3933
The Thin Film Head for VCR—*T. Suzuki, I. Abe, T. Mizuguchi, O. Morita, and H. Takino* 3936
Off-Track Characteristics of Laminated Heads in Azimuth Recording—*M. Ura, H. Kobayashi, S. Horibata, K. Sato, and H. Shibata* 3939

Thin Film Magnetic Recording Media

Effect of Cobalt Oxide Addition on Co-Pt Media—*R. Ranjan, M. Lu, T. Yamashita, and T. Chen* 3942
Exchange Anisotropy in Metal-Evaporated Tapes—*G. Bottoni, D. Candolfo, and A. Checchetti* 3945
Interdiffusion and Grain Isolation in Co/Cr Thin Films—*Y. Feng and D. Faughlin, and D. Lambeth* 3948
NiAl Underlayers for CoCrTa Magnetic Thin Films—*L-L. Lee, D. Laughlin, and D. Lambeth* 3951
Effect of Very Thin Cr-Underlayer on the Magnetic and Recording Properties of CoCrTa Thin-Film Media—*B. Lal, M. Tobise, and T. Shinohara* 3954
Advanced Multilayer Thin Films for Ultra-High Density Magnetic Recording Media—*P. Glijer, J. Sivertsen, and J. Judy* 3957
Magnetic Properties and Crystallography of Double-Layer CoCrTa Thin Films with Various Interlayers—*Y. Feng, D. Laughlin, and D. Lambeth* 3960
High Coercivity and Low Noise Media Using Glass Substrate—*X. Tang, B. Reed, R. Zubeck, D. Hollars, and K. Goodson* 3963
A Study of Magnetic Recording Media on Glass Substrates—*S. Duan, B. Zhang, C. Gao, G. Rauch, J. Pressesky, and A. Schwartz* 3966
Relation between Microstructure of Grain Boundary and the Intergranular Exchange in CoCrTa Thin Film for Longitudinal Recording Media—*J. Nakai, E. Kusumoto, M. Kuwabara, T. Miyamoto, M. Visokay, K. Yoshikawa, and K. Itayama* 3969
The Dependence of Compositional Separation on Film Thickness for Co-Cr and Co-Cr-Ta Magnetic Recording Media—*D. Rogers, Y. Maeda, and K. Takei* 3972
Magnetic and Recording Characteristics of Bicrystalline Longitudinal Recording Medium Formed on an MgO Single Crystal Disk Substrate—*M. Futamoto, M. Suzuki, N. Inaba, A. Nakamura, and Y. Honda* 3975
Microstructure and Recording Properties of Bicrystal Disks with GaAs Substrates—*J. Ding and J-G. Zhu* 3978
Coercivity-Gradient Bi-Layered Thin-Film Media for Longitudinal Recording—*B. Lal and T. Shinohara* 3981
Effects of Highly Permeable Keeper Layer on Transition Shifts for Thin Film Media—*G. Mian, P-K. Wang, W. Reed, R. Zubeck, and D. Hollars* 3984
Transition Noise Spectral Measurements in Thin Film Media—*G. Lin and H. Bertram* 3987
The Relationship of Medium Noise to System Error Rate in a PRML Channel—*J. Fitzpatrick, H. Bertram, X. Che, L. Barbosa, and G. Lin* 3990
Texture-Induced Modulation Noise and Its Impact on Magnetic Performance—*E. Wu, J. Peske, and D. Palmer* 3996
Experimental and Micromagnetic Study of Track Edge Noise Reduction Effect in Mutilayer Thin Film Media—*X-G. Ye, T. Lam, and J-G. Zhu* 3999
Interaction Fields and Media Noise in CoPtCr Thin Films—*P. Huang, J. Harrell, M. Parker, and K. Johnson* 4002
Soft Error Rate Dependence on MrT for Thin Film Media—*O. Allegranza and M. Yang* 4005
Effect of Ta on the Structure, Magnetic Properties, and Recording Performance of CoCrTaPt/Cr Thin Film Media—*K. Sin, J. Sivertsen, and J. Judy* 4008
Magnetic Properties and Recording Performance of Multilayer Films of CoCrTa, Co CrPtTa, and CoCrPtTa with CoCrPtB—*L. Song, R. Gardner, S. McLaurin, and M. Sedighi* 4011
Pd/Co Multilayers for Perpendicular Magnetic Recording—*B. Liarson, J. Perez and C. Baldwin* 4014
Polarization-Dependent EXAFS Studies of Chemical and Structural Anisotropy in Sputter-Deposited $Co_{78}Cr_{22}$ Films—*K. Kemner, V. Harris, W. Elam, and J. Lodder* 4017
Soft Magnetic and Crystallographic Properties of $Ni_{81}Fe_{19}/Co_{67}Cr_{33}$ Multilayers as Backlayers in Perpendicular Recording Media—*S. Nakagawa, T. Ichihara, and M. Naoe* 4020
High Coercivity in Co-Cr Films for Perpendicular Recording Perpared by Low Temperature Sputter-Deposition—*N. Honda, J. Ariake, K. Ouchi, and S. Iwasaki* 4023
Oxygen Effect on the Microstructure and Magnetic Properties of Binary CoPt Thin Films for Perpendicular Recording—*T. Hikosaka, T. Komai, and Y. Tanaka* 4026
Micromagnetic Domain Observations of Co-Cr Films by Neutron Scattering—*K. Takei, J. Suzuki, Y. Maeda, and Y. Morii* 4029
High Coercivity FeSmN Thin Films for Longitudinal Magnetic Recording Media—*D. Wang and W. Doyle* 4032
Nanostructures of Sm-Co on Cr Thin Films—*Y. Liu, B. Robertson, Z. Shan, S. Malhotra, M. Yu, S. Renukunta, S. Liou, and D. Sellmyer* 4035

Magnetic Properties and Microstructure of Sputtered CoSm/X(X = Ti,V,Cu and Cr) Thin Films—*Y. Okumura, H. Fujimori, O. Suzuki, N. Hosoya, X. Yang, and H. Morita* 4038
Magnetic Properties of $(Co_{93}Cr_7)$-P-Pt/Cr Thin Films for Longitudinal Magnetic Recording Media—*H. Sohn, S. Seol, T. Kang, K. Shin, T. Lee, and P. Jang* 4041
Effects of CoTi-Doping on Longitudinal Barium Ferrite Thin Film Media—*X. Sui and M. Kryder* 4044
Longitudinal Recording Performance of Sputtered Barium Ferrite Media on a Carbon Rigid Disk Substrate—*S. Rosenblum, H. Hayashi, J. Li, and R. Sinclair* 4047
Temperature and Orientation Effects on the Magnetic Properties of Doped Barium Ferrite Thin Films—*J. Li, R. Sinclair, S. Rosenblum, and H. Hayashi* 4050
Ba Ferrite Thin Films with Large Statuation Magnetization Deposited by Sputtering in Mixture of Xe, Ar, and O_2—*N. Matsushita, K. Noma, and M. Naoe* 4053
Fabrication and Magnetic Studies of (Co,Zn)-Doped γ-Fe_2O_3 Thin Films—*P. Kuo, Y. Yao, J. Chen, C. Lin, Y. Lo, and J. Huang* 4056

Particulate Magnetic Recording Media

An Investigation of the Archivability of Metal Particle Tape—*P. Sides, G. Spratt, and P. Kampf* 4059
Degradation of Passivated Iron Particles in Humid Atmospheres—*C-S. Jung, G. Bond, S. Raghavan, and R. Emrick* 4065
Protection of Fe Pigments with Amine-Quinone Polymers—*D. Nikles, J. Cain, A. Chacko, and R. Webb* 4068
Dispersion Quality of Magnetic Tapes Prepared from a Waterborne Formulation—*S. Cheng, H. Fan, J. Harrell Jr., A. Lane, and D. Nikles* 4071
Thermal Effects in Small Metallic Particles—*R. Veitch, H. Richter, P. Poganiuch, H. Jakusch, and E. Schwab* 4074
Influence of the Doping on the Time-Dependent Magnetic Behaviour of Fine Particles—*G. Bottoni, D. Candolfo, and A. Cecchetti* 4077
Switching Field Characteristics of Individual Iron Particles by MFM—*Y. Luo and J-G. Zhu* 4080
FMR Spectra of Oriented γ-Fe_2O_3, Co-γ-Fe_2O_3, CrO_2 and MP Tapes—*Y. Yu and J. Harrell* 4083
High Speed Coherent Switching Below the Stoner-Wohlfarth Limit—*L. He, W. Doyle and H. Fujiwara* 4086
Magnetization Reversal in Magnetic Tapes with Sequential Field Pulses—*P. Flanders, W. Doyle, and L. Varga* 4089
Hexaferrite Particles Prepared by Sol-Gel Technique—*C. Surig, K. Hempel, and D. Bonnenberg* 4092
Mean Field Interaction and Transverse Susceptibility—*C-R. Chang and J-S. Yang* 4095
Magnetic Thermal Stability of Mn and Co Volume-Doped Acicular Iron Oxide Particles—*D. Han, J. Wang, Y. Feng, H. Luo, and J. Na* 4098
Transverse Susceptibility and Remanence Characteristics of Barium Ferrite Hand Spread Coatings as a Function of Milling Time—*P. Sollis, P. Bissell, and R. Chantrell* 4101
Preparation and Magnetic Properties of (Co,Zn)-Doped γ-Fe_2O_3 Particles—*C. Lin, P. Kuo, J. Chen, and Y. Yao* 4104
Magnetic Properties of Composite Ba-Ferrite Particles Containing α-Fe—*S. Kitahata and M. Kishimoto* 4107
(Ni,Ti), (Ni,Sn) and (Zn,Ti) Substituted Barium Ferrite Particles Prepared by a Flux Method with δ-FeOOH as a Precursor—*T. Chin, M. Deng, S. Hsu, and C. Lin* 4110

Head/Disk Interface for Magnetic Recording

Tribological Behavior of Thin Film Rigid Disks with Regular Dot Array Texture on Carbon Overcoats—*H. Tanaka, F. Ishikawa, K. Gomi, N. Yamaguchi, and Y. Miyake* 4113
Isotropic Thin Film Texture for Alternative Substrates—*T. Kogure, Y. Matsuno, T. Itoh, and C. Shima* 4116
Sputter-Induced Random Micro Texturing on NiP Plated Aluminum and Alternate Substrates—*E. Teng, P. Nguyen, and A. Eltoukhy* 4119
Numerical Simulation of the Steady State Flying Characteristics of a 50% Slider with Surface Texture—*M. Wahl and F. Talke* 4122
Tribological and Recording Performance of Carbon-Coated Thin Film Head Sliders on Unlubricated and Lubricated Thin Film Media—*G. Wang, T-A. Yeh, J. Sivertsen, J. Judy and G-L. Chen* 4125
Slider/Disk Separation at Rest—*H-L. Leon and S. Chapman* 4128

The Development and Implementation of a Flying Height Tester Calibration Standard—*Y. Li, A. Menon, and P. Goglia* 4131
Performance of Hard DLC Protective Film Prepared by PECVD Method for Thin Film Magnetic Disk—*K. Iechika, Y. Kokaku, M. Ootake, K. Abe, K. Tani, and H. Inaba* 4134
The Role of Disk Carbon and Slider on Water Adsorption—*M. Smallen, J. Lee, A. Chao, and J. Enguero* 4137
Lubricant Bonding Via Hydrogen Bond Network—*K. Sano, H. Murayama, and F. Yokoyama* 4140
Environmental Effects on Phosphazene Lubricated Computer Hard Disks—*M. Yang, F. Talke, D. Pereitie, T. Morgan, and K. Kar* 4143
Vapor Lubrication of Thin Film Disks—*K. Coffey, V. Raman, N. Staud, and D. Pocker* 4146
Single-Pass Flaw Detector for Magnetic Media—*W. Huber* 4149
Mechanically-Induced Readback Errors in Contact Recording—*J. Spong, M. Dovek, and G. Vurens* 4152
A Study of the Head Disk Interface Shock Failure Mechanism—*S. Kumar, V. Khanna, and M. Sri-Jayantha* 4155
Design and Performance of Novel Air Bearing Slider—*M. Matsumoto, Y. Takeuchi, H. Agari, and H. Takahashi* 4158
Vibro-Loading of Magnetic Head Assembly for Hard Disk Drives—*K. Aruga, S. Yoneoka, and T. Ohwe* 4161
Non-Invasive Take-Off/Touch-Down Velocity Measurements—*K. Klaassen, J. Van Peppen, and R. Eaton* 4164
Measurement of Flying Height on Carbon Overcoated Sliders—*K. Lue, C. Lacey, and F. Talke* 4167
Slider Vibrations Induced by Ramp-Suspension Interaction During the Ramp Loading Process—*T-C. Fu and D. Bogy* 4170
Ultra Low Flying Height Measurements Using Monochromatic and Phase Demodulated Laser Interferometry—*T. McMillan and F. Talke* 4173
Friction and Wear of Particulate and ME Magnetic Tapes Sliding Against a Mn-Zn Ferrite Head in a Linear Mode—*B. Bhushan and J. Lowry* 4176
Measurement of Head Wear Rates Using Custom High Sensitivity Electrical Elements—*R. Dee, K. Franzel, J. Cates, and R. Crowell* 4179
Running Characteristics of MIG Heads Against MP, Barium Ferrite and ME Tapes—*T. Tsuchiya and B. Bhushan* 4182
Deformation of Laminated Tapes—*R. Sundaram* 4185
Biquadratic Surface Fits for Two-Dimensional Interferometric Head/Tape Spacing—*E. Baugh and F. Talke* 4188
Drive-Level Flying Height Meaurements and Altitude Effects—*Y. Deng, H-C. Tsai, and B. Nixon* 4191

Magnetic Recording Systems and Coding

Space Data Storage Systems and Technologies—*R. Katti* 4194
The Effects of MR Induced Non-Linearities on Channel Performance—*K. Chopra, L. Nix, and K. Taberski* 4200
Effects of MR Head Track Profile Characteristics on Servo Performance—*D. Cahalan and K. Chopra* 4203
A New MR Head Track Following Method for Submicron Track Servo on Rigid Disks—*B. Tan, G. Pan, D. Mapps* 4206
Characterization of Magnetizing Process for Pre-Embossed Servo Pattern of Plastic Hard Disks—*S. Tanaka, Y. Imai, O. Morita, D. Dericotte, K. Kurokawa, T. Kashiwagi, and H. Takino* 4209
Two-Dimensional Coding for a Multi-Track, Maximum-Likehood Digital Magnetic Storage System—*P. Davey, T. Donnelly, and D. Mapps* 4212
Spectral Properties of (d,k) Codes with Multiple Spacing—*C. Menyennett and H. Ferreira* 4215
A System Architecture for Multi-Level Decision Feedback Equalization—*J. Kenney* 4218
Improved Equalization for Digital Recording Using Nonlinear Filtering and Error Confinement—*S. Nair and J. Moon* 4221
Adaptive Time Optimal Control of a Disk Drive Actuator—*S. Weerasooriya, T. Low, and Y. Huang* 4224
A High-Performance and Low-Profile Moving-Magnet Actuator for Disk Drives—*T. Yamada, S. Koganezawa, K. Aruga, and Y. Mizoshita* 4227

Magnetic Recording Modeling and Phenomena

Thermal Instability at 10 Gbit/in^2 Magnetic Recording—*P-L. Lu and S. Charap* 4230
A Practical Nonlinear Model for Magnetic Recording Channels—*W. Zeng and J. Moon* 4233

A Generalized Frequency Domain Nonlinearity Measurement Method—*X. Che, M. Peek and J. Fitzpatrick* 4236
A Time-Correlation Method of Calculating Nonlinearities Utilizing Pseudorandom Sequences—*X. Che and P. Ziperovich* 4239
Magnetic Force Microscopy Study of Edge Overwrite Characteristics in Thin Film Media—*J-G. Zhu, Y. Luo, and J. Ding* 4242
Experimental Study of Track Edge Noise Distribution in Narrow Track Recording—*T. Lam, J-G. Zhu, and T. Arnoldussen* 4245
Comparison of Magnetic Fields on Thin-Film Heads and Their Corresponding Bit Patterns Using Magnetic Force Microscopy—*P. Rice, B. Hallet, and J. Moreland* 4248
Determination for the Narrow Read Width of Thin Film Magnetic Recording Head Using Error Rate Model—*M. Huang, R. Chu, Y. Hsia, and T. Tran* 4251
Edge Effects in Narrow Track Recording Using Symmetric and Asymmetric Write Pole Geometries—*E. Wu and J. Peske* 4254
Modeling and Measurement of Hard-Magnet Biasing Strengths of MR-SAL Structures—*S. Yuan, S. Liao, and T. Kobayashi* 4257
Moving Vector Preisach Hysteresis Model and δ_M Curves—*F. Ossart, R. Davidson, and S. Charap* 4260
Angular Dependence of Magnetization in Recording Media—*T. Templeton, A. Arrott, and Y. Yoshida* 4263
Physically Based Information Science of Magnetic Recording II. Physical Sources of Medium Noise—*D. Porter, J. O'Sullivan, R. Indeck, and M. Muller* 4266
A Model for Threshold and Timing Error Rate Versus Off-Track Position—*J. Alexander* 4269
Relationship between Overwrite and Transition Shift in Perpendicular Magnetic Recording—*H. Muraoka, S. Ohki, and Y. Nakamura* 4272
Modeling Study of Isolated Read-Back Pulses from Keepered Longitudinal Thin Film Media Using the Boundary Element Method—*J. Loven, Y. Guo, K. Sin, J. Judy, and J-G. Zhu* 4275
Calculation of Head Sensitivity Function from 3-D Magnetic Fields—*E. Burke, R. Gomez, R. Madabhushi, and D. Mayergoyz* 4278
Gauge Testing of Transition Jitter Measurements for Longitudinal Thin Film Magnetic Recording—*M. Huang, R. Chu, Y-T. Hsia, and T. Tran* 4281

Computational Magnetics

Fast Actuator Modeling by Finite Element Method—*K. Takeuchi, M. Shimizu, K. Okazaki, T. Nakata, N. Takahashi, and K. Fujiwara* 4284
Design Techniques for Reduction of Reluctance Torque in Brushless Permanent Magnet Motors—*S. Hwang and D. Lieu* 4287
Modeling of the Influence of Coil Winding Pattern on Tooth Forces in Brushless DC Motors—*G. Jang and D. Lieu* 4290
Modelling and Computation of Nonlinear Magnetic Fields in Linear Step Motors by Finite Element Method—*S. Khan and A. Ivanov* 4293
Utilizing Genetic Algorithms for the Optimal Design of Electromagnetic Devices—*G. Uler, O. Mohammed, and C-S. Koh* 4296
Eddy Current Losses in Saturable Magnetic Materials—*V. Machado* 4299
Perturbed H-Method Without the Lagrange Multiplier for Three-Dimensional Nonlinear Magnetostatic Problems—*I. Saitoh* 4302
Bifurcation Diagram and Large Energy Dissipation Caused by Chaotic Domain-Wall Motion—*H. Okuno, Y. Sugitani and T. Homma* 4305
Hysteresis Modeling of Recording Media with an Interacting Stoner-Wohlfarth Particles System—*A. Stancu and C. Papusoi* 4308
Optimizing Strategy for MR Imaging Gradient Coils—*K. Adamiak, A. Czaja, and B. Rutt* 4311
Electromagnetic Field Analysis in Rotational Electric Machines Using Finite Element-Analytical Hybrid Method—*B. Chao, S. Chen, Z. Liu, and T. Low* 4314
Modeling and Torque Analysis of Permanent Magnet Spindle Motors for Disk Drive Systems—*Z. Liu, C. Bi, C. Tan and T-S. Low* 4317
Genetic Algorithms for Nondestructive Testing in Crack Identification—*A. Arkadan, T. Sareen, and S. Subramaniam* 4320
Analysis of Axial-Field Actuators—*E. Furlani and M. O'Brien* 4323
Modelling the Effects of Eddy Current Losses on Frequency Dependent Hysteresis in Electrically Conducting Media—*D. Jiles* 4326

The Finite Element Solutions of Moving Conductor Eddy Current Problems Based on Triangular Elements—*Z. Wang, G. Dawson, T. Eastham, and Z. Liu* 4329
An Improved Technique for Nonlinear Magnetic Problems—*M. Chiampi, M. Repetto, and D. Chiarabaglio* 4332
Asymptotic Boundary Conditions for Axisymmetric Finite Element Electrostatic Analysis—*Q. Chen, A. Konrad, and S. Baronijan* 4335
Enclosure Losses in High Power Systems—*P. Ryff, T. Fawzi, and A. Hussein* 4338
Two Dimensional Magnetization Model for Anisotropic Soft Magnetic Sheets—*T. Waeckerle and M. Mekhiche* 4341
Domain Walls Interactions with Attractive and Repulsive Defects in the Garnet Films—*V. Karpasyuk and M. Bulatov* 4344
Experimental Analysis of Reversible Processes in Soft Magnetic Materials—*V. Basso, M. Bue, and G. Bertotti* 4347
An Adaptive Mesh Numerical Algorithm for the Solution of 2D Néel Type Walls—*J. Miltat and M. Labrune* 4350
Simulation of Vertical Bloch Lines Non-Reciprocal Dynamics—*V. Dobrovitski, A. Logginov, and A. Nikolaev* 4353
Analytical Expressions for Barkhausen Jump Size Distributions—*F. Hunt and R. McMichael* 4356
Magnetization Reversal Processes Reuled by Grain Interactions: Analysis of Their Dependence on the Direction of the Demagnetizing Field—*J. Gonzalez, R. Ramirez, R. Rueda, L. Dominguez, and J. Gonzalez* 4359
A Model for Lorentz Microscopy and Magnetic Behaviour of Longitudinal Thin Film with an Irregular Lattice—*N. Walmsley, C. Dean, A. Hart, D. Parker and R. Chantrell* 4362
A Fast, Smooth Vector Hysteresis Model with Adjustable Interactions—*T. Hoffend Jr. and M. Vos* 4365
The Input Dependent Preisach Model with Stochastic Input as a Model for Aftereffect—*C. Korman and I. Mayergoyz* 4368
Identification of Parameters in an Accommodation Model—*F. Vajda and E. Della Torre* 4371
Parameter Identification of the Complete-Moving-Hysteresis Model for HTS Steel—*G. Kahler, E. Della Torre, and F. Vajda* 4374
Magneto-Dynamic Field Computation Using a Rate-Dependent Preisach Model—*D. Philips, L. Dupre, and J. Melkebeek* 4377
Computational Hysteresis in Modeling Magnetic Systems—*D. Kinderlehrer and L. Ma* 4380
Numerical Implementation and Testing of New Vector Isotropic Preisach-Type Models—*A. Adly* 4383
Algorithm for Fast Implementation of Vector-Type Preisach Hysteresis Models—*G. Friedman and D. Ahya* 4386
Effect of Damping on Dynamic Distortion in Magnetic Garnet Material—*A. Bagneres, M. Redijal, and F. Humphrey* 4389

Magneto Optic Recording, Media, and Materials

Thermomagnetic Recording Behavior in the NdTbDyFeCo/DyFeCo-Ultrathin Bilayer—*T. Kawase, M. Ishida, S. Hoshina, A. Takakuwa, S. Nebashi, and T. Shimoda* 4392
Ar-Sputtered Pt/Co Multilayers with Large Anisotropy Energy and Coercivity—*P. Carcia, M. Reilly, Z. Li, and H. Van Kesteren* 4395
Nanostructure and Chemical Inhomogeneity in TbFe Magneto-Optical Films—*M. Kim, J. Bow, R. Carpenter, J. Liu, S. Kim, S. Lee, W. Kim, and J. Yoon* 4398
Domain Wall Mobility Meaurements in Magneto-Optic Media—*M. Du and M. Kryder* 4401
Effect of Grooves on Magnetization Reversal in Amorphous TbFeCo Thin Films—*S. Gadetsky, T. Suzuki, J. Erwin, and M. Mansuripur* 4404
Magnetic and Magneto-Optical Properties of Tb-Fe-Co/Ta Multilayers—*K-B. Song, H. Ito, and M. Naoe* 4407
Magneto-Optic Read Channel Modeling in Presence of Bloom—*I. Ozgunes and B. Kumar* 4410
Optimum Design of Optical Storage Media for Drive Compatibility—*T. McDaniel, K. Rubin, and B. Finkelstein* 4413
Deposition of Garnet Thin Films by Metallo-Organic Decomposition (MOD)—*A. Azevedo, S. Barthulwar, W. Eppler and M. Kryder* 4416
Faraday Rotation of Bismuth Substituted Terbium Iron Garnets—*M. Guillot, H. Gall, J. Desvignes, and M. Artinian* 4419

Composition Dependence of the Magnetooptical Properties of HoIG:Al Single Crystals—*J. Ostorero and M. Guillot* 4422
Microstructure of Re-Tm Films and Anisotropy of Domain Wall Motion—*T. Pokhil and E. Nikolaev* 4425
Thermal Stability of Sputtered GdDYFeCo Films with Trilayer Structure—*Y. Uchihara, K. Tanase, Y. Suzuki and K. Torazawa* 4428
Low Temperature Crystal Growth of MnBi Films—*M. Nakada and M. Okada* 4431
Exchange Stiffness Constant and Effective Gyromagnetic Factor of Gd, Tb and Nd Containing, Amorphous Rare Earth-Transition Metal Films—*C. Mathieu, B. Hillebrands, and D. Raasch* 4434
Optical Property Influence on Magneto-Optics of CoNi and TbCo Multilayers on Noble Metal Alloy Substrates—*J. Hilfiker, Y. Zhang, and J. Woollam* 4437
Anisotropy and Magneto-Optical Properties of Sputtered Co/Ni Multilayer Thin Films—*Y. Zhang, J. Woollam, S. Shan, J. Shen, and D. Sellmyer* 4440
Coexistence of Antiferromagnetic and Ferromagnetic Clusters in Ccmpositionally Modulated Amorphous Fe_xZr_{100-x}($66 < x \leq 85$) Thin Films—*B-I. Cho, W. Win, A. Manthiram, and R. Walser* 4443
Preparation of Bi-YIG Particles for Display Device—*N. Kawai, E. Komuro, T. Namikawa, Y. Yamazaki, and T. Hirano* 4446
Giant Magnetic Kerr Rotation for MnSbPt Films with NiAs Structure—*M. Takahashi, H. Shoji, Y. Hozumi, T. Wakiyama, Y. Takeda and Y. Itakura* 4449
Magnetic and Magneto-Optical Properties of (Co-Bi)/Pt and Co/(Pt-Bi) Multilayers—*T. Suzuki, S. Iwata, H. Brandle and D. Weller* 4455
First Principles Study of Magneto-Optical Properties of Half-Metallic Heusler Alloys: NiMnSb and PtMnSb—*X. Wang, V. Antropov, and B. Harmon* 4458
Magneto-Optic Properties of Macroscopic Ferrimagnets—*R. Gambino and P. Fumagalli* 4461
Novel Bulk Iron Garnets for Magneto-Optic Magnetic Field Sensing—*M. Deeter, S. Bon, G. Day, G. Diercks, and S. Samuelson* 4464

Symposium on Magnetic Microscopy

High Resolution Magnetic Force Microscopy of Domain Wall Fine Structures—*R. Proksch, S. Foss, and E. Dahlberg* 4467
A Magnetic Force Microscopy Analysis of Soft Thin Film Elements—*W. Rave, L. Belliard, M. Labrune, A. Thiaville, and J. Milat* 4473
Coherent Magnetic Imaging by TEM—*J. Chapman, A. Johnston, L. Heyderman, S. McVitite, and W. Nicholson* 4479

Magnetic Microscopy and Imaging

An Ultra-High Resolution Single-Domain Magnetic Force Microscope Tip Fabricated Using Nanolithography—*S. Chou, M. Wei, and P. Fischer* 4485
Analysis of 3-D Magnetic Fields Measured Using a Magnetic Force Scanning Tunneling Microscope—*E. Burke, R. Gomez, and I. Mayergoyz* 4488
Magneto-Optical Faraday Effect Probed in a Scanning Tunneling Microscope—*M. Prins, M. Van Der Wielen, D. Abraham, H. Van Kempen, and H. Van Kesteren* 4491
Methods for Wide-Field Kerr Imaging of Small Magnetic Devices—*P. Trouilloud, B. Petek, and B. Argyle* 4494
Absolute Magnetometry of Thin Cobalt Films and Co/Cu Multilayer Structures at Nanometer Spatial Resolution—*M. Mankos, Z. Yang, M. Scheinfein, and J. Cowley* 4497
A New Surface Microscope for Magnetic Imaging—*K. Grzelakowski, T. Duben, E. Bauer, H. Poppa, and S. Chiang* 4500
Optimization of Thin Film Tips for Magnetic Force Microscopy—*K. Babcock, V. Elings, M. Dugas, and S. Loper* 4503
Surface Structure of Fe_3O_4 (110) Studied by Scanning Tunneling Microscopy—*R. Jansen, B. Nelissen, D. Abraham, H. Van Kempen, and V. Brabers* 4506
Imaging Surface Conditions of Ferromagnetic Steel Using Barkhausen Technique—*M. Negley and D. Jiles* 4509

Microwave and Millimeter Devices

Oriented Barium Hexaferrite Thick Films Grown on C-Plane and M-Plane Sapphire Substrates—*P. Dorsey, D. Chrisey, J. Horwitz, P. Lubitz and R. Auyeung* 4512

Ferrite-Superconductor Microwave Phase Shifters—*G. Dionne, D. Oates, and D. Temme* 4518
Characteristics of the Quasi-Optical Reflection Circulator—*N. Harris, G. Dionne, J. Weiss and B. Lax* 4521
Novel Design of Tunable MMW Magnetic Filter—*H. How, T-M. Fang and C. Vittoria* 4524
Polycrystalline $Y_3Fe_5O_{12}$ Garnet Films Grown by a Pulsed Laser Ablation Technique—*C. Yang, S. Kim and Y. Kim* 4527
Low Energy Ion Bombardment and Surface Spin Pinning in Yttrium Iron Garnet Films—*A. Chernakova and D. Stancil* 4530
High Impedance Anisotropic Composite Manufactured from Ferromagnetic Thin Films for Microwave Applications—*O. Archer, P. Jacquart, J. Fontaine, P. Baclet, and G. Perrin* 4533
Comparison of the Auxiliary Vector Function and Adjoint Methods in Solving Anisotropic Media Electromagnetic Problems—*C. Krowne* 4536
Effects of Annealing on the Microwave Properties of Spin-Spray Ni-Zn Ferrites—*P. Lubitz, S. Lawrence, F. Rachford, and B. Rappoli* 4539
Investigation of High Frequency Permeability of Thin Amorphous Wires—*O. Acher, P. Jacquart, and C. Boscher* 4542
Microwave Polymer-Ferroxide Film Absorbers—*I. Nedkov, L. Milenova, and N. Dishovsky* 4545
Drop-On Circulator Design at X and Ka Bands—*H. How, T-M. Fang, and C. Vittoria* 4548
Magnetic Steerable Ferrite Patch Antenna Array—*H. How, T-M. Fang, D-X. Guan and C. Vittoria* 4551
Microwave Absorbing Properties of Sintered Ni-Zn Ferrite—*S-S. Kim, D-H. Han, and S-B. Cho* 4554

Instrumentation and Measurement Techniques

Current Distribution in Spin-Valve Structures—*R. Beech, J. Daughton and W. Kude* 4557
Improved Eddy-Current Decay Method for Resistivity Characterization—*A. Kos and F. Fickett* 4560
Magnetostriction Measurements with a Laser Doppler Velocimeter—*T. Nakata, N. Takahashi, M. Nakano, K. Muramatsu and M. Miyake* 4563
DC Biased Capacitance Method for Measuring Thin Film Magnetostriction and ΔE-Effect—*Y. Lee, Y. Shin, P. Herr, K. Lee, H. Kim, S. Han, I. Kang and J. Rhee* 4566
Design of a Digitally Based ΔE Measurement System—*S. Hogsdon, P. Squire, and D. Atkinson* 4569
Measurement of Magnetostriction in Self-Biased Shielded Magnetoresistive Heads—*J. Cates, R. Crowell, and R. Dee* 4572
Flexible Test System for Measurement of Magnetoresistance in Ferrromagnetic Films—*K. Franzel and R. Dee* 4575
Magneto-Optical High Resolution Measurement of Small Displacements between Light Beams of Different Color—*J. Hochreiter, F. Haberl, H. Hauser, and M. Gaugitsch* 4578
Magnetic Inclination Meaurement and Signal Transmission System for Trench Wall Constructions—*K. Vorlicek, H. Hauser, and M. Franz* 4581
Calculations of the Sensitivity Function of a Mis-Aligned Thin Film in a Mallinson Coil Set—*S-W. Hsu* 4584
Pitfalls in the Determination of Magnetic Permeability—*J. Bernards, A. Kuiper, H. De Wit and E. Van De Reit* 4587
Influence of DC Bias Field, Excitation and Detection Frequencies on Magnetic Barkhausen Noise Analysis—*L. Sipahi* 4590
Variation of Coercivity of Ferromagnetic Material During Cyclic Stressing—*Z. Gao, Z. Chen, D. Jiles, and S. Biner* 4593
Assessment of Creep Damage of Ferromagnetic Material Using Magnetic Inspection—*Z. Chen, M. Govindaraju, D. Jiles, S. Biner, and M. Sablik* 4596
Induction Motor Iron Losses Meaurement with Static Converter Supply Using a Slotless Rotor Test Bench—*A. Boglietti, P. Ferraris and M. Lazzari* 4599
Permanent Magnet Variable Flux Sources—*O. Cugat, P. Hansson, and J. Coey* 4602
10 GHz Cylindrical Cavity Resonator for Characterization of Surface Resistance of High T_c Superconducting Bulk and Thin Films—*M. Kumar, G. Srivastava, and N. Kataria* 4605

Magnetic Sensors

Magnetic Field Sensors Using GMR Multilayer—*J. Daughton, J. Brown, E. Chen, R. Beech, A. Pohm, and W. Kude* 4608
Thin-Film Magnetic Sensor Using High Frequency Magneto-Impedance (HFMI) Effect—*M. Senda, O. Ishii, Y. Koshimoto, and T. Toshima* 4611

New Method for Extracting Signals Generated by Magnetoresistive Sensors—*B.Z. Kaplan and E. Paperno* 4614
Integrated MR Sensors for Automobile—*O. Akiyama, H. Konna, D. Inami, and Y. Kuraishi* 4617
Thin-Film and Micro-Fiber Permalloy Magnetoresistors. A Comparison—*P. Ciureanu, P. Rudkowski, J. Ström-Olsen, and A. Yelon* 4620
Quick Response Large Current Sensor Using Amorphous MI Element Resonant Multivibrator—*K. Inada, K. Mohri, and K. Inuzuka* 4623
Sensitive Magneto-Inductive Effect in Amorphous Wires Using High Pass Filter and Micro Field Sensor—*K. Bushida and K. Mohri* 4626
A Torque Transducer Utilizing Two Oppositely Polarized Rings—*I. Garshelis and C. Conto* 4629
In-Process Detection of Torque on a Drill Using Magnetostrictive Effect—*I. Sasada, N. Suzuki, T. Sasaoka, and K. Toda* 4632
Construction of Electromagnetic Rotation Sensor Using Compound Magnetic Wire and Measurement at Extremely Low Frequency Rotations—*S. Abe and A. Matsushita* 4635
Modulation Effect in the Magnetic Shield with Magnetic Shaking—*I. Sasada* 4638
A New Microstrip Pickup Coil for Thin-Film Permeance Meters—*I. Kawazu, M. Yamaguchi, and K. Arai* 4641
Study of the New Eddy Current Non-Destructive Testing Sensor on Ferrromagnetic Materials—*S. Nath, B. Wincheski, J. Fulton, and M. Namkung* 4644
Silicon Micromachined Two-Dimensional Galvano Optical Scanner—*N. Asada, H. Matsuki, K. Minami and M. Esashi* 4647

Alternative Memories, Magnetic Separation and Fluids

Analysis of 0.1 to 0.3 Micron Wide, Ultra Dense GMR Memory Elements—*A. Polm, R. Beech, P. Bade, E. Chen, and J. Daughton* 4650
Magnetic Cage Filters—*R. Gerber and P. Lawson* 4653
The Small Particle Limit for Electromagnetic Separation—*D. Fletcher and R. Gerber* 4656
The Electromagnetic Separation of Metals from Insulators—*D. Fletcher, R. Gerber, and T. Moore* 4659
Vortex Magnetic Separation(VMS)—*Z. Li and J. Watson* 4662
The Development of a Magnetic Hydrocyclone for Processing Finely Ground Magnetite—*R. Freeman, N. Rowson, T. Veasey, and I. Harris* 4665
Selective Collection of Non-Magnetic Rutile and Quartz by Means of a Magnetic Reagent by HGMS—*Q. Liu and F. Friedlaender* 4668
Initial Susceptibilities of Magnetic Fluids Dispersing Mn-Zn Ferrite and Cobalt Ferrite Particles—*K. Nakatsuka and B. Jeyadevan* 4671
Experimental Observations of the Magnetic Flux Control Characteristics of Magnetic Fluid by Means of an Orthogonal Magnetic Field—*H. Oka* 4674
Use of Magnetic Fluid in a Current to Pressure Transducer—*R. Potter* 4677
Finite Element Calculation of Forces on a DC Magnet Moving Over an Iron Rail—*D. Rodger, N. Allen, P. Coles, S. Street, P. Leonard, and J. Eastham* 4680
Magnetic Design of a Cathodic Arc and Sputtering Polyvalent Source for Vapour Deposition—*N. Heras, A. Torrado, J. Barandiaran and J. Goikoetxea* 4683
Modification of the Nozzle Flow Using Electromagnetic Induction—*L. Kadar, P. Biringer and J. Lavers* 4686

Biomagnetism and Magnetochemistry

Conduction System Ablation Using Ferrite Rod for Cardiac Arrythmia—*T. Hoshino, T. Sato, A. Masai, K. Sato, H. Matsuki, K. Seki, H. Sato, K. Kishiro, S. Urabe and K. Kido* 4689
Ferrite Plating on Porous Silica Microspheres for Ultrasonic Contrast Agents—*M. Zhang, Q. Zhang, T. Itoh, and M. Abe* 4692
Diamagnetic Properties of Fibrin and Fibrinogen—*M. Iwasaka, S. Ueno, and H. Tsuda* 4695
Parting of Water by Magnetic Fields—*S. Ueno and M. Iwasaka* 4698
Enzymatic Activity of Plasmin in Strong Magnetic Fields—*M. Iwasaka, S. Ueno, and H. Tsuda* 4701
Hybrid MCG and ECG Approach to Medical Diagnosis in Human Heart—*T. Doi, S. Hayano, and Y. Saito* 4704
Metal Uptake and Separation Using Magnetotactic Bacteria—*A. Bahaj, P. James and I. Croudace* 4707

Measurement of Auditory Evoked Brain Responses Elicited by Ipsilateral and Contralateral Ear Stimulation with a High-Sensitivity SQUID System—*T. Yoshiura, S. Ueno, K. Iramina, and K. Masuda* 4710
Magnetic Orientation of Red Blood Cell Membranes—*T. Suda and S. Ueno* 4713
Source Localization of Auditory Evoked Magnetic Fields During Waking and Sleep Stages—*K. Iramina and S. Ueno* 4716
Long Latency Motor Evoked Responses to Magnetic Stimulation of the Spinal Roots in the Human Neck—*A. Kyura, A. Hyodo, S. Ueno, M. Fujiki and T. Matsuda* 4719
Magneto-Chemical Characteristics of Copper-Cobalt Catalysts—*A. Murty, U. Donatto, J. Washington, T. Hoard, M. Akundi, and C. Harris* 4722
Structural and Magnetic Characteristic of a Novel Method of $Fe_2O_3 \Rightarrow Fe_3O_4$ Reduction by Magneto-mechanical Activation—*W. Kaczmarek, I. Onyszkiewicz, and B. Ninham* 4725
Ferromagnetic Interactions Through End-On Azido Bridges in a Nickel (II) Dimer: $[Ni_2(C_{15}H_{11}N_3)_2(H_2O)\ (N_3)_3]ClO_4.H_20$—*R. Cortes, L. Lezama, T. Rojo, M. Urtiaga, and M. Arriortua* 4728

Levitation, Propulsion, and Power and Control Magnetics

Optimal Design of the Electromagnetic Levitation with Permanent and Electro Magnets—*Y-K. Tzeng and T. Wang* 4731
A New Electromagnetic Levitation System for Rapid Transit and High Speed Transportation—*T. Wang and Y-K. Tzeng* 4734
Experimental Investigation and 3-D Modelling of Linear Variable-Reluctance Machine with Magnetic-Flux Decoupled Windings—*C-T. Liu and J-L. Kuo* 4737
Levitational Melting of Several Kilograms of Metal with a Cold Crucible—*H. Tadano, M. Fujita, T. Take, K. Nagamatsu, and A. Fukuzawa* 4740
Study of Permanent Magnet Arrangements for Superconducting Passive Bearings—*M-C. Marion-Pera and J-P. Yonnet* 4743
A Compact Magnetic Suspension with Only One Axis Control—*J. Delamare, J-P. Yonnet, and E. Rulliere* 4746
A Passive Damper for Magnetic Suspension—*V. Nguyen, J. Delamare, and J-P. Yonnet* 4749
Three Dimensional Force Prediction in a Model Linear Brushless DC Motor—*J. Moghani, J. Eastham, R. Akmese, and R. Hill-Cottingham* 4752
A Novel High Power Converter for Non-Contact Charging with Magnetic Coupling—*H. Sakamoto and K. Harada* 4755
Development of Film Transformer—*S. Hayano, Y. Midorikawa, and Y. Saito* 4758
A New Inductor Having a Noise Filtering Capability—*Y. Midorikawa, S. Hayano, and Y., Saito* 4761
Fundamental Characteristics of Molten Metal Flow Control by Linear Induction Motor—*K. Fujisaki, J. Nakagawa, and H. Misumi* 4764
Trial Construction of New Magnetic Skew Gear Using Permanent Magnet—*S. Kikuchi and K. Tsurumoto* 4767

Soft Materials, Amorphous Materials and Crystalline Alloys

The Field Induced Magnetic Anisotropy in Amorphous Co-RE Alloys Films—*G. Suran, K. Roky, J. Sztern, F. Machizaud and J. Mackowski* 4770
Influence of Boron on the Magnetic and Transport Properties of FeZr Amorphous and Nanocrystalline Alloys—*J. Barandiaran, P. Gorria, J. Sal, L. Barquin, and S. Kaul* 4776
High Electrical Resistivity and Permeability of Soft Magnetic Granular Alloys—*H. Fujimori, S. Mitani, T. Ikeda, S. Ohnuma* 4779
Engineering Magnetostriction Measurements of Annealed FeSiB Amorphous Wires—*D. Atkinson and P. Squire* 4782
Induced Anisotropy in Nanocrystalline FeCuNbSiB—*M. Emura, A. Severino, A. Santos, and F. Missell* 4785
High-Field Magnetization Meaurements on a Ferromagnetic Amorphous Alloy from 295 to 5 K—*P. Szymczak, C. Graham, Jr., and M. Gibbs* 4788
Effects of Chemical Etching on the Asymmetric Magnetization Reversal in Amorphous Magnetic Alloy—*K. Shin, C. Graham, Jr. and P. Zhou* 4791
Influence of the As-Cast State on the Crystallization Process and Magnetic Properties for FeSiBCuNb Wires—*P. Marin, A. Olofinjana, M. Vazauez and H. Davies* 4794

Nanostructured Materials for Soft Magnetic Applications Produced by Fast dc Joule Heating—*P. Allia, P. Tiberto, M. Baricoo, M. Knobel, and F. Vinai* 4797
Creep Induced Magnetic Anisotropy in Nanocrystaline Fe-Cu-Nb-Si-B Alloys—*G. Herzer* 4800
Domain Structure Studies by Means of High Resolution ΔE Measurements—*S. Hogsdon, P. Squire, and D. Atkinson* 4803
Magnetic and Magnetoelastic Properties of Amorphous Fe-Si-B-C Films—*A. Mattingley, C. Shearwood and M. Gibbs* 4806
In-Plane Moment Canting in Amorphous $Fe_{78}B_{13}Si_9$ in Applied Fields Measured Using Polarized Mössbauer Spectroscopy—*Q. Pankhurst, S. Betteridge, J. Jiang and M. Gibbs* 4809
Effects of Nanocrystallization on the Magnetostriction of Co-Based Amorphous Alloys—*J. Gonzalez, N. Murillo, J. Blanco, P. Quintana, E. Amano and R. Valenzuela* 4812
Effect of Crystallization on Magnetic Domain Structure of Thinned Amorphous FeSiBCuNb Ribbons—*S. Zhou, Y. Wang, J. Ulvensoen and R. Hoier* 4815
The Effect of Surface Layers on Powder Loss in Amorphous Ribbon Materials—*T. Meydan and N. Derebasi* 4818
Influence of Scratching on Domain Structure and Power Loss in Amorphous Ribbons—*N. Derebasi, T. Meydan and G. Derebasi* 4821
A Comparative Study of Processes for the Production of Structured Barium Ferrite Films—*P. Gago-Sandoval, R. Carey, D. Newman, B. Thomas, S. Palmer, T. Jackson and R. Welch* 4824
Limiting Velocity of the Steady State Domain Wall Motion in the Presence of the Field Normal to the Anisotropy Axis—*V. Sobolev, H. Huang, and S. Chen* 4827
Effects of Creep Damage, Shot Peening, and Case Hardening on Magnetic Barkhausen Noise Analysis—*L. Sipahi* 4830
Computation of Intrinsic Permeability from Measured Permeability: Soft Ferromagnetic Thin Films—*J. Rusat and F. Durbin* 4833
Epitaxial Growth and Magnetic Properties of Fe Films on Si Substrates—*S. Yaegashi, T. Kurihara, K. Sato, and H. Segawa* 4836
Electrical and Physical Characterization of SiFe Sheets Insulation—*M. Marion-Pera and T. Waecherle* 4839
Obtention of a Strong (100)[001] Texture Component Based on a Hot-Rolling Process in 3% Al-Fe—*C. Talowski, T. Waeckerle, and B. Cornut* 4842
Soft Magnetic Properties of Fe-M-B-Cu (M = Hf, Zr, Nb) Alloys with Nanocrystalline and Amorphous Hybrid Structure—*J. Lee, K. Kim, T. Noh, I. Kang, and Y. Yoo* 4845
Microstructure and Magnetic Properties of Nanocrystalline bcc Fe-Nb-B Soft Magnetic Alloys—*A. Makino, S. Yoshida, A. Inoue, and T. Masumoto* 4848
Effects of the Interlayers on the Magnetic Properties in Fe-Hf-C/Ceramics Multilayer Films—*J. Choi, J. Lee, S. Han, H. Kim and I. Kang* 4851
Magnetic Viscosity and Activation Volume in Domain Wall Pinning—*D. Ng, C. Lo, and P. Gaunt* 4854
The Dependence of Magnetoacoustic Emission on Magnetic Induction and Specimen Thickness—*D. Ng, C. Lo, S. Cheng and J. Jakubovics* 4857
Performance and Noise Attenuation Mechanism of Noise Reduction Transformer—*T. Yanada, T. Matsuda, O. Ichinokura, and T. Jinzenji* 4860
Variation of the Localised Flux Densities in the Amorphous Toroidal Tansducer Core—*M. Goktepe and T. Meydan* 4863
Finite Element Analysis on Characteristics of Rotary Transformers—*Y-T. Huang, C-J. Chen, and W-B. Shu* 4866
Magnetic Properties of (Fe,Co)-B-Al-Nb Alloys with Ultrafine Grain Structure—*Y. Cho, Y. Kim, C. Kim, K. Lee, and T. Kim* 4869

Ferrites and Domain Walls

Effect of Heat Treatment on the Microstructure and Magnetic Properties of Polycrystalline MnZn Ferrites—*M. Ramesh, R. Crowell, and S. Dey* 4872
Low Temperature Fired NiCuZn Ferrite—*J-Y. Hsu, W-S. Ko, H-D. Shen and C-J. Chen* 4875
Correlation between Magnetic and Structural Properties of $Ni_{80}Fe_{20}$ Sputtered Thin Films Deposited on Cr and Ta Buffer Layers—*R. Jerome, T. Valet, and P. Galtier* 4878
FeGdN: a New Soft Magnetic Metallic Thin Film Material—*E. Van De Riet* 4881
Magnetic Properties of Nanostructure Controlled FeAlSi/FeAlSiO Multilayers—*M. Hiramoto, O. Inoue, and K. Kugimiya* 4884
Supersaturated A2 Solid Solution Induced by Ball Milling in the Fe-Si System: Structural and Magnetic Characterization and Thermal Stability—*M. Abdellaoui, E. Gaffet, T. Barradi, and F. Faudot* 4887

Forsterite Film and Grain Growth in 3% Si Steel—*M. Cunha and M. Cesar* 4890
Dynamic Preisach Model Interpretation of Power Losses in Rapidly Quenched 6.5% SiFe—*V. Basso, G. Bertotti, F. Fiorillo, and M. Pasquale* 4893
The Magnetic and Structural Properties of Ferrite Plated NiZn-Ferrite Films—*C. Williams, M. Abe, T. Itoh, and P. Lubitz* 4896
Ferrite Plating of Fe_3O_4 Films Using Alternate Electric Current—*Q. Zhang, T. Itoh and M. Abe* 4900
Dependence of the Magnetic Disaccommodation Spectrum of YIG with Sintering Temperature—*L. Torres, M. Zazo, J. Iniguez, C. De Francisco, and J. Munoz* 4903
Fine Powder Ferrite for Multilayer Chip Inductors—*H-M. Sung, C-J. Chen, W-S. Ko and H-C. Lin* 4906
Theoretical Analysis and Experimental Research on the Approach-Staturation Curve of Polycrystalline Hexagonal Planar Ferrites—*S. Zhu, H. Chen, F. Wen, and Y. Zhang* 4909
Studies of the Stoichiometrical Variation of Epitaxial $Fe_{3-(1-\delta)}O_4$ Thin Films—*E. Lochner, K. Shaw, R. DiBari, W. Portwine, P. Stoyonov, S. Berry, and D. Lind* 4912
Magnetic Domain Behavior of Cu-Co Spinel Ferrite Systems—*S. Patil and R. Dabhade* 4915
Structure and Magnetic Properties of $Gd_{1-x}Sr_xFeO_{3-\delta}$ Compounds—*C. Kim, Y. Um, S. Park, S. Ji, Y. Oh, J. Park, J. Lee, and C. Yo* 4918
Experimental Study of Local Dynamic Potential Well of Isolated Domain Wall—*V. Synogach and V. Gornakov* 4921
Effects of Surface Stress on Barkhausen Effect Emissions: Model Predictions and Comparison and X-ray Diffraction Studies—*D. Jiles and L. Suominen* 4924
The Effect of Curvature on Domain Wall Energy and Thickness—*J. Jatau and E. Della Torre* 4927

Magnetic Semiconductors and New Materials

Synthesis and Properties of $Cd_{1-x}Mn_xS$ Diluted Magnetic Semiconductor Nanoparticles—*R. Bandaranayake, M. Smith, J. Lin, H. Jiang, and C. Sorensen* 4930
Magnetic and Structural Properties of Laser Deposited Lithium Ferrite Films—*S. Oliver, C. Vittoria, G. Balestrino, S. Martellucci, G. Petrocelli, A. Tebano and P. Paroli* 4933
Magneto-Optical Properties of CdMnTe Films on Quartz Glass and Sapphire Substrates in the Transparent, Visible Region—*M. Imamura, K. Ogata, M. Tokubuchi, and M. Nakahara* 4936
Studies of Structural, Magnetic and Transport Properties of a New Series $R_3Cu_3Sb_4$ (R = La,Ce,Pr,Gd)—*Z. Hossain, S. Patil, R. Nagarajan, L. Gupta, R. Vijayaraghavan, and C. Godart* 4939
Magnetic Ordering in $(U_{0.5}Tb_{0.5})Co_2Ge_2$ Studied by AC-Susceptibility and Neutron-Diffraction Measurements—*M. Kuznietz, H. Pinto, H. Ettedgui, and M. Melamud* 4942
Soft Magnetic Properties of Nano-Structure-Controlled Magnetic Materials—*Y. Sugaya, O. Inoue, and K. Kugimiya* 4945
Microstructure and Magnetic Properties of Semi-Hard Fe-Co-B-Cu Alloys Formed by Rapid Solidification—*A. Zaluska, G. Rudkowska, P. Rudkowski and J. Strom-Olsen* 4948
Structural and Magnetic Properties of RFe_6Ge_6 (R=Y, Gd, Tb, Er) Compounds—*Y. Wang, D. Wiarda, D. Ryan, and J. Cadogan* 4951
Superparamagnetism of Ferrite Particles Dispersed in Spherical Polymeric Materials—*C. O'Connor, Y-S. Lee, J. Tang, V. John, N. Kommareddi, M. Tata, G. McPherson, J. Akkara, and D. Kaplan* 4954
Magnetic Properties of $Sm_3(Fe, Ti)_{29}N_5$ Compounds—*F. Yang, B. Nasunjilegal, W. Gong, and G. Hadijipanayis* 4957
Magnetic Properties of Two New Compounds: $Pr_2Ni_3Si_5$ and $Ho_2Ni_3Si_5$—*C. Mazumdar, R. Nagarajan, L. Gupta, R. Vijayaraghavan, C. Godart, and B. Padalia* 4960
Spin Reorientation Transitions in $RFe_{11.35}Nb_{0.65}$ (R = Dy, Er)—*K-Y. Wang, Y-Z. Wang, B-P. Hu, and W-Y. Lai* 4963
Magnetic Properties of RNi_4B (R=rare Earth Metal)—*N. Hong, T. Holubar, G. Hilscher, M. Vybornov, and P. Rogl* 4966
High Field Magnetization Study of the $Gd_2Fe_{17}H_x$ System—*O. Isnard, S. S. Miraglia, D. Fruchart, and M. Guillot* 4969
The Effects of Arsenic Doping on the Magnetic Properties of $CuCr_2Se_4$—*J. Tang, L. Li, S. Saxena, A. Puri, A. Falster, and W. Simmons, Jr.* 4972

The magnetic properties of ferromagnetic compounds of Sm_2Fe_{17}, $Sm_2Fe_{17}C_{0.6}$, and $Sm_2Fe_{17}C_{0.6}H_{4.4}$ were investigated. Sm_2Fe_{17} nitrides, carbides, and carbohydrides are suitable for making high performance permanent magnets. The high field magnetization measurements performed up to 200 kOe in continuous fields are reported. In this article, the isothermal magnetization curves measured between 2 and 300 K on powder samples embedded in a resin and then aligned under a magnetic field of about 10 kOe in order to get oriented samples are presented. The magnetic anisotropy constants K_1 and K_2 are determined taking into account the angular distribution of the grains axis. The results are discussed in light of previously reported data and then the effects of C or H on the Sm contribution to the anisotropy is compared to that of N. It is shown that carbon and hydrogen have opposite influence on the Sm anisotropy and it is suggested that a wide range of magnetic anisotropy can be obtained depending on the H and C content. The influence of both interstitial elements H and C on magnetic features such as the Curie temperature and the saturation magnetization is analyzed.

The search for new hard permanent magnet materials has recently concentrated on the ternary carbides and nitrides $R_2Fe_{17}C_x$ and $R_2Fe_{17}N_x$. The crystallographic and magnetic properties of the R_2Fe_{17} compounds have been known for many years[1–3] and in a recent article we have reported in detail on the magnetic properties[4] of $Sm_2Fe_{17}N_3$, $Sm_2Fe_{17}D_5$, and $Pr_2Fe_{17}N_3$. Following our previous high field magnetization, we will concentrate in this article on the properties of $Sm_2Fe_{17}C_x$ and $Sm_2Fe_{17}C_xH_{5-x}$ compounds.

Samples of Sm_2Fe_{17} were prepared by induction melting in cold crucible under argon atmosphere, whereas $Sm_2Fe_{17}C_{0.6}$ has been obtained by arc furnace. The samples were found to be mainly single phase with small traces of iron in the case of $Sm_2Fe_{17}C_x$. The x-ray patterns of the rhombohedral compounds were indexed using the hexagonal multiple cell. Hydrogenation was performed in a stainless steel autoclave under hydrogen gas pressure of about 5 MPa leading to a stable hydride. The hydrogen uptake was determined by gravimetric methods and confirmed by volumetric estimation. The accuracy of the hydrogen concentration can be evaluated to about 0.1 hydrogen atom per formula unit; The Curie temperature was determined using Faraday-type torque balance.

Magnetic measurements were performed using an automatic system provided with a cryostat associated to a calorimeter which has been described in detail elsewhere.[5] The magnetization experiments were carried out in a continuous field up to 200 kOe produced by a water-cooled Bitter magnet. No single crystals were available due to the decrepitation process which is known to occur when hydrogen is inserted in R_2Fe_{17} compounds.[6,7] All the samples were sieved down to a particle size smaller than 25 μm. Then the powder was mixed with epoxy resin and subsequently aligned at room temperature using an orientation field of typically 10 kOe.

The crystal structure of the Sm_2Fe_{17} alloys is well established; its crystal symmetry is R-3m whose lattice parameters are reported in Table I. De Mooij and Buschow[8] as well as Gueramian and co-workers[9,10] have shown that $R_2Fe_{17}C_x$ phases can be obtained from a $R_2Fe_{14}C$ series depending upon the heat treatment. R_2Fe_{17} carbides correspond to the high temperature phase and $R_2Fe_{14}C$ correspond to the low temperature phases. Helmholdt *et al.*[11] have shown using

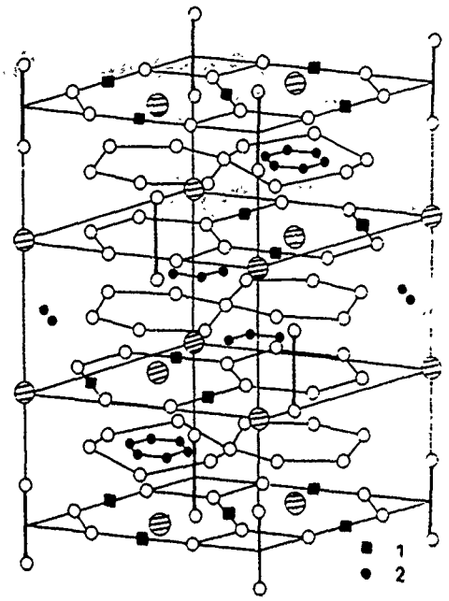

FIG. 1. R_2Fe_{17} crystal structure; large and small circles refer to rare earth and iron, respectively. Octahedral and tetrahedral sites are labeled 1 and 2, respectively.

neutron diffraction experiments that carbon atoms are accommodated within the crystal lattice on an interstitial site called 6*c*. This site can be seen as a pseudooctahedral site with two rare-earth and four iron atoms at the corners. The exclusive occupancy of this 6*c* site has been confirmed by a more recent work.[8]

The large difference in radii between iron and rare-earth atoms leads to large interstitial sites which are often used in rare-earth iron intermetallic compounds to insert hydrogen. Since hydrogen is significantly smaller than C or N, it does not only go to the octahedral site but also into some tetrahedral sites represented in Fig. 1. The location of hydrogen or deuterium in the R_2Fe_{17} lattice has been shown by neutron diffraction[12,13] and is discussed in detail elsewhere. All these atoms are located in the neighborhood of the rare-earth atoms, their influence on the crystal electric field by acting on the rare-earth site is expected to be important. This has been confirmed frequently for N (Refs. 4,14–17) and sometimes for C.[19] The influence of hydrogen on the magnetic features of the R_2Fe_{17} compounds has attracted less attention till now[19,20] but a recent study[4] has shown that the influence of hydrogen on the rare-earth anisotropy is opposite to that of nitrogen. Here we study $Sm_2Fe_{17}C_x$ and $Sm_2Fe_{17}C_xH_{5-x}$ in order to compare the influence of C to that of N and H. Insertion of H in a R_2Fe_{17} carbide is expected to occur in the two interstitial sites: (i) the remaining octahedral site not occupied by C atoms, (ii) the tetrahedral site.[21] These assumptions have been recently confirmed for $Th_2Fe_{17}C_xH_y$ [21] and $R_2Fe_{17}C_xH_y$ (R=Ce,Nd,Ho,...).[22] No neutron diffraction determination is possible on such phases due to the high absorption cross section of Sm for thermal neutrons,[23] nevertheless Sm compounds are expected to behave as others R_2Fe_{17} compounds do.

Insertion of light elements (H, C, or N) in Sm_2Fe_{17} alloys induces a significant lattice expansion. It is worth noting that even for the largest interstitial element, C or N, the symmetry of the host alloy is retained in the interstitial containing compound, no change of structure is observed in Sm compounds. It is not always the case since R_2Fe_{17} (R=Er, Tb, Ho, or even Y) alloys which are known to crystallize in $P6_3/mmc$ symmetry are observed to retain their rhombohedral structure for high carbon content.[24,25] As expressed by Table I, the lattice parameters of the nitrided compounds are larger than that of other interstitial compounds. Whatever the interstitial element used, the increase of the lattice occurs mainly in the basal plain (a,b) of the hexagonal cell, the expansion along the c axis being less pronounced. The volume expansion per interstitial atom deduced from Table I is in close agreement with previous results[21] obtained on Th_2Fe_{17} compounds. Insertion of hydrogen induces an expansion of about 2.3 Å^3/atom which is about one-third of that induced by carbon or nitrogen.

Results reported in Table II show that whatever the interstitial element used the saturation magnetization of the ternaries are significantly higher than that of the Sm_2Fe_{17} compound. In spite of a higher content in interstitial atoms, the hydride or carbohydride compounds exhibit a lower magnetization than $Sm_2Fe_{17}N_3$.

Studying several $Sm_2Fe_{17}C_x$ compounds with different carbon contents Grössinger *et al.*[18] have shown that for concentrations higher than $x=0.5$ the magnetic anisotropy is uniaxial. The magnetization curves measured for $Sm_2Fe_{17}C_{0.6}$ (Fig. 2) reveal a positive value of K_1 at 4.2 K thus confirming the measurements of Grössinger *et al.*[18] and Ding *et al.*[26] It is known that the iron sublattice anisotropy in $R_2Fe_{17}C_x$ compounds remains planar whatever the iron content;[27] the uniaxial character of the $Sm_2Fe_{17}C_{0.6}$ com-

pound is thus due to the contribution of Sm which overcomes that of the Fe sublattice. The insertion of only 0.6 carbon per formula unit is enough to change the sign of the Sm anisotropy from easy plane in Sm_2Fe_{17} to easy axis in $Sm_2Fe_{17}C_{0.6}$. The anisotropy of the rare-earth sublattice is in this structure very sensitive to the interstitial concentration. The measurements performed on $Sm_2Fe_{17}C_{0.6}H_{4.4}$ show that addition of hydrogen within the crystal structure leads to a huge effect on the magnetocrystalline anisotropy since our measurements reveal a change of the sign of the low order parameter K_1 which became negative in $Sm_2Fe_{17}C_{0.6}H_{4.4}$ (Fig. 3). This result is in good agreement with previous experiments on $Sm_2Fe_{17}H_5$ compounds. Nitrogen or carbon insertion have opposite effects. ^{155}Gd Mössbauer[28,29,19] studies have shown that the major effect of the interstitial elements is to modify the quadrupolar interaction on the rare-earth site. The modification of the R contribution to the magnetic anisotropy is thus due to the change of the CEF acting on the rare-earth site. It is worth noting that $Sm_2Fe_{17}C_{0.6}H_{4.4}$ exhibits higher K_1 values than $Sm_2Fe_{17}H_5$ confirming that the role played by carbon on the Sm magnetic anisotropy is opposite to that of hydrogen. It is thus interesting to notice that depending on the H and C concentration, a large range of the anisotropy field should be accessible in the $Sm_2Fe_{17}C_xH_y$ system.

X-ray structural studies of nitrogen diffusion in Dy_2Fe_{17}

Er. Girt, Z. Altounian, X. Chen, Ming Mao, D. H. Ryan, M. Sutton, and J. M. Cadogan[a)]
Centre for the Physics of Materials, Department of Physics, McGill University, 3600 University Street, Montréal, Québec, Canada H3A 2T8

The reaction between N_2 and Dy_2Fe_{17} has been studied by thermopiezic analysis on 20–25 μm sized powders in the temperature range 400–500 °C. Partially nitrided powders were analyzed using CuK_α x-ray diffraction and thermomagnetic techniques. Both high angle x-ray and thermomagnetic data show only the presence of Dy_2Fe_{17} and $Dy_2Fe_{17}N_{3-\delta}$ ($\delta<0.3$) with no evidence of intermediate compositions. The results of the x-ray diffraction experiments at several Bragg peaks were simulated using a two phase model structure: a Dy_2Fe_{17} core with a $Dy_2Fe_{17}N_3$ surface layer. The results show that at low temperatures the nitride layer is too thin to account for all of the nitrogen absorbed by the sample, indicating that a significant amount of the nitrogen diffused into the core of the particles, presumably along grain boundaries.

During a gas–solid reaction, nitrogen diffuses into R_2Fe_{17} (R=rare earth), occupying interstitial sites and expanding the lattice without changing the crystal structure. The enhancement of the magnetic properties was observed[1] as a result of interstitial nitrogen diffusion in R_2Fe_{17}. Neutron powder diffraction[2] showed that the R_2Fe_{17} and $R_2Fe_{17}N_3$ phases are in equilibrium during the reaction. However, it was observed[3,4] that a continuous solid solution $R_2Fe_{17}N_x$ ($0<x<3$) is formed on annealing partially nitrided powders. In this study we use x-ray diffraction and thermomagnetic techniques to characterize nitrogen diffusion in the 2-17 structure. Nitrogen diffusion in the 2-17 structure typically occurs above 350 °C, and significant diffusion through extended defects such as grain boundaries at 400 °C has been observed using metallography.[5]

The polycrystalline Dy_2Fe_{17} alloy was prepared by induction melting of appropriate amounts of Dy and Fe, followed by vacuum annealing at 1173 K for two weeks. Induction melting ensures homogeneity of alloys and mass loss was below 0.03% during preparation. The homogenized ingot was ground and sieved to select powder sizes between 20 and 25 μm. The powder size was confirmed by scanning electron microscopy. Nitrogen diffusion was performed in a thermopiezic analyzer (TPA) at a starting pressure of 1 bar and temperatures ranging from 400 °C (590 min) to 500 °C (25 min) to obtain $Dy_2Fe_{17}N_{0.85}$. The amount of nitrogen diffused into the sample was obtained directly from the gas pressure change in the TPA. Structural analyses on Dy_2Fe_{17}, before and after the gas–solid reaction, were carried out using CuK_α radiation on an automated Nicolet–Stöe powder diffractometer with a graphite monochromator in the diffracted beam. Thermomagnetic analyses were done using a Perkin–Elmer thermogravimetric analyzer (TGA) in a small field gradient.

The x-ray diffraction pattern of $Dy_2Fe_{17}N_{0.85}$ is shown in Fig. 1. As a consequence of nitriding, a new phase was formed with the same structure as Dy_2Fe_{17} but with the Bragg peaks shifted towards lower angles indicating an expansion of the unit cell. This shift is shown more clearly in Fig. 2, where the (300) peaks of $Dy_2Fe_{17}N_{0.85}$ (top) are compared with those (bottom) of pure Dy_2Fe_{17} (N_0) and $Dy_2Fe_{17}N_3$ (N_3). $Dy_2Fe_{17}N_{0.85}$ clearly contains both $Dy_2Fe_{17}N_3$ and unreacted Dy_2Fe_{17}. The position of the Dy_2Fe_{17} peak is shifted towards lower angles, due to the expansion of the unreacted core, while that of $Dy_2Fe_{17}N_3$ is shifted slightly towards higher angles. Careful examination of the (332) Dy_2Fe_{17} and $Dy_2Fe_{17}N_3$ diffraction peaks (inset of Fig. 1), which are well separated, shows no evidence of the existence of an intermediate composition phase. Using TGA two distinct Curie temperatures, $T_{c1}=128$ °C and $T_{c2}=445$ °C are detected as shown in Fig. 3. T_{c1} is 28 °C higher than the Curie temperature of Dy_2Fe_{17} and T_{c2} is 5 °C lower than the Curie temperature of $Dy_2Fe_{17}N_3$. The x-ray and the TGA data are thus in agreement, as T_c changes with the lattice expansion of Dy_2Fe_{17}. Even if the observed experimental data only show the existence of Dy_2Fe_{17} and $Dy_2Fe_{17}N_3$, they are not at equilibrium at 500 °C. After subsequent annealing for 60 h at 480 °C, a uniform $Dy_2Fe_{17}N_{0.85}$ solid solution was obtained. Further work is in progress to study this equilibrium phase. Because $Dy_2Fe_{17}N_3$ and Dy_2Fe_{17} are not in equilibrium, we tried to estimate the amount of the undetected intermediate phase (in the interface between $Dy_2Fe_{17}N_3$ and Dy_2Fe_{17}) by comparing the x-ray patterns of crushed $Dy_2Fe_{17}N_{0.85}$, shown in Fig. 2(b), with

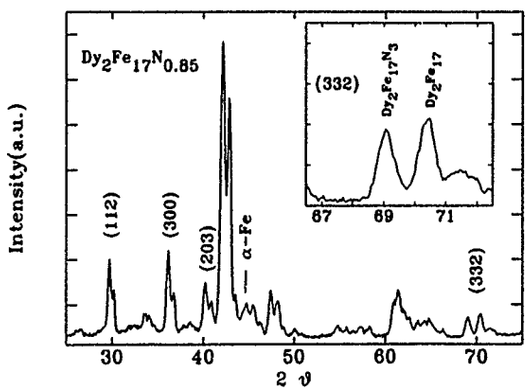

FIG. 1. The x-ray diffraction pattern of $Dy_2Fe_{17}N_{0.85}$ for nitrogen diffused at 500 °C for approximately 25 min. Inset: (332) peak of $Dy_2Fe_{17}N_{0.85}$.

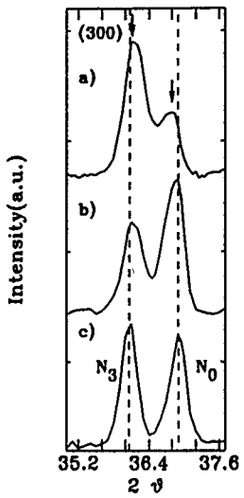

FIG. 2. (a) The (300) diffraction peak of $Dy_2Fe_{17}N_{0.85}$ (powder sizes between 20 and 25 μm). (b) The diffraction peak of the subsequently crushed $Dy_2Fe_{17}N_{0.85}$. (c) The (300) peak of a mixture of pure Dy_2Fe_{17} and $Dy_2Fe_{17}N_3$ powders in the ratio 1:1.

those (bottom of Fig. 2) of pure Dy_2Fe_{17} (N_0) and $Dy_2Fe_{17}N_3$ (N_3). Note that for the crushed $Dy_2Fe_{17}N_{0.85}$ powder the x-ray peaks are mostly relaxed to the unshifted positions. Fitting shows that the possible amount of the intermediate phase is much lower than the amount of the $Dy_2Fe_{17}N_3$ phase.

Nitrogen distribution can be estimated from the ratio of the intensities of the diffraction peaks by using a simple model where the core is nitrogen-free and the surface layer is fully nitrided as shown schematically in Fig. 4. Estimating the volume fractions is complicated because the $Dy_2Fe_{17}N_3$ phase coats the Dy_2Fe_{17} phase and so attenuates the x-ray scattering. In a multilayered system the intensity of the reflected beam from the ith layer can be expressed as

$$I_i = I_0 e^{-\Sigma_{j=1}^{i-1}(2d_j\mu_j/\sin\theta)} \int_0^{d_i} e^{-2x\mu_i/\sin\theta}\, dx \int dS, \quad (1)$$

where I_0 and θ are the intensity and angle of the incident beam, d_i and μ_i are the thickness and absorption coefficient of the ith layer, respectively, and S is the surface area illuminated by the beam. The term $e^{-\Sigma_{j=1}^{i-1}(2d_j\mu_j/\sin\theta)}$ comes from the attenuation of the x-ray beam from the top $(i-1)$ layers. For the two layer model, the intensity ratio becomes

$$I_1/I_2 = (\mu_2/\mu_1)(e^{2d_1\mu_1/\sin\theta} - 1), \quad (2)$$

where we have neglected the term $e^{-2d_2\mu_2/\sin\theta}$ as $d_2 \approx 20$ μm and $\mu_2 = 1.577$ μm^{-1}.

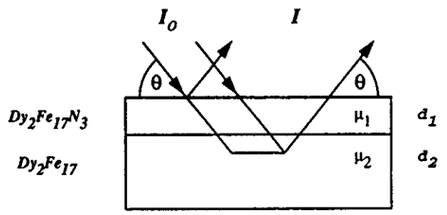

FIG. 4. Two layer model structure used to calculate x-ray diffraction patterns.

The relative intensities (I_1, I_2) were estimated by a simultaneous fitting of the measured (112), (300), and (203) Bragg peaks to Eq. (1) where each Bragg peak is a combination of two Gaussians with position p_i and width w_i ($i = 1,2$), representing the contributions from $Dy_2Fe_{17}N_3$ and Dy_2Fe_{17}. The widths, w_1 and w_2, are adjusted during the fitting. We note that this model assumes that the nitrogen diffuses uniformly through the bulk of the material. Figure 5 shows the CuK_α x-ray diffraction patterns of $Dy_2Fe_{17}N_{0.85}$ samples nitrided at 500 °C. The solid lines in Fig. 5 are the fits to the experimental data and the dotted lines are the contributions of Dy_2Fe_{17} and $Dy_2Fe_{17}N_3$ calculated from the model. Assuming that the average particle has a rectangular shape with the dimensions $20\times15\times10$ μm^3 (this particle shape is an approximate representation deduced from scanning electron microscope photographs) we obtain, using the calculated thicknesses of the layers, that for nitrogen diffusion at 500 °C approximately 90% of the nitrogen can be accounted for by the intensity of the fully nitrided peak. This shows that almost the entire amount of nitrogen is in the surface layer (the penetration of the CuK_α in Dy_2Fe_{17} is restricted to approximately 1–2 μm). To observe the nitrogen

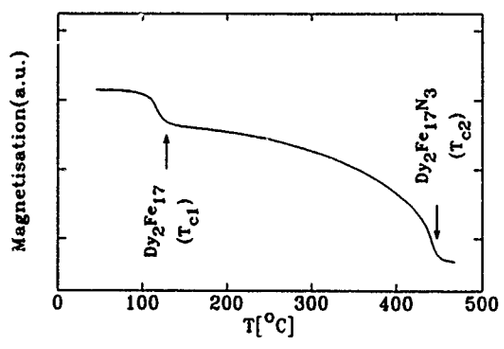

FIG. 3. Thermogravitometric analyses of $Dy_2Fe_{17}N_{0.85}$. T_{c1} correspond to the Curie temperature of the Dy_2Fe_{17} and T_{c2} to Curie temperature of the $Dy_2Fe_{17}N_3$ phase.

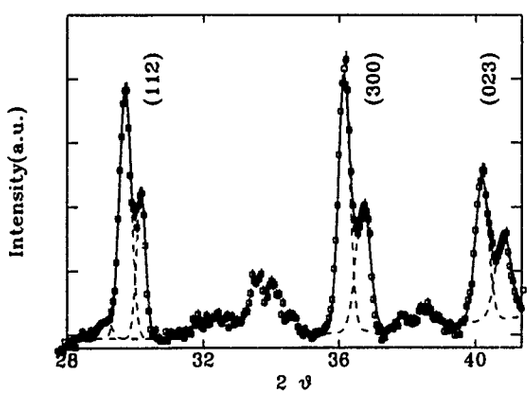

FIG. 5. Simultaneous fitting of (112), (300), and (023) peaks using a two layer model structure. The solid lines are contributions of Dy_2Fe_{17} and $Dy_2Fe_{17}N_3$ calculated from the model.

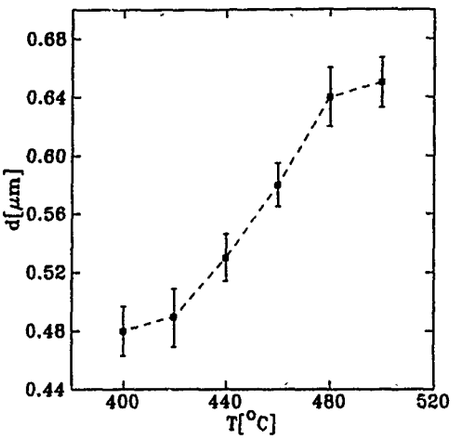

FIG. 6. Effect of reaction temperature on the apparent $Dy_2Fe_{17}N_3$ layer thickness derived from fits to the x-ray diffraction patterns. All samples have the same nominal nitrogen content.

distribution at different temperatures we introduced the same amount of nitrogen (a bulk average of 0.85 atoms per unit formula) to 20–25 μm sized powders at temperatures between 400 and 500 °C.

The values for the thicknesses of the nitrided layer versus the nitriding temperature is shown in Fig. 6. Despite the fact that all of the nitrided samples have the same nominal composition, the $Dy_2Fe_{17}N_3$ surface layer is clearly thinner in the samples prepared at lower temperatures. In the absence of any evidence for the formation of an intermediate composition nitride phase, we attribute the apparent nitrogen deficit to the formation of the nitride phase at depths within the particles beyond the penetration range of the CuK_α radiation ($\approx$1 μm). For this to happen, the nitrogen must find more rapid diffusion paths than bulk diffusion allows, presumably along extended defects such as grain boundaries. Above 480 °C, the two layer model accounts for over 90% of the absorbed nitrogen, and we conclude that for these temperatures nitrogen transport is dominated by bulk diffusion.

In conclusion, using x-ray diffraction and a thermomagnetic technique only Dy_2Fe_{17} and $Dy_2Fe_{17}N_3$ phases were observed. The thickness of the nitrogen layer was obtained by fitting x-ray diffraction peaks with a two phase model structure: a $Dy_2Fe_{17}N_3$ surface layer and a Dy_2Fe_{17} core. Significant nitrogen diffusion through extended defects such as grain boundaries was observed at temperatures below 480 °C.

Atomic diffusion mechanism and diffusivity of nitrogen into Sm_2Fe_{17}

Chris N. Christodoulou and Norikazu Komada
Central Research Institute, Mitsubishi Materials Corporation, 1-297 Kitabukuro-cho, Omiya, Saitama 330, Japan

An atomic diffusion mechanism (voidal diffusion) is proposed where nitrogen atoms migrate inside the Sm_2Fe_{17} lattice by jumping from a $9(e)$ site into a thermodynamically unstable tetrahedral $18(g)$ site and subsequently into a new $9(e)$ site. For the first time, the anisotropic nature of diffusion and growth kinetics together with direct observation of the diffusion fields by Bitter domain patterns have been taken into account and employed for nitrogen diffusivity measurements. The planar and axial preexponential factors were found to be $D_{OX}=0.72\times10^{-6}$ $m^2 s^{-1}$ and $D_{OZ}=2.26\times10^{-6}$ $m^2 s^{-1}$, respectively. The activation enthalpy, ΔH, for diffusion was found to be 143 kJ/mol.

I. INTRODUCTION

The metastable $Sm_2Fe_{17}N_3$ compound is an attractive material for permanent magnets.[1] It can be prepared by direct reaction of Sm_2Fe_{17} particles with N_2 gas. The reaction involves a slow diffusion of N atoms from the surface to the center of the particles. In order to improve the observed low diffusivity it is important to understand the atomic diffusion mechanism operating in this particular case. Such a mechanism has been proposed recently by Christodoulou and Takeshita[2] and Christodoulou and Komada.[3] The present article represents a study of the anisotropic diffusion and experimental results supporting the proposed atomic diffusion mechanism presented. The planar (D_{OX}) and axial (D_{OZ}) preexponential factors and activation enthalpy (ΔH) of the nitrogen diffusivity into Sm_2Fe_{17} are also reported.

II. EXPERIMENT

Clean Sm_2Fe_{17} particles were prepared by applying the interstitial hydrogen absorption desorption process on large pieces of a Sm_2Fe_{17} homogenized alloy.[1] Most of the particles were single grains and only those with particle size of larger than 100 μm were used for the diffusion experiments. The diffusion experiments were performed at temperatures of 400 and 425 °C for 20, 50, and 100 h and at 450 and 475 °C for 5, 10, 20, and 50 h. The pressure was monitored to be constant at 1 atm. Each experiment (temperature-time combination) was conducted twice. The $Sm_2Fe_{17}N_x$ phase was identified by Bitter domain patterns (colloidal solution of magnetite) formed on polished particles which were prealigned in a magnetic field. The thickness of the domain patterns were measured and averaged for at least 20 particles obtained in each run. Phase analysis was also performed by x-ray diffraction (CuK_α) and by thermomagnetic analysis (TMA).

III. THE ATOMIC DIFFUSION MECHANISM

A detailed description of the mechanism can be found in Refs. 2 and 3. Nitrogen atoms can migrate by jumping from a $9(e)$ site into a thermodynamically unstable tetrahedral $18(g)$ site and subsequently into a new $9(e)$ site (Fig. 1). In such a migration path, nitrogen atoms have to encounter an enormous energy barrier accounting for the energy needed to overcome the strong bonding from its nearest neighbors (Fe and especially the Sm atoms) and more importantly for the strain energy needed to break through of the octahedral face [Fe(f)-Sm(c)-Fe(h)] and in through the tetrahedral face [Fe(h)-Sm(c)-Fe(h)]. Although the $18(g)$ sites cannot accommodate any nitrogen atom in an equilibrium fashion,[4] their presence plays a key role for the diffusion of the nitrogen atoms. The temperature dependence of the diffusivity can be written[3] as $D_{XX}=D_{OX}\exp(-\Delta H/RT)$ along the planar α axes and $D_{ZZ}=D_{OZ}\exp(-\Delta H/RT)$ along the c axis, where T is the absolute temperature and R is the gas constant (8.314 J mol^{-1} K^{-1}). Also, it can be shown[3] that the anisotropic ratio of D_{XX}/D_{ZZ} is equal to $\frac{5}{8}(\alpha/c)^2$, where α and c are the lattice parameters of Sm_2Fe_{17}. By substituting $\alpha=8.549$ Å and $c=12.441$ Å, D_{XX}/D_{ZZ} takes the value of 0.3. In the case where the diffusing atoms (like hydrogen) are allowed to move inside the $18(g)$ "circular tunnel" (Fig. 1), the anisotropic ratio of D_{XX}/D_{ZZ} can be as large as $\frac{9}{4}(\alpha/c)^2$ or 1.07 (essentially isotropic).

IV. THE KINETICS OF $Sm_2Fe_{17}N_3$ GROWTH

The solution of the diffusion equation for the nitrogen concentration, $C(x)$, inside the diffusion layer in the case of large particles (almost flat surface) and short times (no overlapping of diffusion fields) can be approximated with that in a semi-infinite medium (Fig. 2) and is given by

$$C(x)=C_s\,\mathrm{erfc}[(x-L)/2\sqrt{(Dt)}], \tag{1}$$

where C_s is the constant surface and growing phase ($Sm_2Fe_{17}N_3$) concentration (Ref. 5), L is the thickness this phase ($Sm_2Fe_{17}N_3$), D is nitrogen diffusivity assumed to be constant, t is the time, and x measures from the surface of the particle.

For diffusion controlled growth

$$C_sL=\int_0^t -D\left[\frac{\partial C(x)}{\partial x}\right]_L dt. \tag{2}$$

From Eq. (1)

$$\left[\frac{\partial C(x)}{\partial x}\right]_L=-\frac{C_s}{\sqrt{\pi Dt}}. \tag{3}$$

By combining Eqs. (2) and (3) and integrating we get

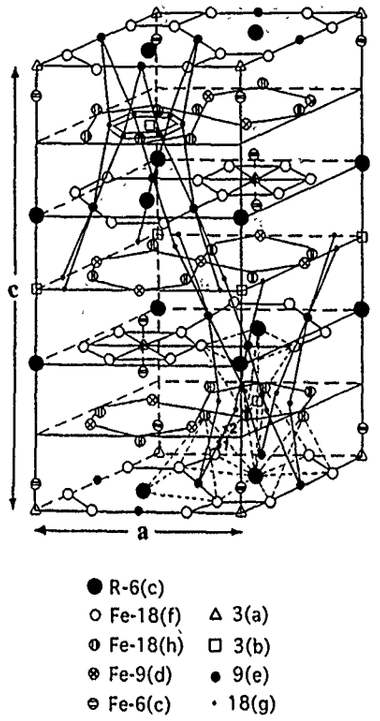

FIG. 1. Schematic representation of the hexagonal cell of the Sm_2Fe_{17} ($R\bar{3}m$) structure and the atomic jump network [single solid lines connecting the 9(e) with the 18(g) sites] of the nitrogen atoms during voidal diffusion. Double solid lines connecting the 18(g) sites represent the "circular tunnel" through where hydrogen atoms can be tunneled. The saddle point configurations, SPC1 and SPC2, are marked by "$\times$."

$$L=(2/\sqrt{\pi})\sqrt{Dt}. \tag{4}$$

The tangent of the concentration profile at the beginning of the diffusion layer (Fig. 2) defines a diffusion length, $D_\lambda = \sqrt{\pi Dt}$, which represents the effective penetration of nitrogen atoms where the magnetocrystalline anisotropy of the nitrogen containing Sm_2Fe_{17} is assumed to become axial and exhibits a domain structure as observed in the Bitter domain patterns. It is to be noted that the nitrogen-free Sm_2Fe_{17} phase does not form any observable domain patterns. The observable thickness of the Bitter domain pattern will be

$$d=L+D_\lambda=[(2/\sqrt{\pi})+\sqrt{\pi}]\sqrt{Dt}. \tag{5}$$

The diffusivity at a particular temperature and direction (planar or axial) will be:

$$D=\pi d^2/(2+\pi)^2 t=D_0\exp(-\Delta H/RT), \tag{6}$$

where, d is measured along that particular direction.

V. RESULTS—DISCUSSION

Typical Bitter domain patterns of nitrogenated Sm_2Fe_{17} particles are shown in Fig. 3. Particles with their c axis perpendicular to the observation plane exhibit a uniform "maze-type" domain pattern around the particle reflecting the uniaxial magnetocrystalline anisotropy and the isotropic nature of diffusivity in the c plane. Particles with their c axis on the observation plane exhibit a "parallel lines-type" domain pattern with deeper penetration reflecting both the uniaxial

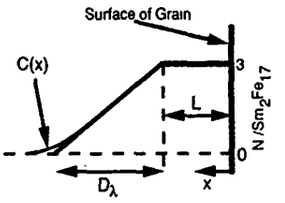

FIG. 2. Growth of $Sm_2Fe_{17}N_3$ from the surface to the center of a Sm_2Fe_{17} grain.

magnetocrystalline and diffusion anisotropy. A typical x-ray diffraction (XRD) pattern and a thermomagnetic analysis (TMA) trace for particles nitrogenated at 475 °C for 20 h are shown in Fig. 4.

By fitting the data in Table I for planar diffusivity according to Eq. (6), the preexponential factor, D_{OX}, and the activation enthalpy, ΔH, were found to be $(0.72\pm0.05)\times10^{-6}$ m^2 s^{-1}, and (143 ± 10) kJ mol^{-1}, respectively (Fig. 5). Applying the same for the axial diffusivity, the preexponential factor, D_{OZ}, and the activation enthalpy, ΔH, were found to be 1.21×10^{-6} m^2 s^{-1} and 139 kJ mol^{-1}, respectively. According to the proposed model, ΔH should be the same along xy and z axes. The experimentally determined values of 143 and 139 kJ mol^{-1} are essentially the same as expected from the proposed model. The degree of confidence for the data obtained for the planar diffusivity is greater than that for the axial diffusivity because the orientation of the particles could be unambiguously confirmed by the uniformity of the thickness of the domains formed around the particles. In the case of the axial diffusivity small misorientations of the particles are very difficult to be detected still revealing "parallel lines-type" of domain patterns. Therefore, the value of ΔH equal to (143 ± 10)

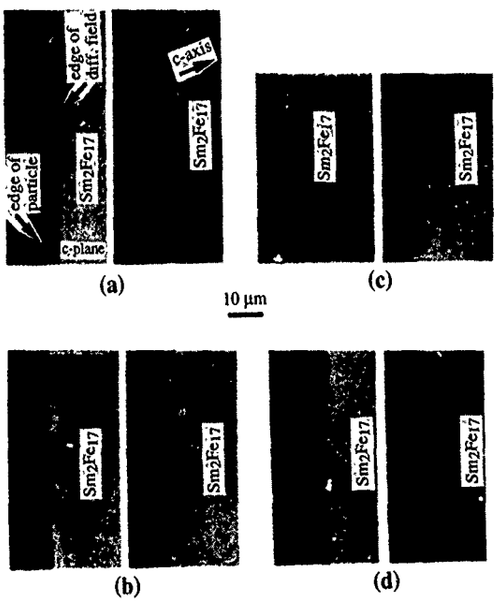

FIG. 3. Bitter domain patterns for Sm_2Fe_{17} particles nitrogenated at (a) 425 °C (50 h), (b) 425 °C (100 h), (c) 475 °C (5 h), and (d) 475 °C (10 h).

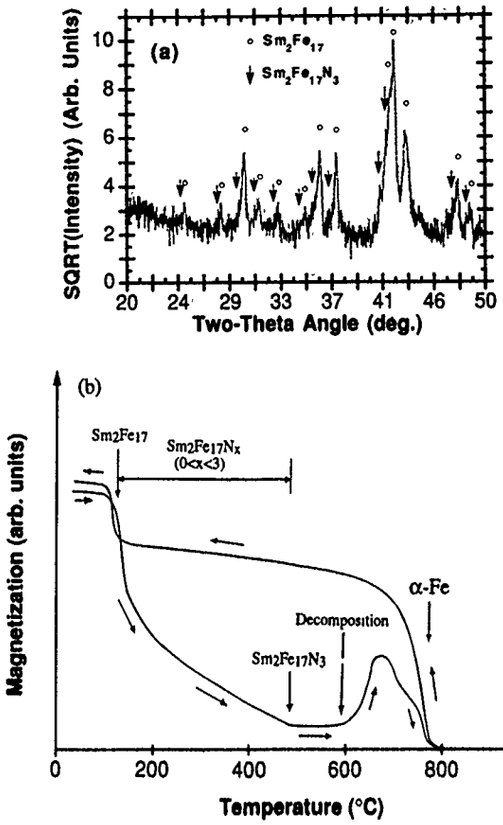

FIG. 4. X-ray diffraction pattern (a) and thermomagnetic analysis (b) of Sm_2Fe_{17} particles nitrogenated at 475 °C for 20 h. They confirm the presence of Sm_2Fe_{17} and $Sm_2Fe_{17}N_3$ phases together with the diffusion layer of $Sm_2Fe_{17}N_x$ ($0<x<3$).

kJ mol^{-1} is considered to be the correct one. Since ΔH was confirmed to be the same along xy and z axes, this restriction can be applied in order to obtain a refined value of D_{OZ} which is very sensitive to ΔH. Hence, $D_{XX}/D_{ZZ}=D_{OX}/D_{OZ}=(d_x/d_z)^2$, where d_x and d_z are the observed thicknesses of the domain patterns along x and z, respectively, at the same temperature and time. From this, the preexponential factor, D_{OZ}, was found to be $(2.26 \pm 0.15)\times 10^{-6}$ m^2 s^{-1}. The D_{OX}/D_{OZ} ratio is 0.32 ± 0.04, a value which is very close to 0.30 predicted by the atomic

	d_z=	7.64	11.57	···	···

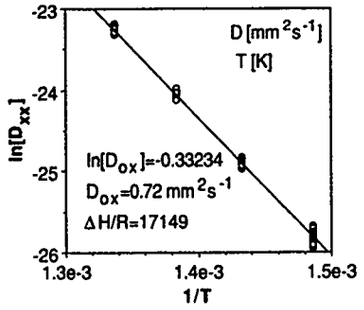

FIG. 5. Arrhenius plot of the planar diffusivity (D_{XX}) vs $1/T$.

diffusion mechanism. This value also suggests that during diffusion, nitrogen atoms are not permitted to move inside the $18(g)$ "circular tunnel,"[3] something expected to be occurring in hydrogen diffusion.

The activation entropy for diffusion,[3] ΔS, can be estimated to be $-0.343R$ through $D_{OX}=\gamma\tilde{\nu}\exp(\Delta S/R)$, where $\gamma=1.015\times10^{-6}$ m^2 s^{-1}, and $\tilde{\nu}=10^{13}$ s^{-1}. Such a negative activation entropy is attributed to the large increase in the vibrational frequencies of the atoms influenced by diffusion. The ratio of the vibrational frequency during diffusion to the initial one, ν_i'/ν_{io}, can be estimated[3] to be 1.4. Such a value is physically reasonable based on the fact that a nitrogen atom has to squeeze through and come in close contact with the atoms at the two saddle point configurations, SPC1 and SPC2 (Fig. 1).

The high value of the activation enthalpy for diffusion (143 kJ mol^{-1}) is indicative of the large energy barrier which a nitrogen atom encounters during its migration from one $9(e)$ site to another. This value falls within the limits predicted by Christodoulou and Komada[3] and it mostly accounts for the huge strain energy needed for a nitrogen atom to break through the two saddle point configurations, SPC1 and SPC2.

It is difficult to compare the values of D_0 and ΔH obtained in the present study with others published in the literature[6–8] because this is the first time that the anisotropic nature of the diffusivity and growth kinetics have been taken into account together with direct observation of the diffusion fields. Nevertheless, the present values compare favorably to the values obtained by Skomski and Coey[8] but are much higher than the ones reported in Refs. 6 and 7.

Effect of nitrogen on the properties of hard magnets

M. Melamud[a] and L. H. Bennett
National Institute of Standards and Technology, Gaithersburg, Maryland 20899

R. E. Watson
Brookhaven National Laboratory, Upton, New York 11973

The enhancement of magnetic properties of RE-TM hard magnet materials, such as RE_2Fe_{17}, upon nitriding is studied using the Wigner–Seitz (Voronoi) construct. In analogy with other RE-TM nitrides, it is concluded that nitrogen has a strong preference to occupy the octahedral $9e$ site in the 2:17 compounds, to the exclusion of the other proposed sites. Additional materials are suggested as candidates for nitriding on the basis of the availability of such an octahedral site. The site preference and its effect on the magnetism in RE_2Fe_{17} is discussed in relation to the Wigner–Seitz cell of the atoms. The magnetic moments on the iron are shown to be correlated with the WS cell volumes, and this dependence differs from that associated with αFe.

Renewed interest in the RE-Fe 2:17 hard magnets[1] has arisen because of the enhanced magnetic properties achieved by alloying them with nitrogen (or carbon). The addition of nitrogen causes an increase in lattice parameters, Curie temperature, sublattice magnetic moment, and anisotropy field. It has been observed theoretically[2,3] and experimentally[4,5] that iron atoms exhibit different moments on different sites in RE_2Fe_{17} and its nitride.

While there is no argument in the literature about these changes, and it has been agreed by all authors that nitrogen is interstitial (not substitutional), different sites have been suggested by different authors. Pr_2Fe_{17} and the other RE_2Fe_{17} compounds discussed in this work are those having the Th_2Zn_{17} structure—space group $R\bar{3}m$ (Table I). The sites suggested for N (or C) in the same space group are $3a$,[6] $9e$,[5,7] $18h$,[8] and $18g$.[9] One of the principal purposes of this paper is to address the problem of where in fact the nitrogen resides in the nitrided compounds. The choice is quite clear if one notes the behavior[10] of ordered TM nitride compounds.

The Wigner–Seitz (WS) cell construct has previously been suggested[11] as a method for studying the relationship of crystal structure and properties, especially with regard to magnetic properties of hard magnets. WS (or Voronoi) polyhedra furnish a useful measure of the local environment of an atom, including a description of the site symmetry of the atom, and a catalog of what atoms constitute its nearest neighbors. A modified WS construction[11,12] also accounts for the relative sizes (i.e., atomic radii) of the various atoms. It has been also observed[11] using the WS construct that "disclination nets" pass through those metal sites which have the largest magnetic moments. (Disclinations are chemically important bond lines.) The nets defined by these disclinations have been shown to be correlated with the anisotropy axes of hard magnets.[11] Structural factors, in addition to Invar-type volume effects, are expected to be important to local $3d$ magnetism in the hard magnets.

Wigner–Seitz cell construction has been employed to derive a measure of the local site volumes, and explore their correlations with the magnetic moments.[11] In αMn, for example, if we assume that all the Mn atoms have the same radius, then the WS cells have different volumes. Relating these volumes to the magnetic moments at the four Mn sites in αMn, a nearly linear relation is found. A similar result is obtained for the four Fe sites in the hard magnet, Pr_2Fe_{17} Ref. 12 (Table I). The relationship of the WS atomic volume and the disclinations to the enhancement of the magnetic properties are discussed in this paper, and suggestions for possible new hard magnet nitrides are given.

Based on calculations of the WS polyhedra for a wide array of TM metalloids[10] (with up to 50% metalloid content) it has been shown that each metalloid prefers a certain local environment defined by a special WS cell. One specific example is nitrogen which is always found in the (0 6) octahedral environment. [This environment competes with the higher coordinated (0 3 6) ninefold Bernal environment in the $3d$ metal carbides. In the $4d$-$5d$ carbide group (except for Nb_2C) the carbides have joined the nitrides in displaying only an (0 6) metalloid environment.[10] Boron is normally encountered in an (0 3 6) or (0 2 8) Bernal environment.] In analogy with these TM nitrides, we conclude that it would be extraordinary (i.e., indicative of a most unusual TM—N bonding) if nitrogen occupied anything other than the octahedral $9e$ site in the 2:17 compounds.

We have calculated the WS polyhedra for the Pr_2Fe_{17} and $Pr_2Fe_{17}N_3$ (assuming full occupancy) with nitrogen occupying any one of the suggested sites. The method of calculation is described elsewhere.[12] The results are presented[13] in Table I. Only in the $9e$ site is the WS polyhedron for nitrogen (0 6), namely, an octahedral array of six nearest neighbors. The other sites result in different, nonstable, polyhedra which have very small facets or edges and in some cases (e.g., $3a$ site) the resulting distances to neighboring atoms are too small.

Table II lists hard magnet materials, in addition to the Pr_2Fe_{17}, which were found to have enhanced magnetism upon nitriding. In all of these, the nitrogen is found to be in an octahedral (0 6) environment. These include $NdFe_{10}V_2$ and $NdFe_{10}Mo_2$, both having the $ThMn_{12}$ structure,[14] the hexagonal 2:17 (Tm_2Ni_{17}),[15] and the Fe_nN (n=3,4,8). In the lower part of Table II(a), we propose some other hard magnet

TABLE II. (a) WS polyhedra of the atoms in a number of hard magnet materials, before and after nitriding, assuming full N occupancy. The definitions of the polyhedra designations are given in (b). In the lower part of (a) we list the WS cells for the proposed sites (listed in the text) for nitrogen in materials not yet known to be nitrided. Due to partial RE and TM occupancy in $PrFe_7$, two possibilities are shown for TM3. (b) Shorthand designation defining various polyhedra types (Ref. 13) computed in some RE-TM-metalloid hard magnet materials, encountered in Table II(a). The designations are sorted according to total number of facets on the polyhedra. Different designations are defined for the three different types of atoms. For the metalloids, the *O* designates the octahedral environment, the *T* and *U* are the nine-fold and ten-fold Bernal environments, respectively.

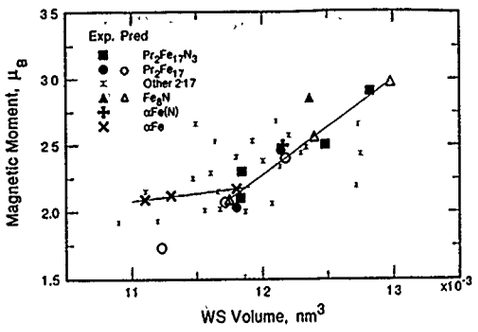

FIG. 1. Relation between the WS cell volume and magnetic moment per Fe atom in Pr_2Fe_{17} and its nitride. Also shown are results for iron nitride (Fe_8N), for αFe under pressure, and for αFe containing 1% N. Experimental and predicted values are represented by different symbols. The lines are the results of linear regression for (1) iron and (2) Pr_2Fe_{17} and its nitride. Also shown are values for Y, Nd, and Gd 2:17 compounds (Ref. 18).

materials which we have found have optional sites for nitrogen, with the same octahedral (0 6) WS cell as above. It is possible that these will also exhibit enhanced magnetic properties. The list includes RE-TM materials of the 1:5 ($CaCu_5$ and the related $CeCo_4B$), the 1:7 ($PrFe_7$) and the 2:14:1 ($Nd_2Fe_{14}B$) structures. The suggested sites for the nitrogen are $3f$ in space group $P6/mmm$, $9e$ in $R\bar{3}m$, and $2b$ in $P4_2/mnm$, respectively.

Iron volumes calculated from WS cell constructions are correlated with the known iron magnetic moments,[4,5] as can be seen in Fig. 1. $Pr_2Fe_{17}N_3$ is used as an example because of the availability of high-resolution neutron diffraction measurements,[5] which provide accurate moments for the four iron sites. The moments on the iron atoms for Pr_2Fe_{17} were derived[4] from Mössbauer experiments. Only the moment for the $6c$ site was resolved, and an average moment was assigned to the other three iron sites. We therefore have six experimental points, to which a linear regression has been applied, and predicted moments for the different sites were computed using their WS volumes. The average of the resulting moments for the three sites ($9d$, $18f$, and $18h$) is $2.18\mu_B$, as compared to the experimental value of $2.03\mu_B$.[4]

Another technologically relevant magnet is represented on Fig. 1, namely, Fe_8N, which is under study for use in reading heads.[16] The known experimental average moment for this material is $2.8\mu_B$ (at room temperature), shown in Fig. 1 using the average volume of the WS cells of these three sites. The iron atoms are in the three sites $4e$, $4d$, and $8h$ of space group $I4/mmm$. Predicted moments for the three sites are also shown on Fig. 1, as calculated from the WS site volumes using the same linear regression used for Pr_2Fe_{17}. The average value of these predicted moments is $2.7\mu_B$, in good agreement with the experimental value of $2.8\mu_B$. (The calculated band theoretical values[3] give an average of $2.4\mu_B$.)

Figure 1 includes also results[17] for αFe (as a function of pressure, at 0, 80, and 122 kbar). There seems to be a well-defined slope for these results, which is different from that in the 2:17 materials. This means that there are other factors which play an important role, such as coordination number, types of neighbors and the different exchange resulting from RE-TM in addition to Fe-Fe exchange. This result is supported by the observation[16] that an increase of ~0.5%–1% in the lattice parameter of αFe is accompanied by an increase of ~15% in its moment, resulting from the addition of a small amount of nitrogen. This result is shown in Fig. 1 to lie on the steeper line, off the αFe line. Other experimental and calculated critically collected[18] RE-TM data have been included in Fig. 1. A substantial scatter is seen resulting from inconsistencies even for the same material, and because not all values are saturation moments. There is no space to discuss this here.

The addition of the nitrogen into the structure in Pr_2Fe_{17} causes some changes in the topology of the WS cells of the neighboring atoms, which are probably correlated with the change in electron density caused by the nitrogen, and likely contribute to the break in slope. The main result is that the three fivefold facets connecting the RE to the Fe4 neighbors change into sixfold facets, thus incorporating the Fe4 into the sixfold disclination net and enhancing this net upon nitriding.

Theoretical analysis of the spin-density distributions in $Y_2Fe_{17}N_3$ and $Y_2Fe_{17}C_3$

W. Y. Ching, Ming-Zhu Huang, and Xue-Fu Zhong
Department of Physics, University of Missouri-Kansas City, Kansas City, Missouri 64110

The electronic structures and spin-density distributions in $Y_2Fe_{17}N_3$ and $Y_2Fe_{17}C_3$ are calculated using the self-consistent spin-polarized orthogonalized-linear-combination-of-atomic-orbitals method. The N or C atoms are assumed to occupy the $(9e)$ sites in the rhombohedral structure. The Fe $(18f)$ and N or C at the $(9e)$ site form covalent bonds which result in a very nonspherically symmetric spin-density distribution. The calculation shows a reduced moment for the Fe $(18f)$ sites due to doping. However, the moments at other sites are increased due to lattice expansion. There are some differences in the spin-density distribution between N and C at the $(9e)$ site. By comparing with the results of calculation on the pure Y_2Fe_{17} at different volumes, changes in moment enhancement and density of states at the Fermi level due to lattice expansion alone and that due to the chemical effect of introducing N or C are separated.

It has been well established that nitrogen (N) or carbon (C) doping in the rare-earth-Fe permanent magnets R_2Fe_{17} can raise the Curie temperature (T_c) substantially.[1,2] This is generally attributed to lattice expansion in the doped samples which increases the Fe-Fe interatomic distances and the exchange interactions. A large number of calculations exist which show the increase in the spin-magnetic moments on different Fe sites and significant changes in the density of states (DOS) at the Fermi level E_F upon N doping.[3–7] However, it is difficult to provide a direct explanation of the increase in T_c based on the electronic structure results since the electronic structure is a zero temperature entity. Mohn and Wohlfarth developed a theory based on a spin fluctuation mechanism which links with electronic structure to the T_c of a magnetic material.[8]

In spite of recent calculations on the electronic structure of the R_2Fe_{17} phases[3,9] and their nitroginated samples,[3–7] several questions remain unresolved. (1) The calculated spin moment on each Fe site is in general agreement with experiment, but discrepancies exist for specific sites such as Fe $(18f)$ and $(18h)$ in Y_2Fe_{17}.[10] The manner in which the spin moments have been obtained by different computational methods has not been fully scrutinized. (2) Separation of a chemical effect and volume expansion with introduction of N is important in understanding the mechanism for T_c enhancement. (3) It is generally assumed that the effects of the N doping or C doping on different R_2Fe_{17} crystals are similar. Realistic calculations may show subtle differences. (4) There is a fundamental question as to whether the local spin density approximation (LSDA) of the density functional theory on which almost all of the theoretical calculations are based, is good enough to answer the question of T_c enhancement. It is well known that the LSDA can give the wrong ground state in the case of elemental Fe crystals.[13]

In order to further understand some of these problems, we have carried out self-consistent, spin-polarized calculations on $Y_2Fe_{17}N_3$ and $Y_2Fe_{17}C_3$. Together with our previous calculations on pure Y_2Fe_{17} with different volume expansions,[10] we are able to separate the effects due to volume expansion and chemical doping. We focus on the details of the spin-density distribution in the vicinity of the doping sites as well as on the differences between systems with different dopings, i.e., N versus C.

We use the orthogonalized-linear-combination-of-atomic-orbitals (OLCAO) method in the LSDA. The procedures of the calculation have been described in the literature[14,15] and will not be repeated. A minimal atomiclike basis set consisting of orbitals of Y, Fe, N (C) which are expanded in terms of Gaussians in real space is employed. The crystal parameters used are listed in Table I. Three special **k** points are used in the self-consistent iterations, while in the final calculation, secular equations are solved at 11 special **k** points in the irreducible wedge of the Brillouin zone of the trigonal cell. The final charge and spin densities are calculated from the resulting eigenfunctions at these 11 **k** points with proper corrections for the core orthogonalization applied. The spin-magnetic moments at each site are ob-

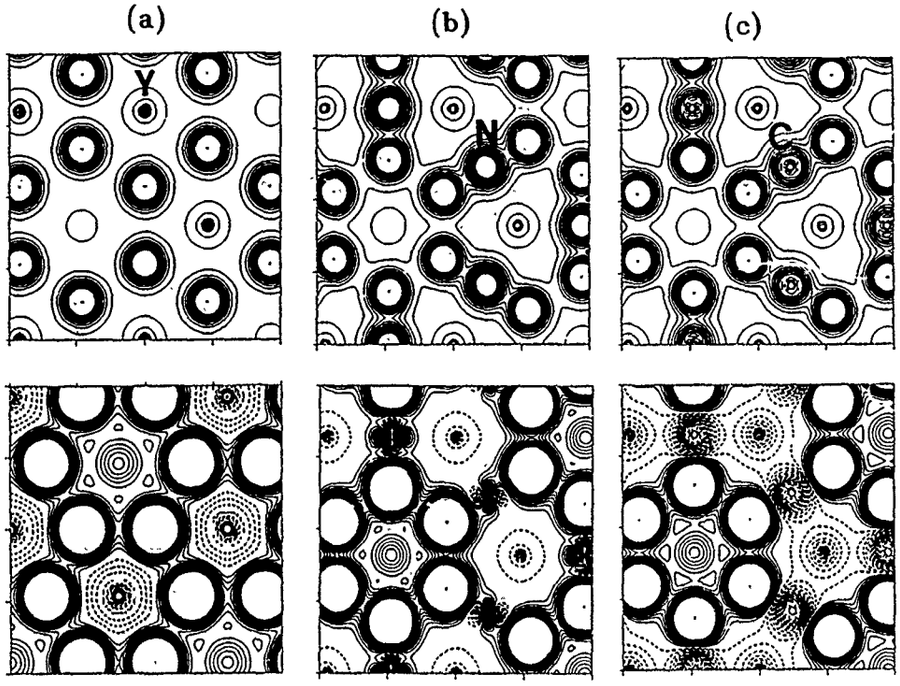

FIG. 1. Calculated charge density (left panel) and spin density (right panel) for (a) Y_2Fe_{17} (top), (b) $Y_2F_{17}N_3$ (middle), and (c) $Y_2Fe_{17}C_3$ (bottom) at approximately the same volume. The contour lines are 0.01, 0.02, 0.04, 0.06, 0.08, 0.10, 0.15, 0.20, 0.25, 0.30, 0.40, 0.50 for charge density and plus or minus of 0.001, 0.002, 0.003, 0.004, 0.006, 0.008, 0.01, 0.015, 0.020, 0.030, 0.040, 0.050. Negative numbers are indicated by dashed contours.

tained by using the Mulliken scheme[17] based on the eigenfunctions and the overlap matrix elements.

The calculated charge-density and spin-density maps on a plane perpendicular to the c axis and containing the Fe ($18f$) sites, the Y atom, and the doping elements are shown in Fig. 1 for Y_2Fe_{17}, $Y_2Fe_{17}N_3$, and $Y_2Fe_{17}C_3$. All three crystals have the same cell volumes. In the calculation for $Y_2Fe_{17}N_3$ and $Y_2Fe_{17}C_3$, we used the internal parameters which determine the atomic positions for $Nd_2Fe_{17}N_x$ as measured by Kajitani *et al.*[16] The results of Fig. 1 can be summarized as follows: (1) In the absence of the doping elements, Fe ($18f$) and Y have rather spherical charge- and spin-density distributions. The Y atom is negatively polarized. (2) When N atoms are introduced at the $9e$ site, expansion of the lattice and changes in the internal parameters make the $9e$ site of sufficient size to accommodate N. There is a significant covalent bonding character between Fe-$3d$ and N-$2p$ electrons in forming a tight Fe-N-Fe unit. The spin density at these sites shows significant distortion from spherical symmetry. The highly nonsymmetric charge- and spin-density distributions have some implications on the proper magnitude of spin-magnetic moments at these sites. (3) Although the moments at the N site are small and negatively polarized, the spin-density map shows that they form pairs of positive and negative lobes. (4) There are some differences in the spin-density distributions due to N and C dopings. For C, there is no lobe structure and the negative polarization at the C site is actually larger.

In Table I, we list the calculated spin moments at each site based on the Mulliken scheme. Also included are the results for Y_2Fe_{17} at zero expansion and some measured data for comparison. Based on these results, we can see that (1) Although the effect of volume expansion increases the negative polarization on the Y atom, the doping actually reduces it. (2) There is a significant reduction of moments on Fe ($18f$) next to N (C) when they are covalently bonded. (3) At other Fe sites, the increase in the moments can be accounted for mainly by the effect of volume expansion, but the chemical effect of doping is important and appears to be site specific. (4) C is slightly more negatively polarized than N and has a bigger influence on the Fe ($18f$) site and less influence on the Fe ($18h$) site.

The calculated numbers in Table I can be compared with the recent experimental Mössbauer data from Chen *et al.*[12] for Y_2Fe_{17}, $Y_2Fe_{17}N_{2.3}$, and $Y_2Fe_{17}C_2$ by dividing the reported hyperfine field data by a rather arbitrary factor of 14.8 T/μ_B. These numbers are listed in parenthesis in Table I. The comparison is only approximate because the samples are not stoichiometric in composition while the calculation assumes the ideal structure. Still, the relative magnitudes of the Fe moments should be meaningful. In the case of undoped Y_2Fe_{17} at equilibrium volume, it has been pointed out that the agreement between calculation and experiment on the relative magnitudes of Fe moments at various sites is marginal at best.[10] On the other hand, the results of different theoretical calculations using different methods are quite close.[10] This reflects either a fundamental inadequacy in the LSDA theory for the magnetic properties of the system of rare-earth-iron magnets, or that the theoretically calculated values may not correspond to quantities that the experiments actually measure. In the doped samples, the experimental data measure an increase of moments on all Fe sites. Our

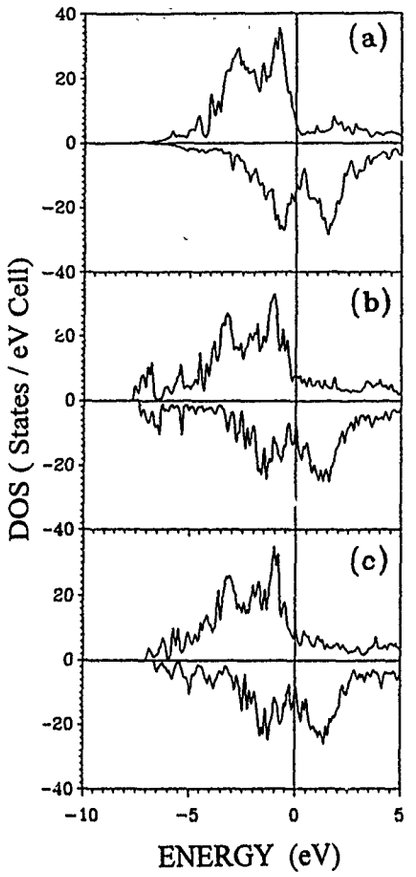

FIG. 2. Calculated total DOS for (a) Y_2Fe_{17}, (b) $Y_2Fe_{17}N_3$, and (c) $Y_2Fe_{17}C_3$ at approximately the same volume. Positive values are for the majority spin band and negative values for the minority spin band.

calculation shows this to be the case, except for the Fe ($18f$) site where there is a large decrease. Jaswal *et al.*[4] obtained the same moment as ours for this site. In the present calculation, the Mulliken scheme was used which gives the effective charges on each atom for the majority and minority spin cases. The difference is taken as the spin moment for that site. The Mulliken scheme for charge partitioning is approximate since it assumes an equal overlap for different atomic pairs. This simple scheme works best when the wave functions are not too extended, and the atoms in the system are more or less of the same size and have similar ranges of interatomic distances.

In the doped sample, the N or C are introduced to interstitial sites. Lattice expansion and local symmetry variation result in quite different interatomic separations. The Mulliken scheme may not work well in these cases. A better approach is to perform a three dimensional real space integration of the charge densities as was done by us in the case of some insulating crystals.[18] With a highly nonsystematic distribution as shown in Fig. 1, this is obviously not an easy job. In addition, the criterion for partitioning the charge or the spin density in real space is always subject to a certain degree of arbitrariness. It may be pointed out that in the linear muffin-tin orbital (LMTO)- or atomic sphere approximation (ASA)-type of calculations,[3,4,9] spin moments are not based on the Mulliken scheme, but on the difference of majority and minority spin charges inside the atomic spheres. The charges outside the atomic spheres are zero. The calculated spin moments depend somewhat on the choice of atomic sphere radii. In compact systems in which the charge distribution is more or less spherical, this approach gives quite accurate moments. However, in doped systems where the spin-density distribution is nonspherical, such an approach may not be reliable.

Figure 2 shows the calculated total DOS for the majority and minority spin bands in Y_2Fe_{17}, $Y_2Fe_{17}N_3$, and $Y_2Fe_{17}C_3$. As can be seen, doping does modify the DOS profiles. Projected partial DOS (not shown) for N and C show that the N states are in the range of -5.3 and -7.5 eV, while those of C are between -2.5 and -7.0 eV. The calculated DOS at E_F are listed in Table I. For the majority band, the reduction in the DOS at E_F in $Y_2Fe_{17}N_3$ by almost a factor of 2/3 is mainly due to lattice expansion. In $Y_2Fe_{17}C_3$, the effect of C doping increases $N(E_F)$ and is largely compensated for by the volume effect. For the minority band, lattice expansion alone reduces $N(E_F)$, and upon doping, it decreases further to about half of the value for undoped Y_2Fe_{17} at equilibrium volume. Thus chemical effect of doping is most pronounced in the $N(E_F)$ for the spin down band and in the moment of the Fe ($18f$) site.

Study on the effect of the previous hydrogenation of the nitride formation of a Sm_2Fe_{17}(4 at. % Nb) alloy

H. W. Kwon
Department of Material Science and Engineering, The National Fisheries University of Pusan, Pusan, South Korea

I. R. Harris
School of Metallurgy and Materials, The University of Birmingham, Birmingham, B15 2TT, England

In order to find an effective means of production of the interstitial $Sm_2Fe_{17}N_x$-type nitride, an alloy modification by the addition of small amount of alloying element (4 at.% Nb) and a hydrogenation treatment prior to the nitriding process have been employed. The effect of previous hydrogenation on the nitride formation of the Sm_2Fe_{17}(4 at. % Nb) alloy has been investigated systematically by means of thermopiezic analysis, thermomagnetic analysis, and vibrating sample magnetometer. It has been found that the previous hydrogen treatment facilitates significantly the formation of the nitride, and this may be due to the clean surface and the finer size of the particles caused by the hydrogen decrepitation. It has also been found that the combination of the alloy modification with the addition of Nb and the previous hydrogen treatment can be utilized effectively for the production of a $Sm_2Fe_{17}N_x$-type nitride.

INTRODUCTION

The $Sm_2Fe_{17}N_x$-type nitride material has been considered to be a potential candidate for the permanent magnetic application.[1–5] It is apparent, however, that there are some practical difficulties in the preparation of the Sm_2Fe_{17} N_x-type nitride material. The cast Sm_2Fe_{17}-type alloys, from which the interstitial $Sm_2Fe_{17}N_x$-type nitride is produced, have a severe structural inhomogeneity. The Sm_2Fe_{17} compound is formed through the peritectic reaction between the previously crystallized solid Fe and the liquid Sm-rich phase,[6] thus leading to the common presence of a considerable amount of free iron(α-Fe) in the cast ingot. In order to overcome this practical difficulty, a modification of the microstructure of the cast Sm_2Fe_{17} alloy by a substitution of M (M=Nb, Ta) for Fe in the alloy has been attempted, and it has been revealed that[7,8] the addition of certain transition elements, such as Nb and Ta to the Sm_2Fe_{17}-type alloy, modifies the crystallizing behavior, thus suppressing the presence of the free iron. The poor kinetics of the nitride formation reaction of the Sm_2Fe_{17}-type alloy is also a limiting factor for the preparation of the nitride material. Because the kinetics of the reaction is so slow, the Sm_2Fe_{17}-type alloy is processed commonly into a fine powder form (typical particle size less than 10 μm) in order to improve the kinetics. Many practical difficulties associated with the powder preparation or handling are, therefore, inevitable. In the present study, in an attempt to find an effective means of production of the interstitial $Sm_2Fe_{17}N_x$-type nitride, a combination of an alloy modification by the small addition of alloying element (4 at. % Nb) and a hydrogenation treatment prior to the nitrogenation process has been employed. The effect of the previous hydrogenation on the formation of the nitride has been investigated in more detail.

EXPERIMENTAL WORK

A Sm_2Fe_{17} alloy containing 4 at. % Nb was prepared using an induction furnace at 1400 °C and supplied by Rare Earth Products (Widnes, UK). The microstructure of the alloy was examined using an optical microscope or a scanning electron microscope (SEM), and the phase analysis of the alloy was performed by a SEM equipped with electron probe microanalysis (EPMA) facility. The supplied as-cast alloy was subjected to a hydrogenation treatment prior to the nitriding process. The hydrogenation was carried out at 300 °C, and it was followed by a degassing treatment at 450 °C under vacuum better than 0.05 mbar. The hydrogenation and the degassing were repeated four times in order to achieve a full decrepitation (it has been found that the Sm_2Fe_{17}-type alloy shows a poor decrepitation behavior with a simple hydrogenation treatment[9]). The cycle hydrogen treated alloy (hereafter the cycle hydrogenated alloy is in a hydrogenated state after the cycle treatment unless stated otherwise) was pulverized for 1 h using an automatic agate pulverizer in a glove box filled with high purity nitrogen gas (oxygen content in the glove box is less than 150 ppm). The as-cast alloy was also pulverized under the same conditions as the one for the cycle hydrogen treated alloy for comparison. The obtained powder materials were then nitrogenated at the temperature range of 450–500 °C for various periods under nitrogen gas (nitrogen pressure: ~1 bar). The nitrided material was then milled for 24 h under cyclohexane using a ball mill (mass ratio of material to steel ball=1:20). A TPA (thermopiezic analysis[10]) was employed in order to study the nitrogenation behavior of the as-cast or the cycle hydrogenated alloy powders. The magnetic properties of the nitrided material were characterized by means of VSM (vibrating sample magnetometer) or TMA (thermomagnetic analysis). For the VSM measurement, the nitride powder was aligned and bonded with wax under the magnetic field of 20 kOe, and the measurement was performed along the aligning direction.

RESULTS AND DISCUSSION

The microstructure of the as-cast alloy examined by a SEM is shown in Fig. 1. It is apparent that the microstructure

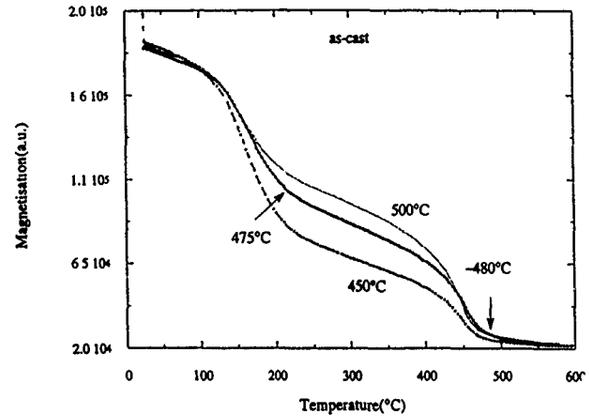

FIG. 3. TMA results for the nitride materials nitrogenated for 4 h at various temperatures using the as-cast alloy powder.

consists of a mixture of the matrix phase and eutectic phase. A minor island phase is also observed in the alloy. The x-ray microanalysis (EPMA) result shows that the matrix phase has a chemical composition of Sm_2Fe_{17} stoichiometry and the eutectic is a mixture of Sm_2Fe_{17} and $NbFe_2$ Laves phase. The island phase has a composition of $NbFe_2$ Laves phase. There is no evidence for the presence of the free iron in the alloy, which is a common feature of the conventional Sm_2Fe_{17} alloy. The as-cast alloy can, therefore, be used straightaway for the production of the Sm_2Fe_{17} nitride without any homogenizing treatment.

Figure 2 shows the TPA traces for the as-cast or the cycle hydrogenated alloy powders carried out under nitrogen gas (nitrogen pressure: ~1 bar). It appears that for the as-cast alloy powder, the nitrogen pressure in the reaction chamber begins to decrease from around 290 °C and a rapid drop is observed above 480 °C, indicating that the as-cast alloy absorbs the nitrogen from around 290 °C and most rapidly at around 480 °C. Meanwhile, for the cycle hydrogenated alloy the pressure drop occurs from around 170 °C, and a rapid increase in the pressure is observed from around 250 °C up to around 450 °C. This pressure increase is due to the desorption of hydrogen from the hydrogenated alloy. The pressure increase is stopped at around 450 °C and then followed by a rapid decrease, indicating that the hydrogen desorption is almost completed at 450 °C and the nitrogen absorption takes place rapidly above this temperature. It can be seen from these results that the cycle hydrogenated alloy powder can pick up the nitrogen at significantly lower temperature with respect to the as-cast alloy powder. This suggests that the hydrogen addition to the Sm_2Fe_{17}-type alloy prior to the nitrogenation may facilitate the formation of a $Sm_2Fe_{17}N_x$-type nitride.

Figures 3 and 4 show the TMA results for the materials nitrided for 4 h at various temperatures using an as-cast or a cycle hydrogenated alloy powder. For both materials, the TMA curves exhibit two deflections at around 150 °C and 480 °C. Those reflections correspond to the Curie temperatures of the unreacted Sm_2Fe_{17} phase and the formed $Sm_2Fe_{17}N_x$-type nitride, respectively. It appears that the deflections at 480 °C are much greater for the cycle hydrogenated alloy than for the as-cast alloy at any nitriding temperature used in the present study, indicating that the nitride can be formed more easily from the hydrogenated material with respect to the as-cast material at the same condition. The nitrided material nitrogenated at 500 °C using the as-cast alloy powder exhibits a large deflection at around 150 °C,

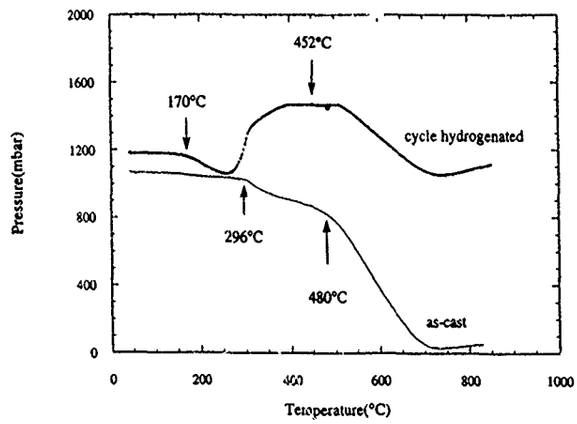

FIG. 2. TPA traces for the as-cast or the hydrogen treated alloy powders under nitrogen.

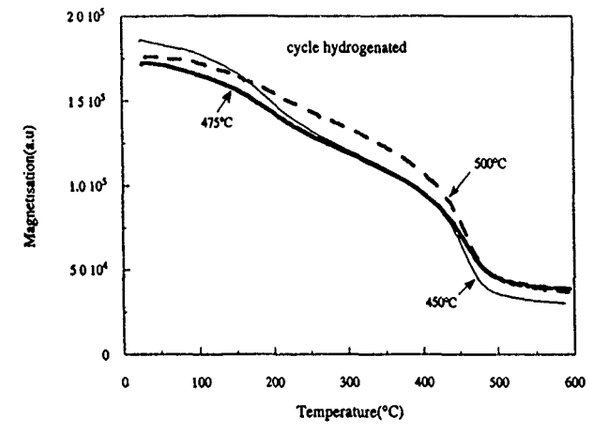

FIG. 4. TMA results for the nitride materials nitrogenated for 4 h at various temperatures using the cycle hydrogen treated alloy powder.

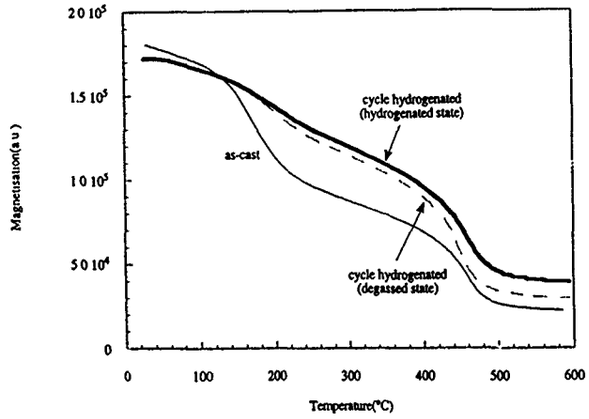

FIG. 5. TMA results for the nitride materials nitrogenated at 475 °C for 4 h using the alloy powders under various conditions.

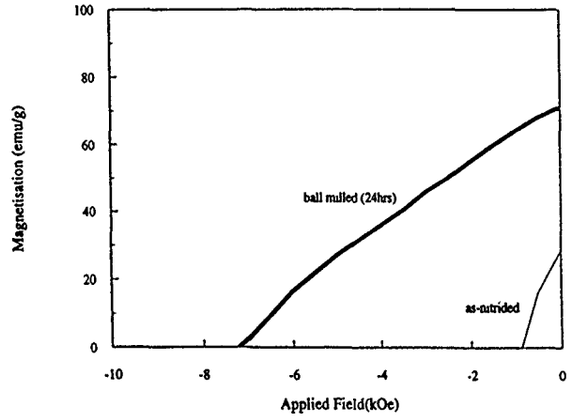

FIG. 6. VSM measurements on the nitride material nitrogenated at 475 °C for 15 h using the cycle hydrogen treated alloy powder.

indicating that there is still a significant amount of the unreacted Sm_2Fe_{17} phase after the nitrogenation. There is, however, little evidence for the presence of the unreacted Sm_2Fe_{17} phase for the cycle hydrogenated alloy powder. These results, together with the results of TPA (Fig. 2), indicate clearly that the previous hydrogenation treatment on the as-cast alloy may facilitate the formation of the nitride. Figure 5 shows the TMA result for the nitrided material which is previously cycle hydrogenated and then degassed prior to being subjected to the nitrogenation at 475 °C. The degassing was carried out *in situ* in the nitriding rig at 475 °C until a vacuum better than 5×10^{-6} Torr was achieved. The nitrogenation was carried out immediately after the degassing. The TMA results for the nitride materials obtained from the nitrogenation at 475 °C using the as-cast or the cycle hydrogenated alloy powders (the cycle hydrogenated alloy powder was in the hydrogenated state prior to the nitrogenation) duplicated from Figs. 3 and 4 are also included in Fig. 5 for comparison. The comparison between the TMA results for the nitrided materials nitrogenated using the as-cast or the cycle hydrogenated alloy powders may reveal the effect of previous hydrogen addition to the Sm_2Fe_{17}-type parent alloy on the nitride formation. It is worth noting that the TMA curves for the nitride materials nitrogenated using the cycle hydrogenated alloy powders which are in the hydrogenated or degassed state appear not to be significantly different. This result indicates that the addition of hydrogen to the Sm_2Fe_{17}-type parent alloy may not influence significantly the nitrogenation reaction of the alloy. It can be concluded, therefore, that the easier formation of nitride caused by the previous hydrogenation may be due to the decrepitation which results in a clean surface and a finer particle size.

The magnetic characterizations performed using a VSM for the nitride material obtained from the nitrogenation of the cycle hydrogenated material at 475 °C for 15 h are shown in Fig. 6. The material immediately after the nitrogenation exhibits poor permanent magnetic properties. The properties are however, improved markedly by the post-nitriding milling for 24 h. The poor properties of the as-nitrided materials may be due to the coarse particle size, and the marked improvement of the properties of the milled material may be attributed to the fine particle size of the nitride. The milled material has a significantly high coercivity (over 7 kOe).

CONCLUSION

The effect of previous hydrogen treatment on the nitride formation of the Sm_2Fe_{17}-type alloy modified with the addition of small amount of Nb has been investigated. It has been found that previous hydrogen treatment facilitates significantly the formation of the nitride, and this may be due to the clean surface and the finer size of the particles caused by the hydrogen decrepitation. The present study also shows that the combination of an alloy modification with the addition of Nb and a previous hydrogenation can be utilized as an effective means of production of a $Sm_2Fe_{17}N_x$-type nitride.

The effects of hydrogen disproportionation, desorption, and recombination on the structure and magnetic properties of $Sm_2Fe_{17}N_x$ and $NdFe_{10}Mo_2N_x$ compounds

Jun Yang, Shengzhi Dong, Weihua Mao, Ping Xuan, and Yingchang Yang
Department of Physics, Peking University, Beijing 100871, People's Republic of China

Hydrogen disproportionation, desorption, and recombination (HDDR) has been used as a pretreatment to prepare high performance $Sm_2Fe_{17}N_x$ and $NdFe_{10}Mo_2N_x$ compounds. Isotropic $Sm_2Fe_{17}N_x$ and $NdFe_{10}Mo_2N_x$ compounds with intrinsic coercivity larger than 12 and 4 kOe have been obtained by nitriding the HDDR-treated powders, respectively. It is found that the magnetic properties are sensitively dependent on the time and temperature of the HDDR process, which determine the grain size, nitrogen content, and the amount of α-Fe in the nitrides.

I. INTRODUCTION

$Sm_2Fe_{17}N_x$ and $Nd(Fe,M)_{12}N_x$ compounds have been discovered as potential new permanent magnetic candidates since 1990.[1,2]

HDDR, as a pretreatment, has been successfully used in the preparation of isotropic $Sm_2Fe_{17}N_x$ and $NdFe_{10}Mo_2N_x$ compounds. The relationship between preparation, structure, and magnetic properties of HDDR treated $Sm_2Fe_{17}N_x$ and $NdFe_{10}Mo_2N_x$ compounds will be presented in this article.

II. EXPERIMENTAL METHODS

Alloys of stoichiometric composition were prepared by arc melting 99.5 wt % pure materials in a purified argon atmosphere. The ingots were heat treated at 1050 °C for 2 days and a week for Sm_2Fe_{17} and $NdFe_{10}Mo_2$ compounds, respectively. The compounds were pulverized into powders with size ranging from 1 to 70 μm, then they were hydrided at 250–1100 °C for 1–5 h. Subsequently, the hydrided compounds were degassed at the above mentioned temperature for 1–4 h. Nitrogenation was carried out in the temperature range from 480 to 510 °C for 2–4 h, then rapidly cooled to room temperature. X-ray diffraction was used to determine the structure.

Powder samples of cylindrical shape were prepared by embedding the powders in epoxy resin, and some were aligned in a 10 kOe field. Hysteresis loops were measured in an applied field of $H=1.4$ T on a vibrating sample magnetometer and $H=7$ T on a superconducting quantum interference device (SQUID) magnetometer. The Curie temperatures were determined from M-T curves obtained with a vibrating sample magnetometer operating in a temperature range from 300 to 1000 K in a field of $H=0.1$ T.

The microstructural changes are observed by powder x-ray diffraction and scanning electron microscopy (SEM). The grain size of the HDDR treated nitrides was determined from observations by transmission electron microscopy (TEM).

III. RESULTS AND DISCUSSIONS

A. Phase formation, structure, and intrinsic magnetic properties

From x-ray diffraction, thermomagnetic measurements, and SEM observations, the alloys are identified as single phase except for a small amount of $SmFe_3$ in the Sm_2Fe_{17} alloy. When hydriding and nitriding the compounds at 250 and 500 °C, respectively, the rhombohedral and tetragonal structure of the Sm_2Fe_{17} and $NdFe_{10}Mo_2$ compounds were retained but with an increase in lattice parameters. Table I lists the lattice parameters a, c, unit cell volume V, Curie temperature T_c, and saturation magnetization M_S as well as the anisotropy field H_A of the compounds and their hydrides and nitrides. It can be seen that hydrogenation and nitrogenation can both increase the Curie temperature and saturation magnetization of the compounds and nitrogenation can change the easy magnetization direction from easy basal plane to easy c axis for the Sm_2Fe_{17} compound and from easy cone to easy c axis for the $NdFe_{10}Mo_2$ compound due to the change of second order crystal field coefficient A_{20} in the phases upon nitrogenation.

TABLE I. The lattice parameters a,c, unit cell volume V, and its relative change $\Delta V/V$, Curie temperature T_c, saturation magnetization M_S, and anisotropy field H_A of Sm_2Fe_{17} and $NdFe_{10}Mo_2$ compounds and their hydrides and nitrides at room temperature.

Compound	Structure	a (A)	c (A)	V (A^3)	$\Delta V/V$ (%)	T_c (K)	M_S (emu/g)	H_A (T)

B. Determination of HDDR parameters

HDDR includes two main processes: hydrogenation and hydrogen desorption. In both of them, time and temperature are vital to the obtained permanent magnetic properties of $Sm_2Fe_{17}N_x$ and $NdFe_{10}Mo_2N_x$ compounds. However, the correct powder size is a prerequisite for the proper HDDR treatment. For comparison, we chose the nitrogenation treatment of 500 °C for 3 h as determined in our previous studies.[3]

Figure 1 shows the demagnetization hysteresis loops of $Sm_2Fe_{17}N_x$ powder samples with an average particle size of 1, 10, and 70 μm with hydrogenation at 500 °C for 3 h and dehydrogenation treatment at 750 °C for 2 h and subsequently nitrogenation treated at 500 °C for 3 h. The results show that the optimized particle size is between 4 and 10 μm in both $Sm_2Fe_{17}N_x$ and $NdFe_{10}Mo_2N_x$ compounds. Powder particles smaller or larger than these size are deleterious to magnetic properties.

X-ray diffraction study of Sm_2Fe_{17} and $NdFe_{10}Mo_2$ compounds after hydrogenation treatment at temperatures from 250 to 1100 °C for 4 h shows that when the hydrogenation temperature is lower than 300 °C, for example, at 250 °C, the $Sm_2Fe_{17}H_y$ and $NdFe_{10}Mo_2H_y$ compounds are formed. At temperatures higher than 500 °C, Sm_2Fe_{17} and $NdFe_{10}Mo_2$ compounds decompose into a mixture of RH_{2-3} and α-Fe(Mo). When temperatures are higher than 1050 °C, Sm_2Fe_{17} and $NdFe_{10}Mo_2$ are partially recombined in the hydrogen atmosphere at 1 bar pressure. However, only when dehydrogenation was carried out at 700–800 °C, can the mixture of RH_{2-3} and α-Fe(Mo) recombine fully into Sm_2Fe_{17} and $NdFe_{10}Mo_2$ compounds. As an example, the x-ray diffraction patterns of the recombined Sm_2Fe_{17} compounds is shown in Fig. 2 in contrast with the decomposed mixture of SmH_{2-3} and α-Fe. The permanent magnetic properties also reveal that the best values were obtained by hydrogen absorption and desorption treatment at 700–800 °C.

Figures 3 and 4 show the effects of hydrogenation and hydrogen desorption time on the permanent magnetic properties of $Sm_2Fe_{17}N_x$ compounds. It can be seen that the best

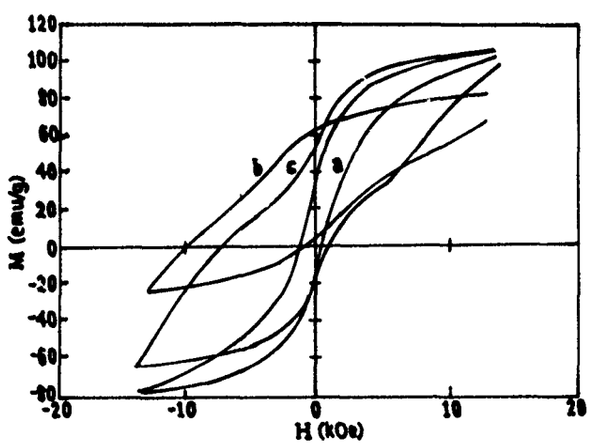

FIG. 1. The hysteresis loops of $Sm_2Fe_{17}N_x$ compounds of average powder particle size $d=1$ μm (a), 10 μm (b), 70 μm (c) by HDDR and nitrogenation treatment as described in the text.

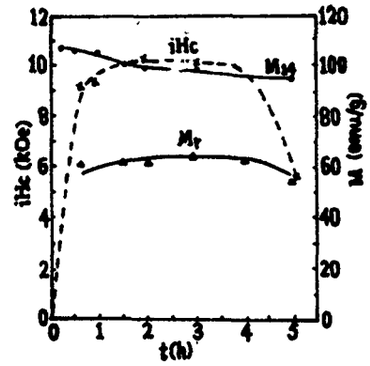

FIG. 2. The permanent magnetic properties of $Sm_2Fe_{17}N_x$ compound powders with the variation of hydrogenation time t (h) at 750 °C.

permanent magnetic properties are obtained at hydrogenation times between 2 and 4 h and a dehydrogenation time of 2 h. Furthermore, we can see from Fig. 4 that the permanent magnetic properties are sensitively dependent on the hydrogen desorption time. Figure 5 shows the hysteresis loops of thus treated $Sm_2Fe_{17}N_x$ and $NdFe_{10}Mo_2N_x$ compounds. From these data, coercivities of 12 and 4 kOe have been obtained for $Sm_2Fe_{17}N_x$ and $NdFe_{10}Mo_2N_x$, respectively.

C. Phase transformation in the HDDR process

As observed in Sec. II, the permanent magnetic properties are sensitive to the hydrogenation temperature, time, and especially to the hydrogen desorption time. X-ray diffraction studies have shown that the HDDR process is a reaction of diffusional phase transformation, which consists of the following two processes:

$$Sm_2Fe_{17}+H_2=SmH_{2-3}+\alpha\text{-Fe}, \tag{1a}$$

$$NdFe_{10}Mo_2+H_2=NdH_{2-3}+\alpha\text{-Fe(Mo)} \tag{1b}$$

and

$$SmH_{2-3}+\alpha\text{-Fe}=Sm_2Fe_{17}, \tag{2a}$$

$$NdH_{2-3}+\alpha\text{-Fe(Mo)}=NdFe_{10}Mo_2. \tag{2b}$$

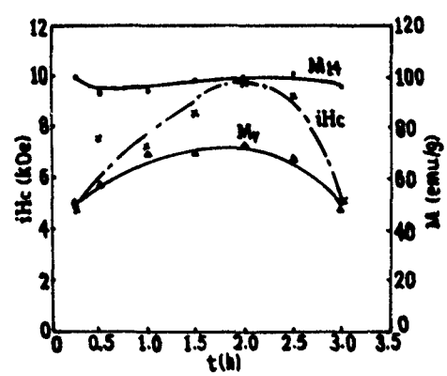

FIG. 3. The permanent magnetic properties of $Sm_2Fe_{17}N_x$ compound powders with the variation of dehydrogenation time t (h) at 750 °C.

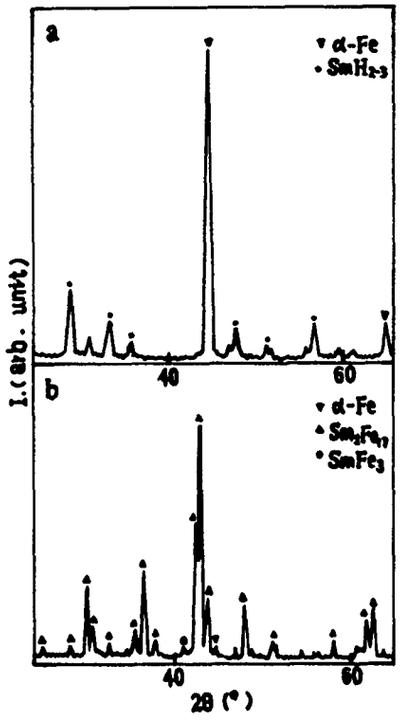

FIG. 4. The x-ray diffraction patterns of Sm_2Fe_{17} compound hydrogenated at 750 °C for 3 h (a) and dehydrogenated at 750 °C for 2 h (b).

In process (1), the reaction begins from the adsorption of H_2 on the particle surface and its decomposition into H atoms, then the H atoms diffuse along grain boundaries, and crystal defects such as twin grain boundaries jump through interstitial sites into the lattice. This results in its decomposition into a mixture of $Nd(Sm)H_{2-3}$ and α-Fe(Mo), which also requires the diffusion of Nd(Sm) and Fe(Mo) atoms to form clusters of $Nd(Sm)H_{2-3}$ and α-Fe(Mo). Therefore, when we hydrogenated bulk $NdFe_{10}Mo_2$ or Sm_2Fe_{17} compounds at 750 °C, the disproportionation process occurs preferentially in the grain boundary region, as shown in Fig. 6. It can be seen that the $Sm(Nd)H_{2-3}$ phase surrounds the α-Fe(Mo) phase and constitutes a maze pattern. From SEM observations, we also see that the size of α-Fe(Mo) and $Sm(Nd)H_{2-3}$ phases increases with hydrogenation temperature and time, because the diffusion rate of H, Nd(Sm), and Fe(Mo) atoms increases with increasing temperature, and the diffusion distance of these atoms increases with time.

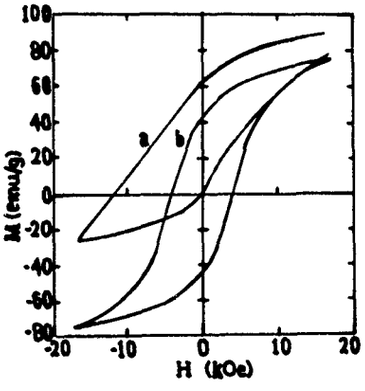

FIG. 5. The hysteresis loops of $Sm_2Fe_{17}N_x$ (a) and $NdFe_{10}Mo_2N_x$ (b) compounds magnetized at a field $H=1.4$ T after optimized HDDR and nitrogenation treatment.

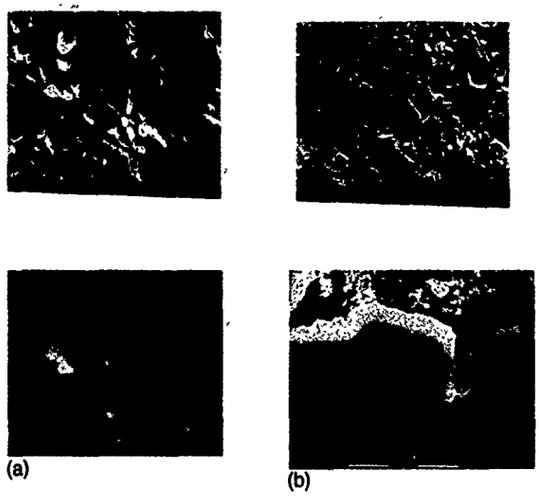

FIG. 6. The SEM backscattered electron graphs of Sm_2Fe_{17} and $NdFe_{10}Mo_2$ compounds after hydrogenation at 750 °C for 3 h (a) and dehydrogenation at 750 °C for 2 h (b).

In processes (2), the reaction starts with the detachment of H atoms from $Sm(Nd)H_{2-3}$, simultaneously, the Fe and R atoms will rapidly diffuse into each other to recombine into the original compounds but with much smaller grain size as shown also in Fig. 6. The size of the recombined grains is vital to permanent magnetic properties of the nitrogenated samples because it determines the nitrogen content, x, and the amount of the α-Fe phase as well as the amount of reverse domain nucleation sites. The grain size is determined mainly by the desorption temperature and time. Certainly, the size of the cluster of the mixture, which is controlled by the hydrogenation time and temperature, will influence the recombined grain size. The grain size in the optimized permanent magnets is around 0.3 to 0.5 μm for $Sm_2Fe_{17}N_x$ and $NdFe_{10}Mo_2N_x$ compounds as determined from transmission electron microscopy (TEM) observations.[3]

Phase formation in melt-spun Nd-Fe-Mo-Ti alloys

F. E. Pinkerton, C. D. Fuerst, and J. F. Herbst
Physics Department, General Motors Research and Development Center, 30500 Mound Road, Warren, Michigan 48090-9055

We report for the first time the range of $ThMn_{12}$-type crystal structure formation in melt-spun Nd-Fe-Mo-Ti ribbons. These materials, which combine the melt-spun microstructure with the favorable intrinsic magnetic properties of the $NdFe_{12-x}(Mo,Ti)_x$ phase, are important as precursors to the formation of hard magnetic materials by nitrogen absorption. Alloys with compositions $Nd_{1.15}Fe_{10+x}Mo_{2-2x}Ti_x$ ($0 \leq x \leq 1$), which grade the composition smoothly between the two end point alloys $Nd_{1.15}Fe_{10}Mo_2$ and $Nd_{1.15}Fe_{11}Ti$, were melt spun at quench wheel velocities 5 m/s$\leq v_s \leq$30 m/s. From x-ray diffraction patterns we construct a phase formation diagram as a function of Ti content x and wheel speed v_s. We find that the desired $ThMn_{12}$ structure is obtained only in ribbons quenched at low v_s. At higher speeds, the ribbons quench instead into the disordered $TbCu_7$-type crystal structure. Further, the $ThMn_{12}$ structure is considerably less stable at the Ti-rich end of the composition range than at the Mo-rich end: for $Nd_{1.15}Fe_{10}Mo_2$, the $ThMn_{12}$ structure is obtained for $v_s \leq 17.5$ m/s, whereas in $Nd_{1.15}Fe_{11}Ti$ only ribbons quenched at $v_s = 5$ m/s are of the $ThMn_{12}$ type. Heat treatments of $Nd_{1.15}Fe_{11}Ti$ ribbons melt spun at 30 m/s confirm the relatively difficult formation of the $ThMn_{12}$ structure type; annealing temperatures in excess of 1000 °C are required to form the $ThMn_{12}$ crystal structure.

I. INTRODUCTION

Compounds of the type $R(Fe,T)_{12}N_y$ (where R=rare earth and T includes Ti, Mo, and V) having the tetragonal $ThMn_{12}$ crystal structure have received increasing scrutiny as potential permanent magnet materials since the discovery by Yang *et al.*[1] that the Curie temperature T_C, saturation magnetization M_s, and magnetocrystalline anisotropy field H_A of $RFe_{11}Ti$ can be enhanced by nitrogen absorption. In the nitrided form, the most promising candidate materials are those with R=Nd, for which large saturation magnetizations and uniaxial anisotropies are obtained. In the case of T=Mo, for example, the anisotropy changes from basal plane in $NdFe_{10}Mo_2$ to uniaxial in $NdFe_{10}Mo_2N_y$ ($y \approx 1$).[2-4] Of T=Ti, Mo, and V, the nitrides of the Ti representative have been reported to have the most favorable intrinsic magnetic properties,[5] with $4\pi M_s = 13.7$ kG and $H_A = 80$ kOe at room temperature, and $T_C = 470$ °C (740 K). Magnetic hardening of the Ti materials to obtain substantial intrinsic coercivity, however, has proven to be difficult: coercivities of only 1.4–2.5 kOe have been reported in mechanically alloyed powders.[6,7] This appears to be due to the formation of a phase having the disordered, hexagonal $TbCu_7$ structure[8] which impedes formation of $NdFe_{11}Ti$ characterized by the $ThMn_{12}$ structure. Greater success has been obtained in nitrides of $NdFe_{10}Mo_2$, where coercivities of 6–9 kOe have been reported by nitriding rapidly quenched ribbons either directly quenched to a microcrystalline state,[9] or else melt spun at high wheel speeds and then annealed.[10] The generation of high coercivity by both of these techniques relies on the formation of $ThMn_{12}$-type material in the ribbons prior to nitriding.

In this article we examine phase formation in melt-spun $Nd_{1.15}Fe_{10+x}Mo_{2-2x}Ti_x$ ribbons ($0 \leq x \leq 1$) as the quench rate is varied by changing the quench wheel surface velocity v_s. The above alloy formulation transforms the composition smoothly between the end point compositions $NdFe_{10}Mo_2$ and $NdFe_{11}Ti$. We will show that slow quench wheel velocities favor the formation of the $ThMn_{12}$-type crystal structure, whereas higher wheel speeds quench the alloy into the disordered $TbCu_7$-type structure. We have previously reported that the $ThMn_{12}$ structure is obtained in ribbons quenched at wheel speeds up to about $v_s = 17.5$ m/s in $NdFe_{10}Mo_2$, but that ribbons spun at $v_s = 20$ m/s and above quench into the $TbCu_7$ structure.[9] Here we find that compositions at the Ti-rich end are much more readily quenched into the $TbCu_7$ structure at wheel speeds at and above $v_s = 10$ m/s. High quench rate Nd-Fe-Ti ribbons can be converted into the $ThMn_{12}$ structure by annealing at temperatures above 1000 °C.

II. EXPERIMENTAL DETAILS

Starting ingots of the form $Nd_{1.15}Fe_{10+x}Mo_{2-2x}Ti_x$ ($x = 0$, 0.25, 0.5, 0.75, and 1) were made by induction melting the pure elemental constituents in an argon atmosphere. $ThMn_{12}$-type Nd-Fe-Mo compounds form over a range of Mo contents from $NdFe_{11}Mo$ to $NdFe_{9.5}Mo_{2.5}$; we selected $NdFe_{10}Mo_2$ as the $x = 0$ end point for this alloy series because it is stable, the melt-spun cognate has been well characterized in our previous study,[9] and it forms high coercivity ribbon powder upon nitriding.[9,10] Excess Nd was included in the alloys because our prior work on nitriding of Nd-Fe-Mo precursor ribbons demonstrated that extra Nd was beneficial for obtaining large coercivities.[9] The ingots were rapidly quenched by melt spinning the molten alloy through a 0.60–0.65 mm orifice onto the surface of a Cr-plated copper quench wheel. The quench rate was adjusted by varying the surface velocity v_s of the wheel. The ribbons were ground to −325 mesh (<45 μm particle size), and x-ray diffraction patterns using Cu-K_α radiation were obtained. Powders made from $NdFe_{11}Ti$ ribbons melt spun at $v_s = 30$ m/s were annealed in vacuum for 10 min at temperatures ranging from

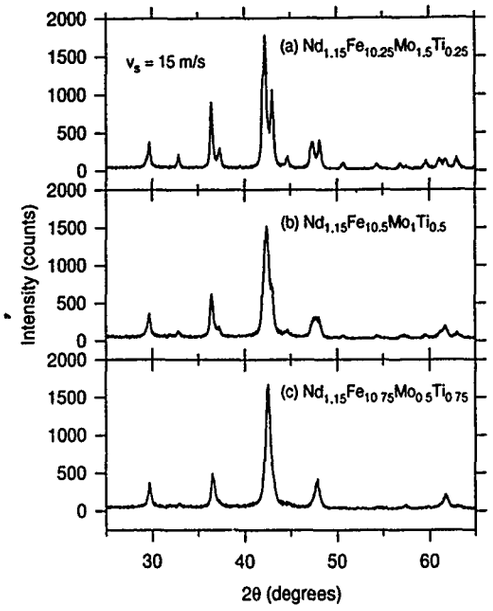

FIG. 1. X-ray diffraction patterns for $Nd_{1.15}Fe_{10+x}Mo_{2-2x}Ti_x$ ribbons melt spun at 15 m/s: (a) $x=0.25$, (b) $x=0.5$, and (c) $x=0.75$.

600 to 1100 °C in order to establish the stability of the $TbCu_7$-type material produced at high wheel speeds.

III. RESULTS AND DISCUSSION

The $ThMn_{12}$ structure is readily formed in $Nd_{1.15}Fe_{10}Mo_2$ ribbons when the wheel speed is less than or equal to 17.5 m/s.[9] At high wheel speeds, above 20 m/s, the ribbons quench instead into the disordered $TbCu_7$ structure type. The x-ray diffraction patterns in Fig. 1 illustrate the effect on phase composition of moving toward Ti-rich alloys. With the wheel speed fixed at 15 m/s, patterns are shown for (a) $Nd_{1.15}Fe_{10.25}Mo_{1.5}Ti_{0.25}$ ribbons, (b) $Nd_{1.15}Fe_{10.5}Mo_1Ti_{0.5}$ ribbons, and (c) $Nd_{1.15}Fe_{10.75}Mo_{0.5}Ti_{0.75}$ ribbons. Like its pure Mo cognate, the $x=0.25$ sample has a clean $ThMn_{12}$ diffraction pattern. At $x=0.5$, however, the diffraction pattern has begun to transform into that characteristic of the $TbCu_7$ structure, and hence it represents a partially disordered material. Line broadening due to decreased grain size alone cannot account for the observed changes in the diffraction pattern. At $x=0.75$, the transformation into the disordered $TbCu_7$ structure is complete.

From x-ray diffraction patterns like those of Fig. 1 we construct in Fig. 2 the phase formation diagram as a function of composition x (abscissa) and wheel speed v_s (ordinate). The filled circles represent samples which fall clearly within the $ThMn_{12}$ structure type, whereas the open circles represent samples having the $TbCu_7$-type structure. Partially filled circles denote samples which do not cleanly fall into either one of the two structure types, and signify in most cases a partially transformed material. The demarcation between the two structure types moves to significantly lower wheel speeds with increasing Ti content, indicating that the formation of the disordered $TbCu_7$ structure is much more favorable at high Ti content.

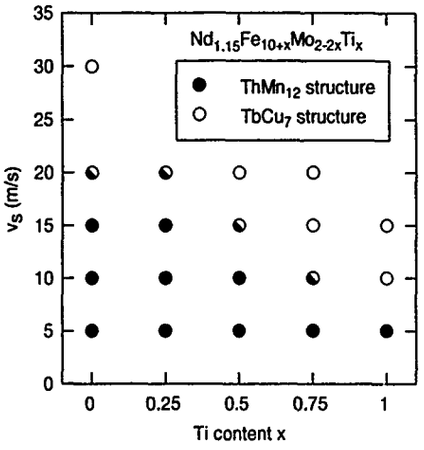

FIG. 2. Phase formation in melt-spun Nd-Fe-Mo-Ti ribbons: (●) $ThMn_{12}$, (○) $TbCu_7$ structure. Half-filled symbols represent partially transformed material.

Lattice parameters as a function of Ti content are shown in Fig. 3 for the $ThMn_{12}$-type ribbons quenched at a wheel speed of 5 m/s. The lattice constants were obtained from the d spacings of the well defined and isolated 301 and 002 diffraction peaks, and checked against the positions of several additional peaks. Contraction of the lattice with increasing Ti content x occurs predominantly in the basal plane, while the change in the c-axis lattice spacing is small. Although the $ThMn_{12}$ structure is maintained throughout the composition range, the lattice constants do not obey Vegard's law: a minimum in each of the lattice constants is observed at about $x=0.75$.

Figure 4 shows x-ray diffraction patterns of $NdFe_{11}Ti$ ribbons melt spun at a wheel speed of 30 m/s and subsequently annealed for 10 min at temperatures between 700 and 1100 °C. The as-spun ribbons, shown in Fig. 4(a), have a few weak diffraction peaks, at line positions consistent with

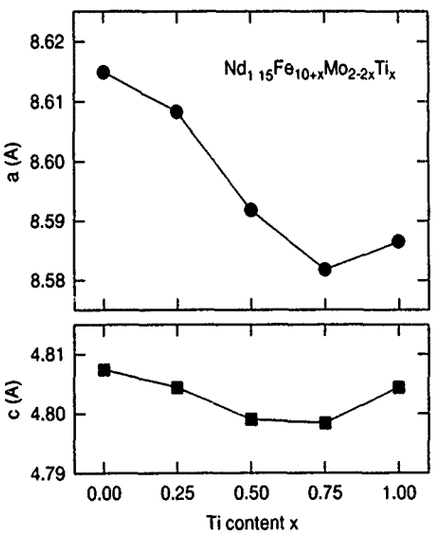

FIG. 3. Lattice parameters a and c for $Nd_{1.15}Fe_{10+x}Mo_{2-2x}Ti_x$ ribbons melt spun at $v_s=5$ m/s as a function of Ti content x.

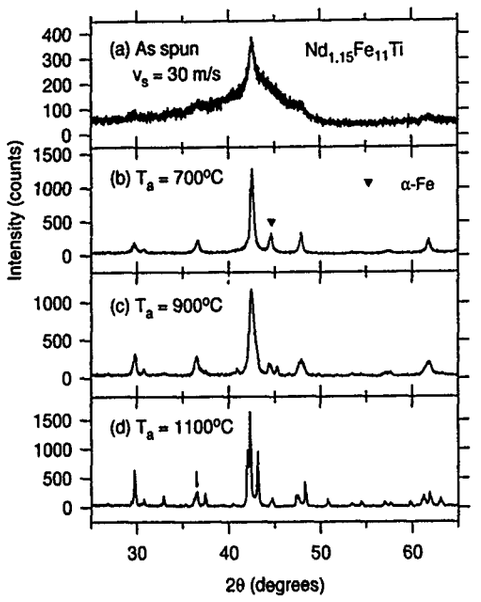

FIG. 4. X-ray diffraction patterns of $Nd_{1.15}Fe_{11}Ti$ ribbons for several annealing temperatures: (a) as spun, (b) 700 °C, (c) 900 °C, and (d) 1100 °C.

the $TbCu_7$ structure, on top of a broad amorphous background. When annealed at 700 °C [Fig. 4(b)], a well-defined $TbCu_7$ line pattern emerges, in agreement with the work of Itsukaichi *et al.*[11] A small amount of α-Fe is also present in this sample. The $TbCu_7$ structure is maintained for annealing temperatures up to 900 °C [Fig. 4(c)], where a close examination shows additional structure in the diffraction peaks indicating that the material has begun to transform into the $ThMn_{12}$ structure. The transformation is complete at 1100 °C, where the diffraction pattern is almost entirely $ThMn_{12}$-like (small impurity peaks are observed at 2θ =26.8°, 30.8°, 40.5°, and 53.5°). The relatively high annealing temperature required to transform the ribbons corroborates the phase formation diagram of Fig. 2, emphasizing the relative difficulty in forming the $ThMn_{12}$-type structure in Ti-rich ribbons.

In conclusion, we have established the phase formation diagram of melt-spun $Nd_{1.15}Fe_{10+x}Mo_{2-2x}Ti_x$ as the composition is changed smoothly between $Nd_{1.15}Fe_{10}Mo_2$ and $Nd_{1.15}Fe_{11}Ti$ and the quench wheel speed is varied from 5 to 30 m/s. The $ThMn_{12}$ crystal structure, which is favorable for the formation of hard magnetic material by nitriding, is obtained only a low wheel speeds. At higher speeds, the ribbons quench into the disordered $TbCu_7$ structure. The $TbCu_7$ structure is particularly stable at the Ti-rich end of the composition range, and in $NdFe_{11}Ti$ the $ThMn_{12}$ structure is obtained only by quenching at very low speeds (v_s=5 m/s) or by annealing the ribbons at temperatures above 1000 °C. This poses a serious challenge to the generation of useful coercivity in $ThMn_{12}$-type Nd-Fe-Ti-nitride.

ACKNOWLEDGMENTS

We wish to thank C. B. Murphy for his assistance in preparing the melt-spun ribbons, as well as A. Wims and M. Balogh of the Analytical Chemistry Department for the x-ray diffraction scans.

In-plane magnetized YIG substrates self-biased by SmCo based sputtered film coatings

F. J. Cadieu and H. Hegde

Highly anisotropic SmCo based films with the $TbCu_7$-type structure have been sputter deposited directly onto YIG substrates. The SmCo crystallites have the c axes approximately randomly splayed about the substrate plane such that the easy direction of magnetization of the SmCo film is in the film plane. The in-plane static energy product of the SmCo film layers was about 16 MG Oe. In-plane vibrating sample magnetometer hysteresis loops of the SmCo film and YIG substrate exhibit a composite form with the YIG field reversal shifted into the first quadrant by the looping field from the SmCo film layer. Approximately 4×4 mm^2 pieces of YIG substrate have been measured to determine the YIG bias field and field required for reverse saturation of the YIG as a function of the SmCo based film layer thickness to YIG substrate thickness. It is observed that for SmCo to YIG thickness ratios greater than 0.22, the looping field from the SmCo film layer is sufficient to saturate the YIG magnetization in the reverse direction. SmCo film thicknesses in the range from 80 to 120 μm have been used in these studies. Special boundary layers have been used to promote thick film adhesion to the YIG substrates.

INTRODUCTION

Magnetic ceramics are often used in microwave circuits to provide an active element for microwave circulators and isolators. In use the magnetization of the magnetic ceramic is generally saturated through the use of bulk pieces of magnet surrounding the device.[1,2] Such an arrangement is not amenable to direct film integration of such devices. To provide an alternative arrangement in which the magnetic ceramic can be biased we have deposited SmCo based permanent magnet film layers directly onto YIG substrates. The SmCo based films were directly crystallized onto the YIG substrates such that the permanent magnet film layer has the easy axis of magnetization strongly aligned onto the substrate plane. The looping field of the SmCo film layer then acts to bias the YIG substrate in the reverse direction. The YIG bias field level and the field required for complete reverse field saturation of the YIG has been studied as a function of the SmCo film layer thickness to YIG substrate layer thickness. Permanent magnet film layer thicknesses from 80 to 120 μm have been studied. To promote adhesion of such films onto the YIG substrates special boundary layers have been used.

EXPERIMENT

Highly anisotropic SmCo based films containing traces of Cu and Zr as in SmCo based 2-17 magnets have been RF sputter deposited onto polished YIG substrates. The substrates were heated so that the deposit crystallized upon deposition into a single phase $TbCu_7$-type structure.[3] The nominal film Sm concentration was 14 at. %. The sputtering conditions were adjusted so that the c axes of the $TbCu_7$ structure were in the film plane and nearly randomly splayed about the film plane.[4] To promote thick film adhesion a boundary layer of dense Al was deposited onto the polished YIG substrates before the SmCo based deposition.[5] The magnetic properties were measured at room temperature to ±18 kOe using a vibrating sample magnetometer (VSM). In addition, a bipolar power supply was used to sweep the low field region for certain samples. Sample pieces of SmCo based film and YIG substrate were cut for VSM measurements using a diamond wire saw.

RESULTS AND DISCUSSION

Figure 1 shows the cross section of a 118 μm thick SmCo based film that was directly crystallized onto a 635 μm thick YIG substrate. A 1.5 μm boundary layer of dense aluminum was first sputter deposited onto the YIG substrate to promote film adhesion. The resulting film and YIG substrate can be patterned by photolithography methods or cut

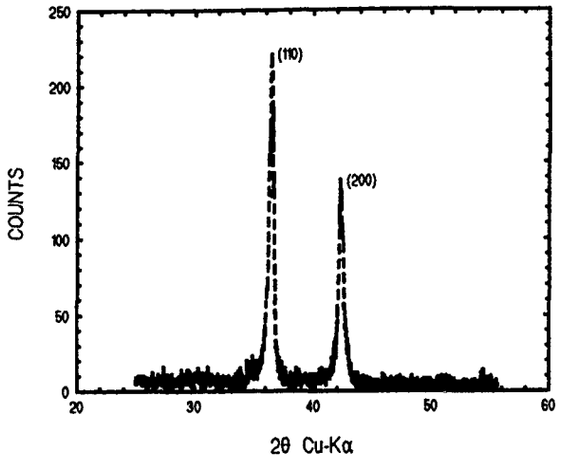

FIG. 2. An x-ray diffractometer trace, CuKα radiation, of the SmCo film of Fig. 1 is shown. Note that the crystallites have the c axes aligned onto the film plane.

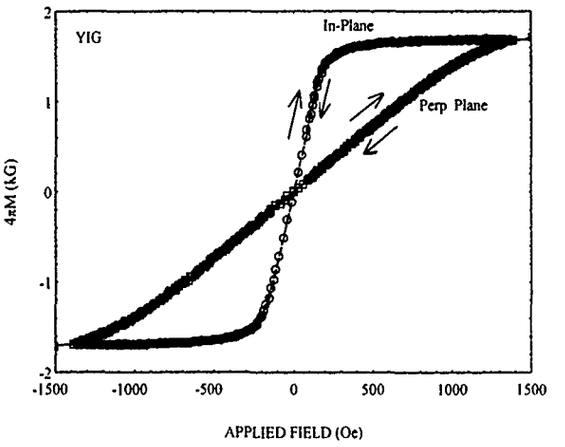

FIG. 4. Hysteresis loops measured in-plane and perpendicular to the plane of a 635 μm thick YIG piece are shown. The YIG area was 4.3×4.5 mm^2. Arrows are shown to indicate that each loop retraces itself.

as desired without the film and substrate delaminating. The SmCo based film was crystallized into the $TbCu_7$ disordered 1-5 type structure. An x-ray diffractometer trace of such a film is shown in Fig. 2. The only lines above background correspond to the (110) at 2Θ=36.43° and the (200) reflection at 42.25°. It should be noted that all crystallites have the c axes aligned onto the plane of the substrate, but that there is a nearly random splaying of the c axes about the film plane. In some cases the SmCo based film was sputter deposited with a mask used to form a pattern in the film deposited onto the YIG substrate. The hysteresis loops measured in the film plane and perpendicular to the plane for a piece removed from the mask are shown in Fig. 3. In this way the magnetic properties of the SmCo based film can be measured from the same sputter deposition as used for the SmCo film layer deposited onto the YIG substrate. The magnetic properties show that the easy direction of magnetization of the SmCo film layer is in the film plane. The typical remanent flux density is approximately 8 kG which is consistent with a random splaying of the crystallites in two dimensions. The expected remanent to saturation flux density in this case is $2/\pi$=0.64.[6] The room temperature static energy product of the SmCo based film is ≈16 MG Oe. In this particular case the room temperature $_iH_c$ = 6.0 kOe so that the energy product is not coercivity limited.

Figure 4 shows in-plane and perpendicular to the plane hysteresis loops for a bare YIG substrate piece measuring 4.3×4.5×0.635 mm^3. Arrows are shown to indicate that each loop retraces itself with no apparent hysteresis to the scale shown. The YIG flux density passes through zero for zero applied field so that the YIG bias value is zero. For this size piece a reverse in-plane applied field of 200 Oe is required to saturate the bare YIG substrate. The perpendicular applied field required for saturation is about 1200 Oe. The field values required for saturation are set by the demagnetization field due to the shape of the YIG piece.

Figure 5 shows the composite in-plane hysteresis loop of

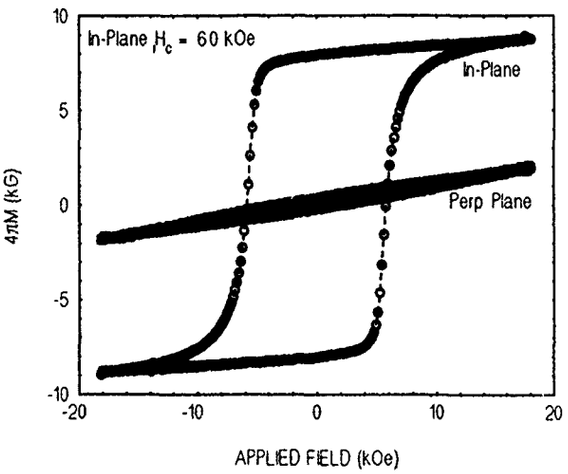

FIG. 3. Hysteresis loops are shown measured in-plane and perpendicular to the plane for a 118 μm thick $TbCu_7$-type SmCo based film.

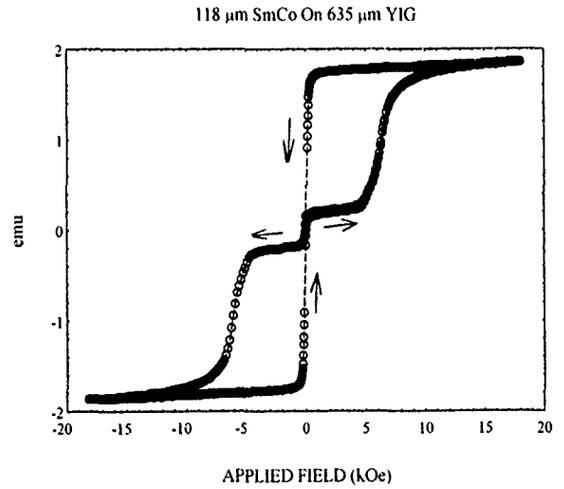

FIG. 5. An in-plane hysteresis loop for 118 μm thick SmCo based film deposited onto a 635 μm thick polished YIG substrate are shown. Arrows indicate the magnetization progression.

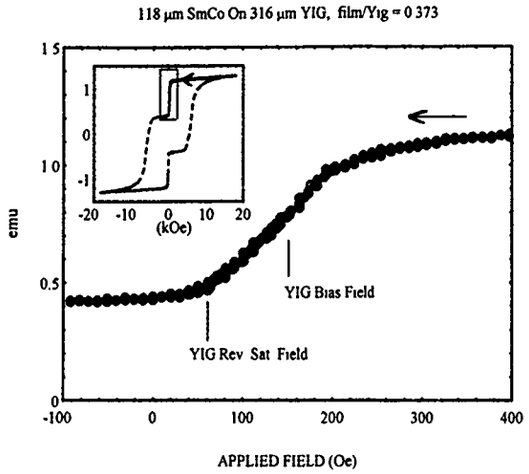

FIG. 6. An in-plane hysteresis loop for a 118 μm thick SmCo film on a 316 μm thick YIG substrate is shown in the inset. The main figure shows an expanded field view of the region indicated by the rectangle. The YIG bias level due to the presence of the SmCo film is indicated as well as the field at which the YIG becomes saturated in the reverse direction. Note that the YIG is saturated in the reverse direction when the applied field is still +60 Oe in the opposite direction. The arrow indicates that the applied field was decreased.

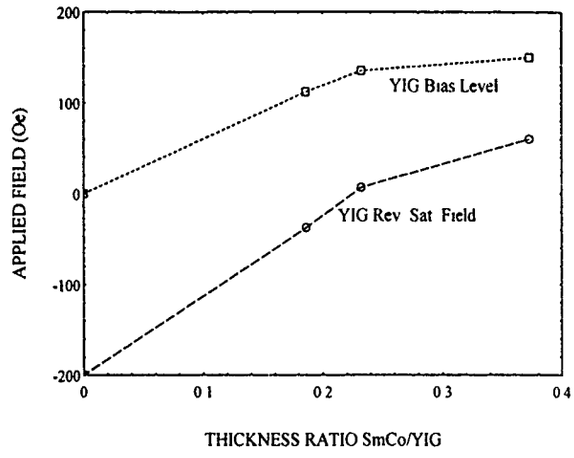

FIG. 7. The YIG bias level and the applied field level following magnetization at which the YIG becomes saturated in the reverse direction as a function of the SmCo to YIG thickness ratio are shown.

a 118 μm thick SmCo based film as deposited onto a 635 μm thick YIG substrate. The applied field range shown is from $\pm$20 kOe. Arrows on the curve indicate the magnetization and demagnetization progression. For the upper branch the sharp drop near $H=0$ is when the YIG emu value reverses. In this case the SmCo and YIG substrate size measured was 3.5×3.3 mm^2. The relative SmCo to YIG emu value jumps are in the ratio of the remanent flux density of the SmCo layer times the thickness of the SmCo layer to the saturation flux density of the YIG layer times the YIG thickness. The remanent SmCo flux density is 8.0 kG while that of the YIG is 1.7 kG. A SmCo to YIG film thickness ratio of 1.7/8.0 $=0.21$ would show the YIG reverse saturation step level at the zero net emu level. For Fig. 5 the SmCo to YIG thickness ratio is 0.186 and thus the YIG emu contribution exceeds the SmCo contribution.

Hysteresis loops were measured to saturation in the film plane for a 118 μm thick SmCo based film on a YIG substrate for successive steps as the YIG substrate was mechanically thinned. Figure 6 shows the SmCo-YIG magnetization progression as the field was swept from $\pm$18 kOe. The decrease in the total SmCo-YIG emu value due to the YIG magnetization reversal is shown with an expanded scale as the applied field was lowered from +400 to -100 Oe, as indicated by the arrow direction. This expanded scale region corresponds to the rectangular region indicated in the inset figure. The expanded scale date was collected with a field step size of a few Oe. The expanded scale part of the figure shows that the YIG reversal occurred before the applied field had been reduced to zero. For the substrate thinning step shown in Fig. 6 the YIG substrate thickness was 316 μm for a film to YIG thickness ratio of 0.373. In this case it should be noted that the YIG bias field value due to the presence of the SmCo film is 150 Oe. The internal field of the YIG is thus zero when the applied field has only been lowered to +150 Oe. In this case the YIG reverse emu value has saturated when the applied field has been reduced to +60 Oe. The looping field from the SmCo based layer is thus sufficient to completely saturate the YIG in a reverse direction when the external applied field is $\leq$60 Oe. The looping field from such a SmCo based film has been used similarly to bias permalloy strips[7] and in the construction of a magneto-optic waveguide isolator.[8]

Figure 7 shows the YIG bias level, and the field required for reverse saturation of the YIG, as a function of the SmCo to YIG thickness ratio. For SmCo to thickness ratios of $>$0.22 the magnetization of the YIG is reverse saturated by the presence of the SmCo layer. The YIG bias level and the field required for reverse YIG saturation become closer together as the YIG thickness is decreased because the demagnetization values decrease.

Transverse susceptibility and magnetic anisotropy of CoTi-doped barium hexaferrite single crystals

G. Zimmermann and K. A. Hempel
Institut für Werkstoffe der Elektrotechnik, Aachen University of Technology, Templergraben 55, 52056 Aachen, Germany

Measurements of the reversible transverse susceptibility (RTS) were performed on $BaFe_{12-x-y}Co_xTi_yO_{19}$ single crystals with doping concentrations $x \approx y \leq 0.77$ under different angles ϑ_0 between the easy axis and applied field. For intermediate doping concentrations the occurrence of a peak in the RTS curve for $\vartheta_0=90°$ indicates that the domain walls are not free to move. This assumption is confirmed further by the large component of the RTS being out of phase with respect to the excitation field H_E. The phase angle of the initial susceptibility measured parallel to the easy axis becomes maximum at a characteristic excitation field value $H_{E,C}$ and a relaxation of the susceptibility is observed if H_E steps from zero to a value larger than $H_{E,C}$. Using the RTS curve for $\vartheta_0=0$ and assuming that the peak of the RTS is located at the same field strength as if the particle were single domain, the first-order anisotropy field $H_A=2K_1/(\mu_0 M_s)$ and the second-order anisotropy constant K_2 can be determined. The values found this way are compared to results from magnetization-curve analysis and from other authors.

I. INTRODUCTION

Due to their wide applicability, *M*-type barium hexaferrites with substitutions of Co^{2+} and Ti^{4+} were the subject of many theoretical and experimental investigations.[1] Most of the experimental work was done on isotropic polycrystalline powder samples and aimed at the dependence of saturation magnetization and magnetic anisotropy on the doping concentration.[2,3]

There was an attempt recently to clarify the resulting and partially conflicting theories of magnetization and anisotropy by analyzing magnetization curves of single crystals over a wide range of fields and temperatures.[4] One focal point of this investigation was the independent determination of the first- and second-order anisotropy constants K_1 and K_2. The aim of this paper is to present new data for these constants obtained by measurements of the reversible transverse susceptibility (RTS) on $BaFe_{12-x-y}Co_xTi_yO_{19}$ single crystals at room temperature. Results from analysis of the magnetization curve in the magnetically hard direction are given for comparison, and the observed time dependence of the initial susceptibility is described in order to give more insight into the magnetization process.

II. TRANSVERSE SUSCEPTIBILITY

The reversible transverse susceptibility (RTS), which measures the change of magnetization in the direction of a small excitation field applied perpendicular to a bias field **H**, was investigated theoretically for uniaxial single-domain particles by Aharoni *et al.*[5] In the case of perpendicular orientation of bias field **H** and easy axis ($\vartheta_0=90°$), the theory predicts an infinite RTS in the (**H**, easy axis), plane at field strengths sufficient for saturation. Assuming a single crystal with an ellipsoidal shape, coinciding crystalline and rotational axes, and demagnetizing factors $N_\parallel$ and $N_\perp$ parallel and perpendicular to these axes, the saturating field is given by

$$H_s = H_A\left(1+\frac{2K_2}{K_1}\right)+(N_\perp - N_\parallel)M_s = H_A' + \frac{2K_2}{K_1}H_A,$$

where $H_A=(2K_1)/(\mu_0 M_s)$ is the first-order anisotropy field, $K_{1,2}$ are the first- and second-order anisotropy constants, M_s the saturation magnetization, and $\mu_0=4\pi\times10^{-7}$ (V s)/(A/m).

If the direction of **H** coincides with the easy axis of the particle ($\vartheta_0=0$), the transverse susceptibility measurement yields H_A', which is not influenced by K_2.[6,7] Thus, the comparison between H_s and H_A' in principle gives the opportunity to determine both the anisotropy constants of a single-domain particle. If, on the other hand, a multidomain single crystal is considered, the theory predicts a jump of the RTS at the transition into the single-domain state. Since in practice there is no sharp kink, as expected theoretically, it is generally impossible to get information about K_2 from RTS measurements of multidomain particles.[8]

III. DETERMINATION OF ANISOTROPY CONSTANTS

We investigated five irregularly shaped $BaFe_{12-x-y}Co_xTi_yO_{19}$ single crystals, which were prepared by slow cooling[9] of $BaO\text{-}BaF_2\text{-}B_2O_3$ melts (Table I). The samples were oriented in a field of 1600 kA/m and fixed using liquid adhesive. Subsequently, we measured the magnetization curves parallel and perpendicular to the easy axis in a vibrating sample magnetometer and the RTS under dif-

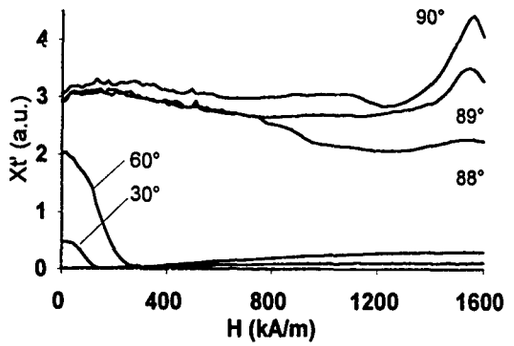

FIG. 1. In-phase component of the RTS of sample 2 for different angles ϑ_0. The measuring frequency was 5 kHz and the excitation field strength 15 A/m.

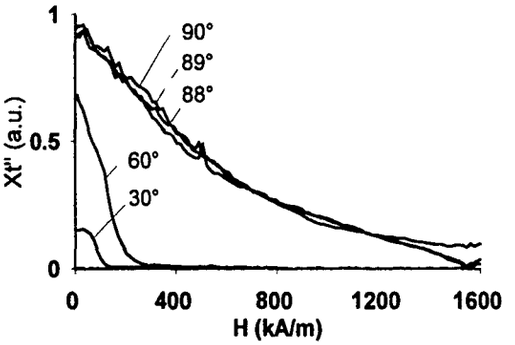

FIG. 2. Out-of-phase component of the RTS of sample 2 under the same conditions as in Fig. 1.

ferent angles ϑ_0 with an experimental setup similar to that described in Ref. 7, each time starting with a field of 1600 kA/m.

Whereas the undoped single crystal exhibits a qualitatively good agreement with the theoretical RTS curves for the multidomain case, a peak of the RTS occurs for $\vartheta_0=90°$ even for the small doping concentration $x\approx 0.1$ (Fig. 1). If x and y increase, the RTS curves become more and more similar to the curves predicted by single-domain theory, indicating that the domain walls do not move without energy consumption (as presumed for the theoretical investigation).[8] The location of the peak, as well as its shape, do not depend on the measuring frequency in the range between 1 and 150 kHz and on the strength of the excitation field which was increased to 90 A/m.

Identifying the field of the RTS peak with H_s and using the RTS curve and the magnetization curve for $\vartheta_0=0$ for the determination of H_A', $N_\parallel$, and $N_\perp$, the values of H_A and K_2 given in Table II are yielded. In addition, we evaluated H_A and K_2 using a Sucksmith–Thompson (ST) plot of the magnetization curve in the magnetically hard direction.[10] The room temperature values of H_A obtained in Ref. 4 by the same method are given for comparison.

IV. OUT-OF-PHASE COMPONENT AND TIME DEPENDENCE

The assumption of a damped domain wall motion is confirmed further by the appearance of a large out-of-phase component of the RTS for samples 2, 3, and 4 (Fig. 2). In order to get more insight into this effect, we measured the initial susceptibility parallel to the easy axis. Figure 3 shows the dependence of the phase angle of the initial susceptibility on the strength of the excitation field H_E, where we use $\underline{\chi}=\chi'-i\chi''$ ($i=\sqrt{-1}$). The most striking result is the existence of a maximum for the three samples with low and medium degree of doping at a characteristic excitation field $H_{E,C}$ of about 45 Å/m. The χ''/χ' ratio depends weakly on the measuring frequency in the 1–150 kHz range (Fig. 4). As a corresponding effect in the time domain, a relaxation of the susceptibility with a time constant τ of about 20 s at room temperature can be observed on samples 2, 3, and 4 (Fig. 5), provided that H_E steps from zero to a value larger than a threshold value $H_{E,T}\approx H_{E,C}$. If the temperature is increased up to 50 °C, τ decreases to one-tenth of its room-temperature value and becomes undetectable with our measuring equipment at a temperature of 100 °C. If we thus assume a thermally activated process with $\tau=\tau_0\exp(\Delta W/kT)$, we yield $\tau_0\approx 2\times 10^{-11}$ s and $\Delta W\approx 0.7$ eV at a rough estimate. A similar activation energy, as well as the existence of a threshold field, was found by Enz *et al.*[11] on Si-doped YIG and ascribed to a diffusion aftereffect[12] involving electron transitions between Fe^{2+} and Fe^{3+} ions. It is remarkable, in this context, that Šimša *et al.* deduced from their measurements a preferred occupation of $12k$ instead of $4f_2$, sites by the Co and Ti ions in the hexagonal fundamental cell in case of

increasing dopant concentrations.[4,13] The present results are not sufficient to enlighten the conceivable connection between these observations.

V. CONCLUSION

The first-order anisotropy field values determined by measurement of the reversible transverse susceptibility parallel to the easy axis of the single crystals and by analysis of the magnetization curve in the perpendicular direction are in a good agreement with the results of other authors.[2,3,4]

By contrast, the values obtained for the second-order anisotropy constant differ both for the two methods used here and in comparison with results published elsewhere. On one hand, this reflects the general difficulty in the experimental determination of K_2; on the other hand, it might indicate that the observed curvature of the magnetization curves is not due to the influence of the second-order anisotropy constant. Despite a possibly large error in the absolute value of K_2, both methods however do not indicate a decrease for higher dopant concentrations, as was found by other authors.[4]

The existence of a peak in the reversible transverse susceptibility as well as the appearance of a large out-of-phase component indicates a heavily impeded wall motion for intermediate doping concentrations. This assumption is confirmed by time domain measurements, which show a relaxation of the initial susceptibility with a thermally activated relaxation time. Further investigations are necessary to clarify the suggestive interpretation of these results in terms of a diffusion damped domain wall motion, possibly due to distribution of the Co and Ti ions on energetically different lattice sites depending on the direction of magnetization.

ACKNOWLEDGMENT

The authors would like to thank Dr. K. Fischer from IPHT Jena for the growth of the crystals.

Preparation of high-coercivity fine barium ferrite powder

W. A. Kaczmarek and B. W. Ninham
Research School of Physical Sciences and Engineering, Australian National University, Canberra, A.C.T. 0200, Australia

The structural and magnetic properties of the thermally activated transformation from nanostructural material, mechanically disordered and decomposed $BaFe_{12}O_{19}$ ferrite powder to pure crystalline phase, have been studied by x-ray diffraction, scanning electron microscopy, and vibrating sample magnetometry analysis techniques. All experiments were performed on as-milled (1000 h) in air, and in vacuum and annealed Ba-ferrite samples (4 h at 773 and 1273 K). In parallel with the structure and particle morphology changes, we investigate the influence of heat treatment on the powder M-H hysteresis parameters in relation to the preparation routes, i.e., powder obtained by ball milling in air and vacuum, and annealed in air or vacuum.

I. INTRODUCTION

The first experiments dealing with the effect of milling on the magnetic properties of barium ferrite were conducted more than twenty years ago.[1,2] However, particles obtained were well above the single-domain critical size (~1 μm at room temperature); and the results of magnetic measurements were ambiguous because they reflect the influence of structural deformation and lattice defects. Likewise, simple milling techniques used in those studies suffered from lack of control and precision in prescribing required milling conditions. Only in a recently introduced new type of ball mills can the milling process be controlled with required precision.[3,4] The present report is part of a wider project in which the influence of effects induced during mechanical processing on the gas-solid state surface interface on complex oxide systems is investigated. The influence of ball milling of $BaFe_{12}O_{19}$ ferrite powder on its structure and particle morphology was described in a previous paper.[5] In this study, along with the structure changes we investigate the influence of heat treatment on the powder particle morphology and magnetic properties in relation to preparation routes, i.e., powder obtained by ball milling in air and vacuum.

II. EXPERIMENT

High-purity (99.99 wt %) barium ferrite powder ($BaFe_{12}O_{19}$) with particle size distribution in the 0.5–50-μm range from Alfa Products/Johnson-Matthey was used as a starting material. Starting sample characterization and mechanical ball milling preparation details were described extensively in the previous paper.[5] An additional two samples were obtained by milling in air and in low-pressure "technical" vacuum (~10^2 Pa) for 1000 h. All three samples will be denoted in this paper as Ba-ferrite, A1000, and V1000, respectively. Heat treatment was performed on A1000 and V1000 powders at temperatures of 773 and 1273 K in air atmosphere, and in vacuum (sealed quartz tube) for 4 h. The experiments then yielded samples designated: for air milled material AA773, AA1273 (annealed in air) and AV773, AV1273 (annealed in vacuum) samples and for vacuum milled powder VA773, VA1273 (annealed in air) and VV773, VV1273 (annealed in vacuum) respectively. Particle morphology was examined by direct observation of gold-coated samples on a JEOL SEM 6400 scanning electron microscope. Structural characterization was performed using a Philips x-ray powder diffractometer employing Co $K\alpha$ (λ =1.789 nm) radiation. Supplementary thermo-gravimetric experiments were performed in a Shimadzu TGA-50H system. The dc magnetic field behavior of the material was investigated from the initially magnetized sample using a vibrating sample magnetometer PAR 155. All magnetic measurements were performed at room temperature on disk-shaped (4 mm) samples.

III. RESULTS AND DISCUSSION

A. X-ray diffraction

X-ray diffraction (XRD) patterns of as-milled powders are presented in Figs. 1(a) and 2(a). For sample A1000 two main crystalline phases were distinguished: dominant lines characteristic for α-Fe_2O_3 structure indexed and marked by F(hkl), and the remaining, most intense, reflections from barium ferrite marked as (B) and indexed below for sample AA1273. In the early study,[1] directly after milling no second phase was detected by XRD analysis (only subsequently, after annealing at 1273 K). Comparing the above with the XRD pattern for sample V1000, a strong tendency to form disordered phase was found. Peaks observed belong to the hematite phase, but additional broad features were assumed to be from nanocrystalline Ba-ferrite phase. Annealing at 773 K shows a complex mixture of two phases, and the influence of air pressure during heat treatment was observed. Characteristic XRD lines for both structures are clearly visible, and the broad feature (2θ=36° and $\Delta 2\theta$=10.5°) of V1000 has a tendency to disappear. XRD patterns from AV773 and VV773 are more similar than those seen for air-annealed powders. We assume that unlike the air-milled sample, the vacuum-milled sample has oxygen deficiency. Annealing in air allows restoration of stoichiometric proportions. Heat treatment at 1273 K for 4 h produces complete hexagonal structure restoration for either vacuum- or air-annealed samples and, contrary to results presented above for lower annealing temperature, present XRD patterns are the same. In Figs. 1(d) and 2(d) powder samples annealed in air are presented. We note that particle crystallographic structure is uninfluenced by different annealing atmosphere and the time required for "recrystallization," or to annihilate any defect induced by ball milling is relatively short when compared to

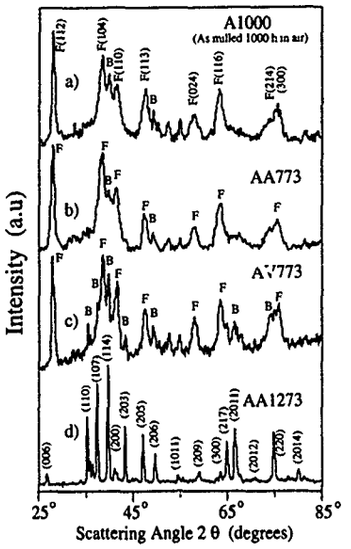

FIG. 1. XRD patterns evolution of the air-milled $BaFe_{12}O_{19}$ powder for different annealing temperatures. Peaks are indexed by: F: α-Fe_2O_3 and B: $BaFe_{12}O_{19}$.

that usually expected for "ordinary powder process." Partial decomposition during prolonged milling cannot produce completely separated hematite and barium oxide particles. Rather, it takes place as a microscale phase separation, and produces multigrain nanostructural particles of the three phases. Then, the subsequent reaction requires only a short-distance diffusion between the grains within a particle.

B. Scanning electron microscopy

In Fig. 3, SEM micrographs of A1000 and V1000 as-milled powders as compared with samples annealed at 1273 K are presented. Different behavior was observed for each. As a result of milling, instead of clusters of fine particles

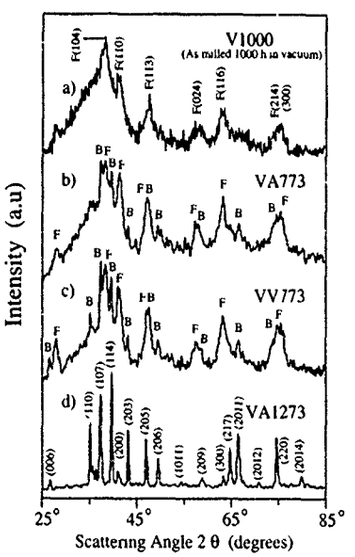

FIG. 2. XRD patterns evolution of the vacuum-milled $BaFe_{12}O_{19}$ powder for different annealing temperatures.

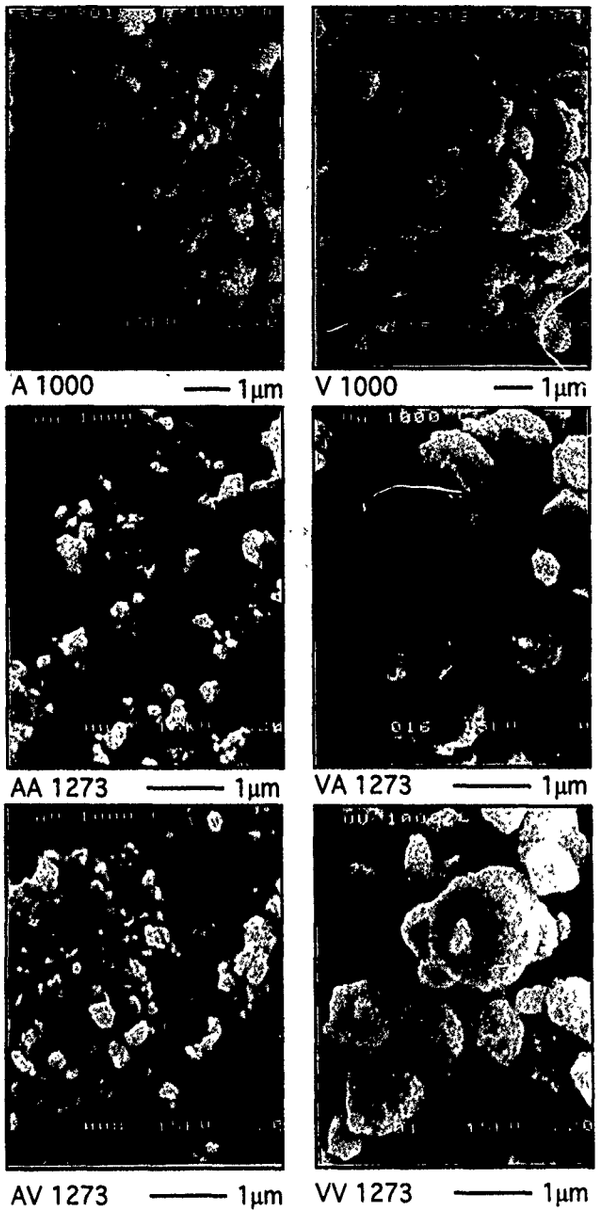

FIG. 3. SEM analysis of as-milled (A1000) and (V1000), and annealed at 1273 K in air (AA and VA) and vacuum (AV and VV) powders.

seen for the first powder, a tendency to form larger and more spherical particles can be noticed for the vacuum milled powder. Annealing at both 773 and 1273 K (air or vacuum) of A1000 and V1000 powders results in the same particle characteristics, as compared with material before annealing. Due to the short time of heat treatment, individual particle shape was found to be insensitive to process temperature and atmosphere. After annealing the particle size remains in the range 0.1–0.4 μm and 1–3 μm, respectively, for air- and vacuum-milled powders.

C. Magnetic properties

From early reports on magnetic properties of milled barium ferrite it has been well established that overall mag-

TABLE I. Values of magnetic hysteresis parameters: volume saturation, remanence, and coercivity. All parameters measured at room temperature. Maximum magnetic field applied 1 T.

Sample	M_s (kA/m)	M_r (kA/m)	H_c (kA/m)
$BaFe_{12}O_{19}$	380.0	254.7	74.4
A1000	13.0	2.7	44.6
AA773	28.4	5.3	99.5
AV773	52.1	25.2	187.8
AA1273	347.8	222.8	445.6
AV1273	344.1	203.5	393.9
V1000	13.8	3.2	35.0
VA773	13.9	3.6	58.5
VV773	22.9	5.6	60.9
VA1273	335.4	197.6	434.5
VV1273	343.0	199.2	429.7

netic properties are greatly affected by milling and annealing processes.[1,2] Our findings confirm these conclusions. From the results of hysteresis measurements performed at room temperature presented in Table I, it is clear that for as-milled samples A1000 and V1000 all parameters are extremely low by comparison with the premilled powder. After subsequent annealing at 773 K, only minimal changes of hysteresis parameters are observed. The most significant improvement of overall magnetic properties was recorded for powders annealed at 1273 K. Magnetic hysteresis curves for some of these powders are presented in Fig. 4 and all parameters are listed in Table I.

We note that after annealing at 1273 K hysteresis parameters are weakly dependent on the milling air pressure. However, slightly higher M_s values were observed for air-milled powders AA1273 and AV1273. On the other hand, annealing in air promotes minimally higher H_c values. We assume that different particle morphology as seen in Fig. 3 is directly responsible for magnetic parameter value fluctuations. It is obvious that independently of particle size, for either air- or vacuum-milled powders, the observed M_s values are close to values measured for a starting powder (~90%), but of importance is the fact that the coercivity increases over six times and reaches a value 445.6 kA/m. This value is typical of chemically coprecipitated fine Ba-ferrite powders where perfect crystal structure assures a defect and stress-free spin arrangement with high magnetocrystalline anisotropy energy.[6] According to the Stoner and Wohlfarth theory of coherent rotation,[7] the theoretical coercivity for a random assembly of Ba-ferrite particles would be $H_c = 0.96\ K_1/M_s = 664$ kA/m (substituting $K = +33$ MJ/m^3 and $M_s = 390$ kA/m). The last value is higher than any experimental value ever obtained on mechanically processed powders. Mössbauer spectroscopy results in the same powders will be presented subsequently.[8]

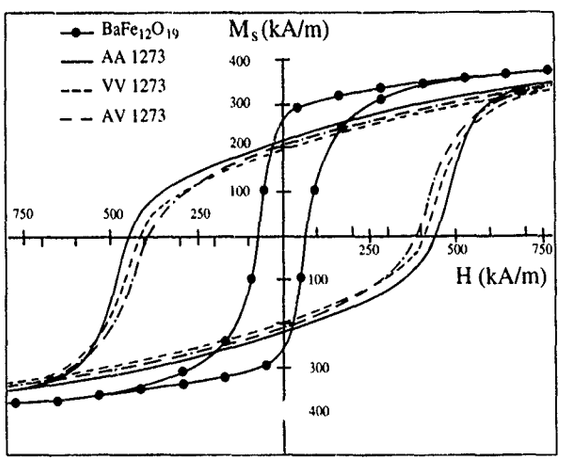

FIG. 4. Magnetization in a function of external magnetic field showing the effect of annealing at 1273 K on milled Ba-ferrite powders.

IV. CONCLUSIONS

We found that, depending on milling atmosphere (air or vacuum), the final average particle sizes are different ~0.3 and ~1 μm, respectively, with multiphase nanostructure. Low values of magnetization and coercivity, characteristic for decomposed Ba-ferrite, were found for as-prepared samples. With heat treatment, structural and magnetic properties were altered, but the particle morphology is retained. Annealing at 773 K produces more obvious changes in magnetic properties; however, with powders annealed at higher temperature, significant values $M_s = 335.4-347.2$ kA/m and $H_c = 393.9-445.6$ kA/m were obtained. The M_s value is near the typical value for Ba-ferrite powder (<10%), but the H_c value was improved quite remarkably, by a factor of six, as a result of fine crystal grain size produced by short annealing time.

Nitriding studies of aligned high anisotropy $ThMn_{12}$-type $NdFe_{11}Co_{1-y}Mo_yN$ film samples (abstract)

A. Navarathna, P. Samarasekara, H. Hegde, R. Rani, and F. J. Cadieu[a)]
Physics Department, Queens College of CUNY, Flushing, New York 11367

Highly aligned film samples of $ThMn_{12}$-type $NdFe_{12-y-z}Co_yMo_z$, $y+z\approx1$, have been directly crystallized onto heated substrates by rf sputtering. The deposited films have then been nitrided at different nitriding pressures and temperatures to determine the optimum conditions to maximize the coercivity. The films have generally been (002) textured so that the easy axis of magnetization of the nitrided films is perpendicular to the film surface. For low Co concentrations it has been possible to enhance the saturation flux densities, the coercivity, and the anisotropy field of the nitrided samples. Maximum room temperature coercivities and anisotropies of 11.3 and 145 kOe were obtained for a $ThMn_{12}$-type $Nd_{8.9}Fe_{80.3}Co_{6.0}Mo_{4.8}N$ (002) textured film sample. At lower temperatures the coercivity and anisotropy rose smoothly to 29.5 and ≈200 kOe respectively by 10 K. Based on nitriding studies on similar films, all nitride sites should be occupied at ≈1 N per $ThMn_{12}$ formula unit for the high coercivity films. Previously $NdFe_{11}Co_{0.5}Mo_{0.5}N$ films were reported with a room temperature BH_{max}=46.3 MGOe at 293 K and 59.6 MGOe at 10 K.[1] In general, films that have been made to exhibit a gradient in any one component have exhibited lower energy products due to either a reduced coercivity or to shouldered hysteresis loops.

Theoretical predictions of interface anisotropy in the presence of interdiffusion (invited)

J. M. MacLaren
Department of Physics, Tulane University, New Orleans, Louisiana 70118

R. H. Victora
Imaging Research and Advanced Development, Eastman Kodak Company, Rochester, New York 14650-2017

The first *ab initio* electronic structure calculations of the magnetocrystalline anisotropy of superlattices with imperfect interfaces are presented. Specifically the possibility of an interdiffusion between the layers at the interface in Co/Pd and Co/Pt superlattices is considered. The electronic structure calculations use the local spin-density formalism as implemented with the layer Korringa–Kohn–Rostoker method. Interdiffusion at the interface is modeled in two distinct ways. In the first approach a diffuse interface is represented by ordered arrangement of substitutions, while in the second approach interdiffusion is assumed to produce a substitutionally disordered random alloy on the layers at the interface, which is solved using the coherent potential approximation. The calculated interface anisotropies for superlattices with perfect and imperfect interfaces are, on average, modeled accurately by a simple Néel-type model. This model always predicts a reduction in magnetic anisotropy resulting from the presence of defects.

I. INTRODUCTION

Recently there has been considerable effort aimed at developing high-density magneto-optic storage devices. One proposed method for reading the stored data is to use the polar Kerr effect. A prerequisite for using this technique is a medium with perpendicular magnetic anisotropy, since this leads to optimal coupling between the incident light and the magnetic media. Transition-metal superlattices have a number of desirable properties which make them potential magneto-optic media, including large Kerr rotations, which are still significant at short wavelengths, and perpendicular anisotropy for certain multilayer geometries.

Perpendicular magnetic recording also offers the potential of higher aerial storage densities than longitudinal recording because of the properties of the demagnetization fields. Many short-period magnetic multilayers exhibit a perpendicular anisotropy resulting from the influence of the interfaces, despite the tendency for in-plane anisotropy caused by demagnetization energies. Beyond a critical multilayer period, the volume anisotropy will dominate the influence of the interfaces and in-plane anisotropy results. While the volume term always favors in-plane magnetization in a thin-film geometry, the interface term can in principle produce either a longitudinal or a perpendicular contribution to the magnetic anisotropy. In most of the magnetic multilayers it appears that the interface contributions favor perpendicular anisotropy. The range of superlattice periods which have the desired perpendicular anisotropy clearly depends on the relative strengths of the interface and volume terms. The value of the interface anisotropy depends upon the quality of the interface, thus, the strength of the magnetic anisotropy and the range of superlattice periods which exhibit useful perpendicular anisotropy will depend on sample preparation. Thus, it is of great interest to understand and predict the influence of defects on the magnetic anisotropy energy.

The magnetocrystalline anisotropy energy in transition metals is electronic in origin and results from the spin-orbit interaction. The magnetic anisotropy can be obtained theoretically from an electronic structure calculation by computing the electronic energy as a function of the spin direction. These types of calculations are, however, challenging owing to the small changes of energy (as compared to the total electronic energy) accompanying changes in the magnetization direction. Calculations for the elemental magnets Fe, Ni, and Co[1,2] predicted incorrect easy axes of magnetization for Co and Ni and while finding the correct easy axis for Fe the value of the anisotropy energy was too small. Systems with lower symmetry such as artificial free-standing monolayers,[3] embedded monolayers, surface overlayers,[3–5] and superlattices[6,7] typically have anisotropies which are an order of magnitude bigger and are large enough that the anisotropy energy can be reliably calculated using electronic structure theory.

In this article first-principles electronic structure calculations and a simple symmetry model are used to study the influence of defects produced by interdiffusion on the magnetic anisotropy. In particular, superlattices with three ordered arrangements of defects are considered. For the specific case of Co/Pd these are: (1) $1(Co_3Pd_1)/1(Pd_4)$ and $1(Co_3Pd_1)/2(Pd_4)$—a Pd substitution in the Co layer of 1Co/1Pd or 1Co/2Pd; (2) $1(Co_4)/1(Co_1Pd_3)/1(Pd_4)$—a Co substitution in one of the Pd layers of 1Co/2Pd; and (3)

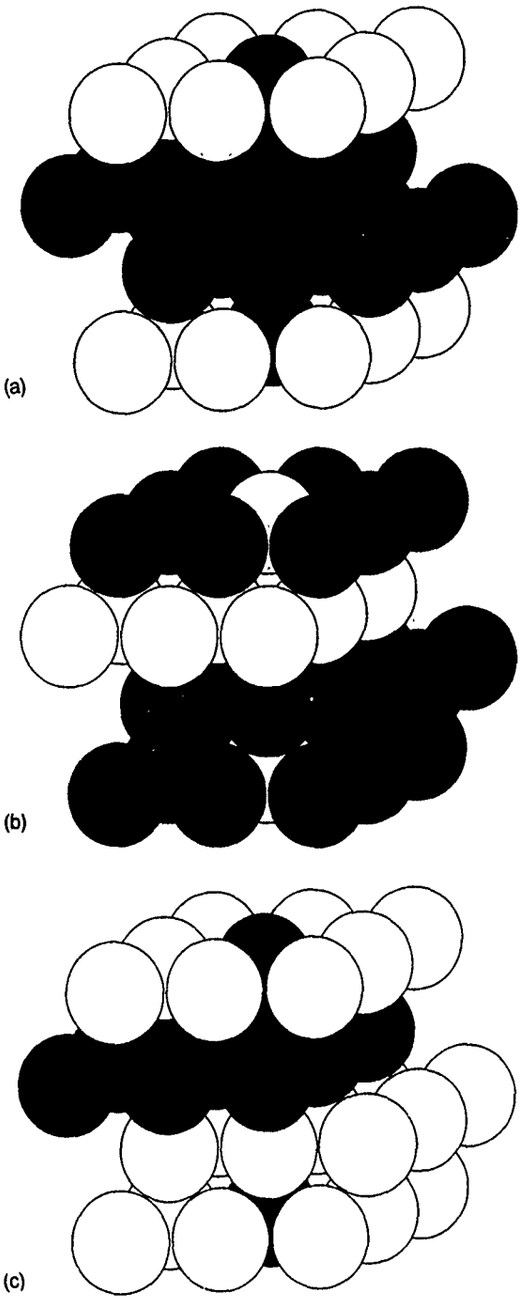

FIG. 1. Crystal structures of ordered arrangement of superlattice defects. Light and dark spheres correspond to Co and Pd/Pt atoms, respectively. (a) Monolayer substitution; (b) monolayer adatom; and (c) bilayer substitution.

$1(Co_4)/1(Co_3Pd_1)/1(Pd_4)$—a Pd substitution in one of the Co layers of 2Co/1Pd. These three defect structures are denoted as a monolayer substitution, monolayer adatom and bilayer substitution, respectively, and are shown in Fig. 1. The notation adopted is that all atoms between parentheses belong to the same layer, thus $1(Co_4)$ is a single layer with four Co atoms in the two-dimensional layer unit cell. For each of these structures, the defects are only connected at third nearest neighbors, a separation at which the defects are assumed to be essentially isolated.

In addition to these ordered defect structures, we have also studied the magnetic anisotropy of 1Co/3Pd and 1Co/3Pt superlattices where the interdiffusion between Co and Pd or between Co and Pt at the interface produces a substitutionally disordered random alloy. The profile of Co interdiffusion has been chosen to follow a trapezoidal distribution, i.e., $1(Co_{1-2x}Pd_{2x})/1(Co_xPd_{1-x})/1Pd/1(Co_xPd_{1-x})$ and $1(Co_{1-2x}Pt_{2x})/1(Co_xPt_{1-x})/1Pt/1(Co_xPt_{1-x})$ for various values of x. This composition profile is one which is consistent with experimental x-ray studies[8] where interdiffusion is often seen to occur. In all cases the atoms were assumed to lie on a perfect fcc lattice whose lattice constant was taken to be a weighted average of the constituent atoms. This choice was consistent with all the experimental x-ray determinations of the superlattice crystal structure.[9]

II. THEORY

A. Electronic structure theory

The electronic structure of both ordered and disordered superlattices is found self-consistently using the layer Korringa–Kohn–Rostoker (LKKR) method within the local-spin-density approximation.[10] The Janak, Moruzzi, and Williams[11] parameterization of the exchange correlation energy and potentials has been used. Unlike other studies where the spin-orbit interaction has been included in a second variational step using self-consistent potentials obtained in the absence of the spin-orbit interaction,[1,3,6] the calculations reported in this article solve the Kohn–Sham equations self-consistently with the spin-orbit interaction when the magnetization is normal to the superlattice. The longitudinal magnetization calculation is treated as a perturbation on the self-consistent solution for the perpendicular orientation of the magnetization. The energy difference is obtained using the force theorem[12] which we have found to give essentially identical answers to within numerical accuracy to full self-consistent results with a longitudinal magnetization. Calculations with an in-plane magnetization are significantly more time consuming because of the lower symmetry.

The LKKR method has been described in detail in Ref. 10. In this section, therefore, we present a brief outline of the method, paying attention mainly to those aspects that are unique to this work.

The potentials are assumed to be spherically symmetric within contiguous muffin-tin spheres and a constant in the interstitial region (the muffin-tin approximation). This approximation is known to be accurate for close-packed metallic structures, and since the anisotropy energy is predominantly determined by the d states which are primarily located within the muffin-tin spheres, it is an excellent approximation for the anisotropy energies of the metallic superlattices discussed in this article.

Inside the muffin-tin spheres the Hamiltonian can be conveniently partitioned into the usual scalar relativistic H_{SR} and spin-orbit H_{SO} terms. In Rydberg atomic units, which are assumed throughout this work, H_{SR} is given by

$$H_{SR} = -\frac{1}{2M}\begin{pmatrix}\nabla^2 & 0\\ 0 & \nabla^2\end{pmatrix} + \begin{pmatrix}V_\uparrow & 0\\ 0 & V_\downarrow\end{pmatrix}$$

$$-\frac{1}{4M^2c^2}\begin{pmatrix}\frac{\partial V_\uparrow}{\partial r}\frac{\partial}{\partial r} & 0\\ 0 & \frac{\partial V_\downarrow}{\partial r}\frac{\partial}{\partial r}\end{pmatrix}. \quad (1)$$

This term is spin dependent but diagonal in spin space. The spin-orbit interaction in Rydberg atomic units is given by

$$H_{SO}=\frac{1}{2M^2c^2}\frac{\partial V}{\partial r}LS=\frac{1}{4M^2c^2}\frac{\partial V}{\partial r}\begin{pmatrix} l_z & l_-\\ l_+ & -l_z\end{pmatrix}. \quad (2)$$

The forms of H_{SR} and H_{SO} are taken from Koelling and Harmon.[13]

In the above equations, $V_\uparrow$ and $V_\downarrow$ are the spin-up and spin-down one-electron potentials, V is the average of spin-up and spin-down potentials, c is the speed of light, $M=1/2+(E-V)/2c^2$ is the effective electron mass, $l_+=l_x+il_y$ and $l_-=l_x-il_y$ are the raising and lowering orbital angular momentum operators, and l_x,l_y,l_z are the Cartesian components of the orbital angular momentum operator. In the spin-orbit term H_{SO}, V is chosen to be the average of the spin-up and spin-down potentials to ensure that this term is Hermitian for real energies. H_{SO} couples spin-up and spin-down wave functions and this mixing depends upon the direction of the magnetization. The matrix elements of H_{SO} can be readily obtained by using spinors appropriate for a magnetization direction specified by the polar angles θ and ϕ,[4]

$$|\uparrow\rangle=\begin{pmatrix}\cos(\theta/2)e^{-i\phi/2}\\ \sin(\theta/2)e^{i\phi/2}\end{pmatrix}, \quad |\downarrow\rangle=\begin{pmatrix}\sin(\theta/2)e^{-i\phi/2}\\ -\cos(\theta/2)e^{i\phi/2}\end{pmatrix}. \quad (3)$$

Writing the solution to this effective Schrödinger equation as a product of radial solutions, spherical harmonics, and spinors, defined by Eq. (3), results in a set of coupled differential equations which are solved by standard techniques.

In contrast to most electronic techniques which calculate single-particle wave functions and eigenvalues, the LKKR method uses multiple scattering theory to obtain the one-electron Green's function at a given energy and wave vector in the Brillouin zone. The valence charge density is obtained from the imaginary part of the Green's function from integrations over the two-dimensional Brillouin zone and over energy from the bottom of the valence band to the Fermi energy, rather than from the sum of squares of occupied orbitals. This energy integral is performed numerically as a contour integral in the complex plane which ensures rapid convergence of both energy and Brillouin zone integrations.

Multiple scattering theory provides a convenient framework for calculating the Green's function by combining the atoms together to form the solid in a recursive manner. In a LKKR calculation the solid is partitioned into planes of atoms within which only two-dimensional translational symmetry is assumed. The multiple scattering is then factored into intra- and interlayer terms. First the scattering properties of the unique layers are found from those individual atoms. Multiple scattering within each layer is solved in the angular-momentum basis whose size scales with the number of atoms in the layer. Multiple scattering between the layers is solved using the layer coupling algorithms, derived for low-energy electron-diffraction theory,[14] in a plane-wave basis whose size is independent of the number of layers. Computing times scale roughly cubically in the number of atoms per layer and linearly in the number of layers rather than as the cube of the total number of atoms in the unit cell as is typical for most conventional electronic structure methods. This makes the LKKR method a very efficient technique for studying superlattice electronic structure since typically each layer has a simple structure and all the complexity in the superlattice lies in the stacking together of the layers.

The coherent potential approximation (CPA) provides a technique for describing the electronic structure of the random substitutionally disordered alloy by appropriately averaging different configurations,[15] and when combined with multiple scattering theory provides a first-principles density functional theory of alloys.[16] The physical picture behind the CPA is as follows: A mean field treatment of the alloy allows the construction of an effective medium which has translational invariance. Each atomic component in the alloy has the electronic structure of that particular atom embedded in this effective medium. The concentrations of atoms can be made site dependent, thus, realistic interdiffusion profiles can be modeled. The details of the implementation of the CPA within the LKKR method are given in Ref. 17.

The basis set included s, p, and d partial waves to describe the scattering in the layers from the individual muffin-tin potentials. In order to converge the anisotropy energy to 4 μRy, 13 plane waves to describe the interlayer scattering, 135 k points per irreducible Brillouin zone wedge, and 48 energy points were needed. The spin-orbit interaction lowers the symmetry of the crystal, thus care must be taken to include all inequivalent wedges of the Brillouin zone.

B. Simple theory

Results of our previous electronic structure calculations[7] showed that the magnetic anisotropy had significant contributions from all points in the Brillouin zone and that Pd atoms distant from the interface contributed negligible amounts to the anisotropy. This suggested that the magnetic anisotropy could be interpreted in terms of a real space model with near-neighbor interactions and that only Co-Co and Co-Pd or Co-Pt interactions were important.

Symmetry dictates that the lowest-order contribution to the magnetic anisotropy is $L(\hat{R}\cdot\hat{\mathrm{M}})^2$ where L is the interaction strength, $\hat{R}$ is an interatomic unit vector, and $\hat{M}$ is a unit vector pointing along the magnetization direction. The total anisotropy of the superlattice can be found by summing the basic interaction over all nearest-neighbor pairs of atoms. In the Co/Pd multilayers the simple model is parameterized by the geometrical arrangement of the atoms, and by two constants L_f describing Co-Co interactions, and L_m describing Co-Pd interactions. A similar pair of constants are needed to describe the Co/Pt system. The philosophy of this model is the same as that suggested by Néel in 1954 in his study of surface anisotropy;[18] differences include the use of two parameters to characterize the two different interactions, and the correction of some algebraic errors in Néel's original work.

In contrast to our previous work[7] where explicit numerical values for the different atomic interactions were required

TABLE I. Energies of superlattices with ordered arrangements of defects.

Defect		Perfect		Difference	
System	Energy (μRy)	System	Energy (μRy)	LKKR	Simple theory
$1(Co_3Pt)/1(Pt_4)$	186	$1(Co_4)/1(Pt_4)$	389	$-4.2K_p$	$-4.0K_p$
$1(Co_3Pd)/1(Pd_4)$	46	$1(Co_4)/1(Pd_4)$	72	$-2.9K_p$	$-4.0K_p$
$1(Co_3Pt)/2(Pt_4)$	98	$1(Co_4)/2(Pt_4)$	322	$-5.6K_p$	$-4.0K_p$
$1(Co_3Pd)/2(Pd_4)$	165	$1(Co_4)/2(Pd_4)$	242	$-2.5K_p$	$-4.0K_p$
$1(Co_4)/1(CoPt_3)/1(Pt_4)$	393	$1(Co_4)/2(Pt_4)$	322	$+1.8K_p$	$-2.0K_p$
$1(Co_4)/1(CoPd_3)/1(Pd_4)$	173	$1(Co_4)/2(Pd_4)$	242	$-2.3K_p$	$-2.0K_p$
$1(Co_4)/1(Co_3Pt)/1(Pt_4)$	211	$2(Co_4)/1(Pt_4)$	240	$-1.0K_p$	$-2.0K_p$
$1(Co_4)/1(Co_3Pd)/1(Pd_4)$	-29	$2(Co_4)/1(Pd_4)$	30	$-16K_p$	$-2.0K_p$

to quantify the simple theory, in the case of superlattices with interfacial defects the changes in anisotropy can always be expressed as a fraction of that found in the perfect structure. This obviously makes the results more useful in interpreting experimental results.

First we will derive an expression for the anisotropy of an unstrained (111) superlattice which is composed of n layers per cell where the probability of finding a Co atom on layer j is given by P_j. All nearest-neighbor atoms are contained either within the plane or in the adjacent planes for this superlattice orientation, thus it is more convenient to consider the effective interactions between atoms in the same plane W_0, and the effective interactions between atoms in adjacent planes W_1. These effective interactions take into account the geometric arrangement of the atoms in the [111] planes. A superscript m or f is added to differentiate between ferromagnetic-paramagnetic and ferromagnetic-ferromagnetic atom interactions. Specifically W_0^f sums the interaction between a Co atom and six Co first nearest neighbors in a [111] plane, while W_0^m sums the interaction between a Co atom and six Pd or Pt first nearest neighbors in a [111] plane. Similar definitions apply to W_1^f and W_1^m. All four of these effective interactions can be expressed in terms of the basic interatomic interactions L_f and L_m. Using these effective interactions gives the following for the magnetic anisotropy of the disordered superlattice:

$$2K_i=\sum_{j=1}^{n} P_j^2W_0^f+2(1-P_j)P_jW_0^m+P_jP_{j+1}W_1^f$$
$$+P_j(1-P_{j+1})W_1^m+(1-P_j)P_{j+1}W_1^m. \quad (4)$$

Two identities can be derived immediately since the anisotropy of the pure material and the 50:50 alloy are zero because of the cubic symmetry. This yields

$$W_0^f+W_1^f=W_0^m+W_1^m=0. \quad (5)$$

Using these relations and noting that the n-layer superlattice has two interfaces per unit cell it follows that the interface anisotropy for the imperfect interface K_i can be simply obtained from that of the perfect interface K_p by

$$K_i=\tfrac{1}{2}K_p\sum_{j=1}^{n}(P_j-P_{j+1})^2, \quad (6)$$

where the interface anisotropy of the ordered superlattice is

$$K_p=W_1^m-\tfrac{1}{2}W_1^f. \quad (7)$$

In a similar way one can derive expressions for the reduction in anisotropy energy of the three ordered defects; They are $4K_p$, for the monolayer substitution, and $2K_p$ for the monolayer adatom and bilayer substitution. A simple geometric picture would suggest that a Pd substitution in the Co monolayer would modify two interfaces and thus might be expected to reduce the anisotropy by $2K_p$, while the Co adatom and the bilayer substitution only modify one interface and thus might be expected to reduce the anisotropy by K_p. The simple Néel theory predicts that the influence of the defects is twice as large as naively expected, demonstrating the dramatic effect of defects on the magnetic interface anisotropy.

1Co/5Pd superlattices fabricated under a variety of different experimental conditions show a wide variation in the measured magnetic anisotropy. A 1Co/5Pd superlattice grown by molecular-beam epitaxy has the largest anisotropy of 5.9×10^7 erg/cm^2 (Ref. 19), and a 1Co/5Pd superlattice grown epitaxially in UHV had an anisotropy of 4.9×10^7 erg/cm^2 (Ref. 20). Sputtered 1Co/5Pd superlattices made by different groups have anisotropies of 2.6×10^7 erg/cm^2 (Ref. 21) and 2.4×10^7 erg/cm^2 (Ref. 22), respectively. These can be compared to the theoretical values for a perfect 1Co/5Pd superlattice of 6.6×10^7 erg/cm^2 (Ref. 7) and 8.7×10^7 erg/cm^2 (Ref. 6). All of the experimental superlattices will contain defects, with the sputtered samples having the largest concentration. The range of values observed is clearly consistent with the theoretical expectations for superlattices with defects.

III. RESULTS AND DISCUSSION

Table I shows the calculated anisotropies for all of the ordered defects in Co/Pd and Co/Pt. As was stated in the previous section, the simple theory predicts a reduction of $4K_p$ for Pd and Pt substitutions in a Co monolayer. The results of the electronic structure theory for substitutions in the Co monolayer also show a reduction in the anisotropy. In previous work on perfect Co/Pd superlattices[7] we have noticed that the simple model reproduces average trends in the magnetic anisotropy while the results of electronic structure

TABLE II. Energies of superlattices with random arrangements of defects.

Defect		Perfect		Difference	
System	Energy (μRy)	System	Energy (μRy)	LKKR	Simple theory

$1(Co_{0.8}Pd_{0.2})/1(Co_{0.1}Pd_{0.9})/1Pd/1(Co_{0.1}Pd_{0.9})$	28.8	1Co/3Pd	56.6	$-1.0K_p$	$-1.0K_p$
$1(Co_{0.6}Pt_{0.4})/1(Co_{0.2}Pt_{0.8})/1Pt/1(Co_{0.2}Pt_{0.8})$	8.0	1Co/3Pt	64.6	$-1.8K_p$	$-1.6K_p$
$1(Co_{0.6}Pd_{0.4})/1(Co_{0.2}Pd_{0.8})/1Pd/1(Co_{0.2}Pd_{0.8})$	14.6	1Co/3Pd	56.6	$-1.5K_p$	$-1.6K_p$

calculations for individual systems can show significant deviations from the predictions of the simple theory. The standard deviation of the fit in this case was $1.2K_p$. These variations can probably be explained by noting that while each point in the Brillouin zone contributes to the anisotropy, certain points are more important than others and that these points are superlattice dependent.

For the four monolayer substitutions studied, the average reduction is $3.8K_p \pm 1.4K_p$ which is statistically the same as the simple theory prediction of $4K_p$. In the case of the ordered defects structures with substitutions in the Co bilayer and Co substitutions in the Pd or Pt layer (last four lines of Table I) the simple theory predicts a reduction of $2K_p$ in the anisotropy. The agreement between the electronic structure results and the simple theory is clearly not as good. Excluding the 2Co/1Pd superlattice, leads to an average reduction of $0.5K_p \pm 1.7K_p$ which is still consistent with the simple theory though the standard deviation is larger. Defect-free 2Co/1Pd has a much smaller anisotropy than simple theory would predict and thus it is not too surprising that the introduction of defects produces an anomalous result.

Since the simple theory works best in an average sense one might expect better agreement between the predictions of the simple model and the results of the electronic structure calculations for superlattices where the defects are placed in a random manner. To model a realistic interdiffusion profile we have assumed a trapezoidal distribution; this distribution is consistent with the x-ray-diffraction data which we have examined. The superlattices which we have examined are $1(Co_{1-2x}Pd_{2x})/1(Co_{1-x}Pd_x)/1Pd/1(Co_{1-x}Pd_x)$ and $1(Co_{1-2x}Pt_{2x})/1(Co_{1-x}Pt_x)/1Pt/1(Co_{1-x}Pt_x)$ for $x=0.1$ and 0.2. The results of the LKKR CPA and the predictions of the simple theory are shown in Table II. The Néel-type model predicts a reduction of $1.0K_p$ and $1.6K_p$ for $x=0.1$ and $x=0.2$, respectively. Electronic structure theory gives $1.2K_p \pm 0.4K_p$ for the former and $1.6K_p \pm 0.2K_p$ for the latter, in excellent quantitative agreement with the simple theory. Simple theory also reproduces the results of the individual first-principles calculations as well as the average trend, and deviations are significantly smaller than those seen in the ordered calculations. The better agreement is attributed to the fact that the LKKR CPA calculations represent ensemble averages of many possible superlattices with the same layer compositions. Thus, the assumption of uniform contributions to the anisotropy from points in the Brillouin zone, implicit in the Néel-like theory, is likely to be a better approximation.

IV. CONCLUSIONS

Using the LKKR electronic structure method we have performed first-principles calculations of the magnetocrystalline anisotropy energy of a superlattice with imperfect interfaces. Both ordered arrangements of defects and a random substitutional alloy have been studied. Using a simple Néel-type theory, expressions for the expected changes in anisotropy associated with each type of defect have been derived. Detailed comparisons show the value of the simple symmetry-based model as a quantitative predictor of the expected trends. The imperfect superlattices where the interdiffusion causes a random arrangement of defects are expected to be a more realistic model of the experimental interface, and in this situation the simple theory is both found and expected to be more useful. We have shown that the influence of imperfections is generally larger than geometric arguments would suggest, and that defects act to reduce the magnetic anisotropy.

Magnetic anisotropy of metal/Co/metal and metal/Co/insulator sandwiches

Michael H. Wiedmann, Brad N. Engel, and Charles M. Falco
Physics Department and Optical Sciences Center, University of Arizona, Tucson, Arizona 85721

In situ polar Kerr-effect measurements have been used to study the magnetic anisotropy of MBE-grown Au(111)/Co/X and Pd(111)/Co/X sandwiches, where X is the nonmagnetic metal Ag, Au, Cu, and Pd or the insulator MgO. For the metals it was recently found that the magnitude of the Co/X perpendicular interface anisotropy is strongly peaked at ~1 atomic layer (1.5–2.5 Å) coverage. To investigate structural influences on the anisotropy, reflection high-energy electron diffraction (RHEED) and low-energy electron diffraction (LEED) have been used to measure changes resulting from overlayer coverage. Analysis of digitized RHEED images captured every ~1 Å during metal overlayer coverage shows no abrupt change of the in-plane lattice constant. The out-of-plane lattice spacing has also been investigated as a function of nonmagnetic metal coverage by measuring LEED I-V curves along the (0,0) rod. In the case of Cu, where the LEED behavior is nearly kinematic, no evidence was seen of any abrupt structural changes at ~1 atomic layer coverage. These results suggest the observed peak in magnetic anisotropy is not structural in origin. To further study this phenomenon, the influence of an insulating overlayer, MgO, on the perpendicular magnetic properties has been measured.

I. INTRODUCTION

A fundamental understanding of the magnetic anisotropy arising from the interface between magnetic and nonmagnetic metal films is an important current problem in magnetism. Of particular interest for optical data storage applications are material systems that display perpendicular anisotropy, such as Au/Co and Pd/Co. Possible explanations advanced for this strong anisotropy include the reduced coordination symmetry,[1] altered electronic structure,[2] and localized epitaxial strain at the interface between two different materials.[3] Previously, we have investigated influences on the interface anisotropy by varying overlayer coverage and material species.[4,5] For Ag, Au, and Cu we have found that the magnitude of the Co/metal perpendicular interface anisotropy is strongly peaked at ~1 atomic layer coverage.

In this article we report on detailed structural characterization of the metal overlayers by reflection high-energy electron diffraction (RHEED) and low-energy electron diffraction (LEED). We also investigated the effects of an insulating overlayer (MgO) on the magnetic properties of single crystal Co films grown on Au(111) surfaces.

II. EXPERIMENT

The results reported here are for Co films in the thickness range 2 Å$\leq t_{Co} \leq$30 Å deposited on 500-Å-thick buffer layers of either Pd(111) and Au(111). The buffer layers were grown on annealed, Co-seeded GaAs(110) substrates. We used an effusion cell for Pd deposition at 0.15 Å/s, and optical-feedback-controlled electron-beam evaporators to deposit the Au (0.1 Å/s), Co (0.25 Å/s), Cu (0.1 Å/s), and MgO (~2 Å/s). All deposition rates were determined from Rutherford backscattering spectrometry (RBS) analysis of thick calibration films. The background pressure for the metals was $\leq 5\times10^{-10}$ Torr during deposition and $\leq 1\times10^{-8}$ Torr for the insulator. The crystalline quality of the films was monitored during growth with RHEED. The RHEED images were captured with a charge-coupled-device (CCD) camera system capable of resolving changes in in-plane lattice spacings of ~1%. A reverse-view LEED system with an identical CCD camera was used to measure changes in perpendicular lattice spacings upon coverage by measuring intensity versus voltage (I-V) curves of the specular beam. The growth must be interrupted after each coverage step in order to rotate the sample stage to perform LEED. I-V curves can be completed in less than 20 min with minimal surface contamination between depositions.

Magnetic and magneto-optic characterization of the samples was carried out by *in situ* polar Kerr-effect measurements. The sample can be transferred between the deposition chamber of our molecular-beam-epitaxy (MBE) system and another connected ultrahigh-vacuum chamber ($P<2\times10^{-10}$ Torr) where it is aligned between the poles of an external electromagnet. The magnetic field is applied along the sample normal with a maximum field of ±2.2 kOe. We use a 50 kHz photoelastic modulator and lock-in–amplifier–based detection scheme with a HeNe laser to measure the polar Kerr ellipticity of the sample as a function of applied field.

III. STRUCTURAL CHARACTERIZATION OF METAL OVERLAYERS

The role of crystal structure in our observed coverage-dependent anisotropy is an important question that is difficult to address. Because magnetic anisotropy is very sensitive to the local environment, subtle changes in atomic spacings could cause significant effects. We have used RHEED and LEED to investigate coverage-dependent changes in the surface lattice spacing. Using RHEED, we have measured intensity profiles across a streak pattern of a Co surface as it is progressively covered with Au.[6] Starting with a 30 Å Co film deposited on a 500 Å Au(111) buffer layer, RHEED images were captured every 4 s during uninterrupted Au deposition at a rate of 0.1 Å/s, giving a coverage interval of ~0.4 Å. At the coverage equivalent of 1 atomic layer (2.4 Å), the diffraction peak is composed of contributions from both bulk Au and bulk Co spacings. After 2 atomic layers of coverage, the peak is dominated by diffraction from the bulk Au spac-

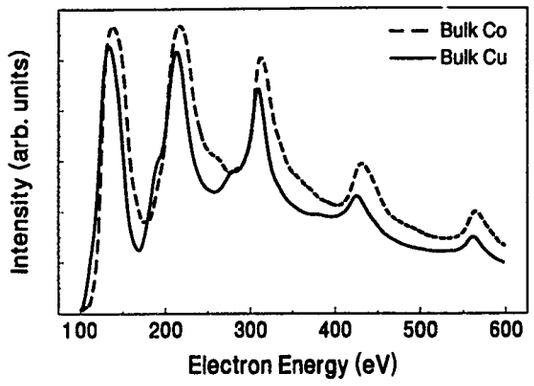

FIG. 1. LEED I-V curves of (0,0) specular beam for Co(111) surface and a thick Cu film (200 Å) deposited on top of it.

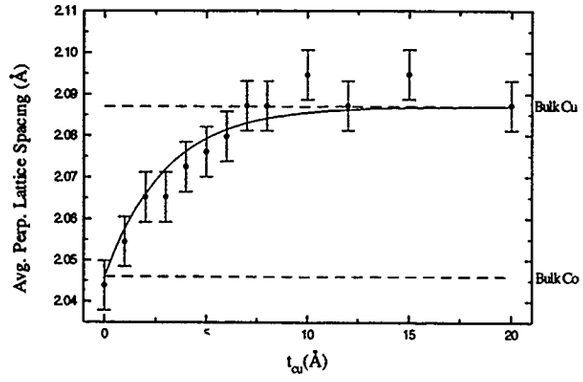

FIG. 2. Change in average perpendicular lattice spacings determined from shifts in lowest-energy peak locations in Fig. 1. The continuous curve is calculated assuming bulk Co and Cu lattice constants and a mean sampling depth of 3 Å. There is no evidence of any abrupt change at 1 atomic layer coverage.

ing. Because the Au immediately grows incoherently and strain free, these measurements suggest that the Co in-plane lattice spacing is unaffected by the Au overlayer. A similar experiment was carried out for a Cu overlayer on Co, where the two materials have a roughly 2% lattice mismatch. In this case we also see no abrupt changes in the surface lattice spacing.

Because the RHEED geometry is only sensitive to the in-plane lattice spacings, we can obtain information about the out-of-plane spacings from LEED versus I-V measurements. Although not as rigorous as a full dynamical analysis, one can determine the average out-of-plane lattice spacing of the top few monolayers from measured I-V curve of the specular or (0,0) beam. This simple analysis is only valid for materials which show weak or no multiple scattering. The average lattice spacing is deduced by comparison of the resulting intensity peak locations to calculated Bragg peaks. In this article we report results from I-V curves of the (0,0) beam of Cu deposited on Co(111). In this case, the overlayer is a different material from the substrate and therefore this analysis provides a combined weighted average lattice spacing of both materials. As an example of the sensitivity of this technique, Fig. 1 shows an I-V curve of a clean Co(111) surface and that from a bulklike thick Cu film deposited on top of the Co surface. The two representative curves show well-defined Bragg peaks which are slightly shifted from each other. To measure the effect of the overlayer as it is grown, I-V curves were taken after each of many Cu depositions of ~1 Å each (the equivalent of 0.5 atomic layers of Cu). As the bare Co is increasingly covered with Cu we observe a continuous shift from the Co peak positions to the Cu peak positions. Further deposition of Cu beyond 8 Å coverage does not change the location of the peaks. These peaks can be associated with Bragg diffraction by taking into account an inner potential correction, indicating that both the materials Co and Cu behave nearly kinematically. The peak location of the specularly reflected beam can be calculated from the following relation.[7]

$$2(E^B+V_0)\cos^2\theta=(n\pi/d)^2, \quad (1)$$

where E^B are the Bragg energies, V_0 is the inner potential, θ is the angle of incidence, n the order of the peak, and d the out-of-plane lattice constant. The energies and distances are given in hartrees, 1 hartree=27.18 eV, and bohrs, 1 bohr =0.529 Å, respectively. The angle of incidence of the electron beam was ~7° in the ⟨11-2⟩ azimuth. The measured spectra of the Cu(111) surface are very similar to those measured by Reid.[8] We have measured the inner potential shift for bulk Co and bulk Cu to be 7.7 and 8.5 eV, respectively. It should be noted that we do not know how the inner potential V_0 varies as Cu is deposited; however, because the two bulk values are nearly the same, we used their average (8.1 eV) in all of our calculations. This causes only a small uncertainty in our determined lattice spacings and is included in the error estimates.

From the shifts in the Bragg peaks upon coverage we can calculate changes in the average out-of-plane lattice spacing according to Eq. (1), and which are shown as the circles in Fig. 2. Here we have used the lowest-energy peak at 137 eV which is the most surface sensitive with a mean sampling depth of only ~3 Å. The mean free path of LEED electrons at 137 eV is roughly 6 Å;[7] however, in a reflection-diffraction experiment in which a monoenergetic beam must enter and exit the crystal, the mean sampling depth is half the value of the mean free path. We have also calculated the coverage dependence of the average lattice constant that would be expected if both the Co and Cu remain at their bulk spacings. This average spacing is calculated using depth-dependent weighting factors derived assuming an exponential decay of the LEED electrons with a probing depth of 3 Å. The calculated solid curve in Fig. 2 is in good agreement with the measured data indicating that, to within our uncertainty, Cu grows at its bulk perpendicular lattice constant on the Co surface. We see no evidence of any abrupt structural changes of greater than ~0.6% at ~1 atomic layer coverage that would correlate with our observed peak in the anisotropy at this coverage.

We have also taken LEED I-V spectra of the specular beam for Au and Pd overlayers on Co. Both materials show strong multiple scattering where the peaks do not correspond

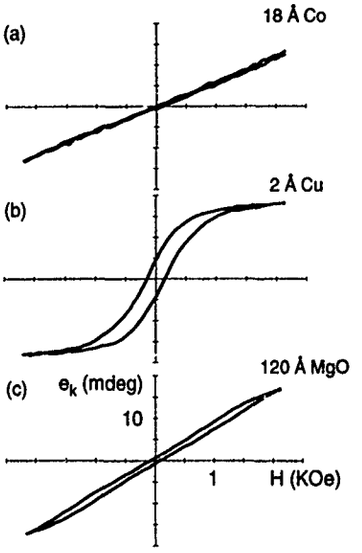

FIG. 3. *In situ* polar Kerr ellipticity loop from: (a) uncovered 18 Å Co on Au(111); (b) 2 Å Cu deposited on 18 Å Co; (c) 120 Å MgO deposited on 2 Å Cu.

to Bragg peaks and therefore the above simple analysis cannot be applied.

IV. MAGNETIC CHARACTERIZATION OF MgO OVERLAYERS

In order to further study this phenomenon we have measured the influence of an insulating overlayer, MgO, on the perpendicular magnetic properties. For the noble metals Ag, Au, and Cu, for which we observe the anomalous anisotropy behavior near 1 atomic layer coverage, there is also a hybridization between the ferromagnetic metal and the overlayer electronic states.[9] In the case of an insulating MgO overlayer this electronic interaction between the ferromagnetic material and overlayer is extremely weak.[10] Therefore, one would not expect significant changes in anisotropy upon insulator coverage.

The deposition of the MgO was carried out by *e*-beam evaporation. RBS analysis of the MgO film showed a 1:1 stoichiometric ratio of Mg to O, in agreement with previously reported results from *e*-beam-evaporated MgO.[11] We have also carried out Auger electron spectroscopy on the samples immediately after deposition. The Auger spectra of the deposited MgO film agree with those in the literature.[12] Thus, we do not expect any oxidation of the metal surface due to dissociation of MgO.

Figure 3 shows polar Kerr ellipticity loops of 18 Å Co deposited on a thick Au(111) buffer layer, 2 Å Cu deposited on the bare Co, and ~120 Å MgO deposited on top of the Cu. The initial magnetic moment of the bare Co is in plane. As we previously reported, upon coverage with just 2 Å of Cu we see a large increase in the perpendicular anisotropy. Interestingly, after depositing a MgO cap of ~120 Å thickness we observe a decrease in the perpendicular anisotropy. The MgO shows polycrystalline growth as evidenced by the disappearance of the Cu RHEED streak pattern. In a different experiment we started with a perpendicularly magnetized 4 Å Co film with a coercive field of $H_c \approx 470$ Oe; subsequent deposition of ~30 Å polycrystalline MgO reduces the coercive field to $H_c \approx 70$ Oe with no change in the magnitude of the measured ellipticity.

It is surprising to find such a large change in anisotropy since the electronic interaction between the metals and MgO should be very weak. It is possible that the MgO overlayer induces strain in the Co. Unfortunately, because MgO grows polycrystalline in this case we are unable to use *in situ* structural characterization techniques to investigate changes due to MgO coverage. Work is in progress to investigate other insulating materials.

V. SUMMARY

We have used RHEED and LEED to investigate structural influences on the perpendicular anisotropy of Co(111) ultrathin films upon coverage with the noble metals Ag, Au, and Cu. Neither RHEED nor LEED show evidence for abrupt changes in surface and out-of-plane lattice spacings for Au and Cu, respectively. We have also investigated the effect of an insulating overlayer (MgO) on the magnetic anisotropy with *in situ* polar Kerr-effect measurements and observe a reduction in the perpendicular anisotropy.

Using *in situ* polar magneto-optical Kerr-effect measurements, the variation of the Kerr rotation and magnetic anisotropy of a (0001)Co ultrathin film on a (111)Au substrate has been precisely recorded, during the first stages of the growth of an overlayer of metal M=Au, Cu, and Pd. As reported earlier, a drastic increase of the magnetic anisotropy was observed, with a peak around 1 monolayer of overlayer thickness. From a careful study of the variation of the remanent Kerr rotation, it could be shown that only the interface contribution to the anisotropy changes with the overlayer thickness, while the bulk contribution remains mostly constant. The overall behavior can be interpreted in terms of electronic effects in the metal overlayer, acting on the interface anisotropy via band hybridization at the interface.

Considerable work has been devoted in the last few years to the study of the magnetic anisotropy in ferromagnetic ultrathin films.[1] Besides the magnetocrystalline interface anisotropy introduced by Néel,[2] strain-induced magnetoelastic anisotropy[3] or spin polarization of the interface layer in the nonmagnetic substrate[4] have been proposed to explain the observed behaviors of anisotropy versus the ferromagnetic film thickness, or for different nonmagnetic metal substrates. A new powerful way to investigate the origin of the magnetic anisotropy in ultrathin films is to measure its development *in situ*, during the first stages of the growth of an interface between the film and a metallic overlayer. It has been reported recently[5–7] that the coercivity and the perpendicular anisotropy of Co ultrathin films on Pd(111) and Au(111) substrates exhibit drastic increase with only submonolayer coverage by Cu, Ag, Au, and Pd, while a clear peak is observed around one atomic layer (AL) of overlayer thickness; however, owing to the complexity of *in situ* experiments, only total anisotropy for one Co thickness could be measured.[7,8] We have proposed[6] an original method, based on the analysis of the evolution versus the Co film thickness t_{Co} of the polar magneto-optical Kerr (PMOKE) rotation at remanence. We report here a detailed application of this method to the case of a (0001)Co film on a (111)Au substrate, upon coverage by a metal M=Au, Cu, or Pd.

Details of our sample preparation method have been published previously.[6,9] To achieve maximum precision and reliability in our study of the magnetic properties versus films thicknesses, we grow stepped-wedge samples using a moving shutter between sample and evaporation sources. For each sample, ten 1-mm-wide steps are made, with increasing Co thicknesses. Then the M overlayer is grown in successive thin (0.5–1 AL) layers, and after completion of each new layer, comprehensive PMOKE and reflection high energy electron diffraction (RHEED) scans are performed by moving the sample in front of a fixed e^- or laser beam.

As we reported earlier, a smoothing of the free surface with 1–2 ML of Au coverage is observed by RHEED.[6] This is a major phenomenon, which involves an important reorganization of the Co layer to rub out at least short-range roughness. It may be attributed to a surfactant effect of Au: Indeed, the surface energy of (111)Au is lower than the (0001)Co one. This behavior is not observed for Cu and Pd coverage.

Our PMOKE configuration, in which both magnetic field and laser beam are perpendicular to the sample, allows direct determination of the anisotropy coefficients only for films magnetized in plane, and provided that sufficiently high fields can be applied to saturate the magnetization of the sample. In the present study, this would restrict the determination to only a few selected values of t_{Co}.[7,8] To get an evaluation of the variation of the anisotropy coefficients for any t_{Co} and t_M combination we have proposed[6] an original method that uses the fact that, for hcp Co thin films, the two first anisotropy coefficients K_1 and K_2 have comparable magnitude (with $K_2>0$), and the change in easy axis from perpendicular to in plane with t_{Co} occurs via an intermediate state where the easy direction lies on a cone of half-angle γ. Provided the sample remains in a single-domain state, which is likely at least for low to intermediate values of γ, the ratio of the remanent to saturated Kerr rotations θ_R/θ_S, in this intermediate state, should be equal to $\cos(\gamma)$, given by

$$\cos(\gamma)=[(-2\pi M_S^2+K_1+2K_2)/2K_2]^{1/2}. \quad (1)$$

Here, M_S is the saturation magnetization, which in the following we shall assume constant and equal to the bulk value.

Assuming that K_2 does not change much with t_{Co} (this assumption is confirmed *a posteriori* at the end of this article), a good characterization of the dependence of K_1 vs t_{Co} is given by the crossover thickness t^* at which $\theta=45°$. By introducing for K_1 the usual expressions with interface anisotropies K_{S1} and K_{S2}, respectively, for the first (Co/Au) and second (vacuum/Co or M/Co) interfaces, and a volume contribution K_v, one obtains the expression

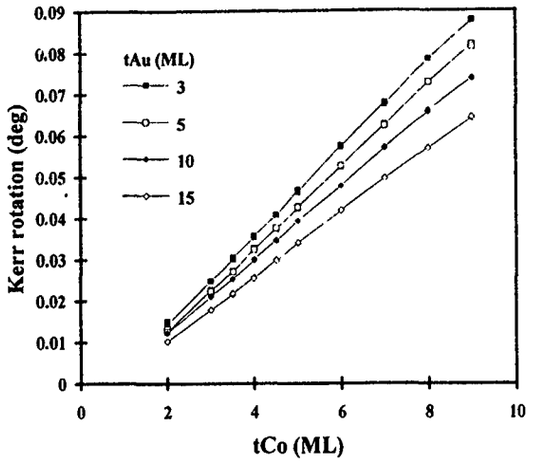

FIG. 1. Saturation polar Kerr rotations measured on a Au/Co/Au(111) sandwich vs the Co thickness t_{Co} for different values of the overlayer thickness t_{Au}.

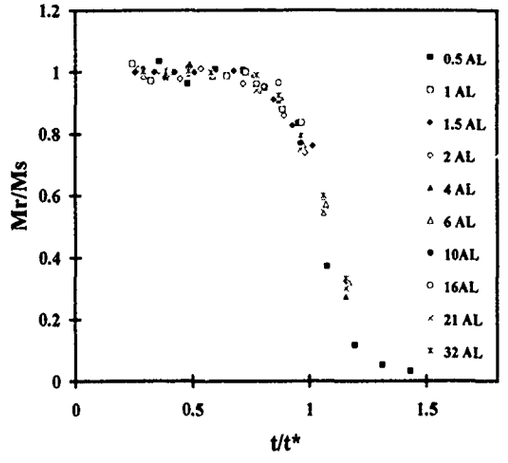

FIG. 2. Normalized remanent Kerr rotation vs normalized Co thickness, measured on a Au/Co/Au(111) sandwich for different values of the Au overlayer thickness (see legend inside the figure).

$$K_{S1}+K_{S2}=t^*(2\pi M_s^2-K_v-K_2). \quad (2)$$

Furthermore, if both volume contributions K_v and K_2 do not depend on the overlayer thickness t_M, one can easily see by combining Eqs. (1) and (2) that, for a given metal M, the θ_R/θ_S vs t_{Co} dependencies for any t_M values should superimpose on the same θ_R/θ_S vs (t/t^*) scaling curve.

Examples of hysteresis loops measured *in situ* at different stages of the interface growth have been given earlier.[6] For t_{Co} values above 7 AL (4 AL for Cu coverage), where the loops are not perfectly square, the maximum magnetic field in our setup is too low to allow direct determination of θ_S. For lower t_{Co} values the measured θ_S values vary linearly with t_{Co}, as can be seen for Au coverage in Fig. 1. To evaluate θ_S for any Co thickness, we thus extrapolate this linear variation to higher t_{Co} values. By high-field (20 kOe) measurements in air on samples with a thick coverage, we checked that this extrapolation is valid at least up to 15 AL of Co. An important effect seen in Fig. 1 is the occurrence of a nonzero intersect with the t_{Co} axis, in agreement with Ref. 10. This can be attributed to an interface effect. A more detailed study will be published elsewhere.[11]

Figures 2 and 3 display the variation of θ_R/θ_S vs t/t^*, respectively, for Au and Pd coverages. In both cases, within experimental precision all points appear well on the same scaling curve. This good agreement with scaling hypothesis confirms that K_2 is rather constant and does not change much with t_{Co}. A similar behavior is obtained for Cu coverage. Those curves appear actually more rounded than the ones calculated for perfect films.[12] This can be easily accounted for by introducing a narrow distribution of anisotropy coefficients, which could originate from nonuniform Au substrate roughness, or from inhomogeneous densities of stacking faults or strains.

As stated above, this scaling behavior allows us to assume confidently that measurement of t^* versus overlayer thickness characterizes precisely the variation of the interface anisotropy $K_{S1}+K_{S2}$ vs t_M. The variation of t^* vs t_M for M=Cu, Au, and Pd is given in Fig. 4. We observe a very fast increase in t^* at the very beginning of the overlayer growth. For Cu and Au, a narrow peak appears around $t_{Cu}=1.0$ AL (respectively, $t_{Au}=1.5$ AL), followed by a subsequent decrease of t^* toward saturation. A smoother increase of t^* is observed with M=Pd, as in Ref. 8. In agreement with previous reports,[5–8] the coercivity of perpendicularly magnetized Co films ($t_{Co}<t^*$) displays a dependence versus t_M very similar to that of t^*. Note also that the value of t^* that we measure on uncovered Co film ($t^*=4.3$ ML) is in very good agreement with that reported previously.[12]

Not much can be said at this point on the evaluation of absolute values of $K_{S1}+K_{S2}$, which would require knowledge of K_v and K_2 for each overlayer metal M. One can, however, observe that the scaling curves of Figs. 2 and 3 are very similar, which leads one to expect similar values for K_v and K_2 for M=Au and Pd. It is difficult to conclude for M=Cu, as a much smaller perpendicular anisotropy results

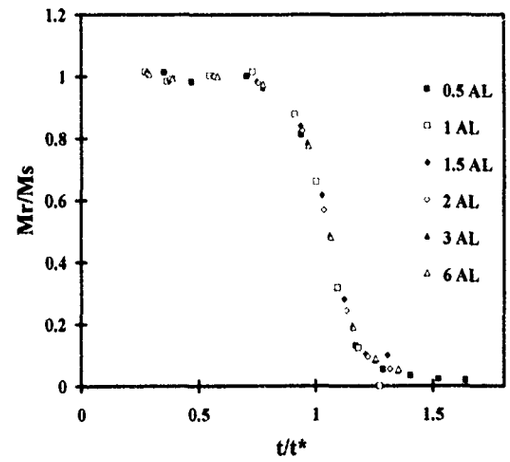

FIG. 3. Normalized remanent Kerr rotation vs normalized Co thickness measured on a Pd/Co/Au(111) sandwich for different values of the Pd overlayer thickness (see legend inside the figure).

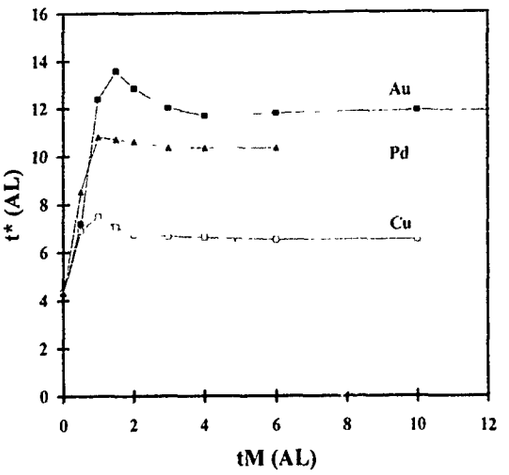

FIG. 4. Variation vs M overlayer thickness t_M of the Co thickness t^* where the remanent Kerr rotation is equal to $1/\sqrt{2}$ times the saturation Kerr rotation, for M=Au, Cu, and Pd.

in a narrow observation range, and thus in less precise evaluations. Nevertheless to get comparative values of interface anisotropies for all coverages, we have assumed one set of volume coefficients K_v and K_2, measured on similar Au/Co/Au samples,[13] and made the assumptions that: (i) in the Au/Co/Au sandwich both interfaces have the same K_S; (ii) the first (Co/Au) interface keeps the same K_S for any coverage. This last assumption in particular corresponds to the intuitive feeling that, after deposition of several atomic layers of Co, deposition of a thin overlayer should not change much the first interface. The obtained values of K_S are given in Table I. Note that the interface anisotropies for thick coverages are in good agreement with previously reported ones.[1] One interesting result is the negative (in-plane) interface anisotropy of the vacuum/Co interface, in agreement with theoretical predictions.[14]

The most interesting behavior remains the peaked dependence of the anisotropy versus t_M. We have shown here, for the first time, that the changes occur in the "interface" contribution. In principle, strain-induced anisotropy (MEA) can give a pseudo-surface term,[3] which, as observed here, should be higher for Au and Pd coverage, those metals having a large lattice mismatch with Co. This MEA is unlikely to be the dominant contribution here, as it could explain neither the negative sign of K_S for the vacuum/Co interface, nor the peak, nor even the amplitude of the change in K_S for Au and Pd coverage. Also, a t_M-dependent relaxation of the distance between subinterface and interface atomic planes in Co could contribute. However, the most likely origin of the behavior reported here is an evolution with t_M of the electronic band structure of the metallic overlayer, acting on the interface anisotropy through band hybridization with the Co. Indeed, very important changes have been observed by photoemission on electronic structures of ultrathin layers of Cu on Co(0001),[15,16] or Au. Moreover, in both cases the t_M dependence of the band structure bears striking similarities with the behavior displayed in Fig. 4 here, with, for instance, the existence of specific two-dimensional (2D) electronic structures for 1–1.5 AL coverage that relax very rapidly toward the bulk structure with further deposition of less than 1 AL. The existence of such 2D structures requires abrupt and flat interfaces. In this scheme, the more rounded behavior observed here for Pd coverage could be attributed to some alloying at the interface, as we have evidenced earlier on similar samples.

Finally, we cannot rule out the occurrence of a small spin polarization in the Au or Cu monolayer on Co, as observed recently at the Co/Cu interface.[17]

This research has been sponsored by a HCM-EEC program.

TABLE I. Interface anisotropy coefficients evaluated from the measured t^* displayed in Fig. 4. We assumed one set of volume anisotropy constants for all overlayer metals, measured on similar Au/Co/Au sandwiches (Ref. 13): $K_v=5.8\times10^6$ erg/cm^3 and $K_2=1\times10^6$ erg/cm^3. The peak values have been estimated for respective thicknesses 1.5, 1, and 1 AL of Au, Cu, and Pd overlayers.

	K_S	
Interface	Peak value (erg/cm^2)	Thick overlayer (erg/cm^2)
Vacuum/Co		−0.17
Au/Co	0.83	0.58
Cu/Co	0.17	0.06
Pd/Co	0.53	0.48

The contrasting effects of ion implantation and thermal annealing on structural and magnetic properties of Co/Pd multilayers have been studied. Ion implantation causes local damage to the multilayers, resulting in enhanced magnetization due to the polarization of the neighboring Pd. Thermal annealing generates massive interdiffusion across the interfaces into the formation of Co-Pd alloys with a lower magnetization. Effects on coercivity and remanence have also been studied.

Magnetic multilayers have been the subject of numerous studies[1,2] owing to their unusual properties and potential applications. Novel properties such as enhanced magnetization, large (sometimes perpendicular) magnetic anisotropy, tailored spin structures, and giant magnetotransport properties, have been uncovered. Among the multilayers, Co/Pd has been extensively studied in recent years,[3,4] stimulated by both fundamental interests and technological applications. For constituent layers with very small thicknesses, the perpendicular anisotropy together with substantial Kerr effect have led to the application of Co/Pd multilayers in magneto-optical recording media.[5]

While the novel properties of multilayers are intimately related to the high degree of structural coherency of the layered structure, a complete understanding of the relationship between interfacial characteristics and physical properties remains lacking. In this work we have systematically altered the interfacial characteristics of Co/Pd multilayers using ion implantation and thermal annealing, and studied the resultant structural and magnetic properties. Our studies show that these two methods give rise to very different effects on the multilayer structure.

The Co/Pd multilayer samples have been deposited onto glass substrates using two electron-beam-deposition sources in a vacuum of 1×10^{-8} mbar. The samples are denoted as $[\text{Co}(x\ \text{Å})/\text{Pd}(y\ \text{Å})]_n$, where x and y are the Co and Pd layer thicknesses, respectively, and n is the number of repeats of the Co/Pd bilayers. One set of samples with $[\text{Co}(10\ \text{Å})/\text{Pd}(59\ \text{Å})]_{18}$ has been subjected to 230 keV of Ar^+ implantation at room temperature at a low current density of 50 nA/cm^2 to avoid sample heating. Low fluences of 1×10^{13}–5×10^{14} ions/cm^2, which are small compared with 1 monolayer of ions (1×10^{15} ions/cm^2), have been used. Another set of samples of $[\text{Co}(14\ \text{Å})/\text{Pd}(44\ \text{Å})]_{18}$ have been thermally annealed for 30 min in a helium atmosphere at various temperatures up to 700 K. Structural characteristics of all the samples have been made by a θ-2θ x-ray diffractometer with Cu$K\alpha$ radiation. Magnetic properties have been measured using a vibrating sample magnetometer (VSM) with the magnetic field parallel to the film plane.

Figure 1 shows the x-ray-diffraction data of the as-prepared and the ion-implanted $[\text{Co}(10\ \text{Å})/\text{Pd}(59\ \text{Å})]_{18}$ samples. The as-prepared sample [Fig. 1(a)] shows several satellite peaks near the Pd(111) peak. Because Co layers are thin and have a much lower scattering factor, no substantial diffraction peaks near the Co(111) peak are revealed nor expected. It is well known that the intensity of the satellite peaks is dictated by the layer profile and the repeatability of the bilayers. The structural coherence of the multilayers is manifested by the width of the diffraction peaks. From the width of the main diffraction peak, beyond the instrumental width, the structural coherence length L has been determined to be about 270 Å, which is about four bilayers. These results show that the as-prepared sample has a well-defined layer structure with [111] crystalline orientation.

Figures 1(b)–1(e) show the diffraction data for ion-implanted samples of $[\text{Co}(10\ \text{Å})/\text{Pd}(59\ \text{Å})]_{18}$ with Ar fluence varying from 5×10^{13} to 7.5×10^{14} ions/cm^2. Several features are noted for samples within this fluence range. For increasing fluence, the satellite peaks decrease progressively in intensity but remain observable in all cases. More important, the width of the main diffraction stays essentially the same as that of the as-prepared sample. These results indicate that layer structure and the structural coherence length L remain intact, but the layer profile becomes more diffuse as a result of ion implantation.

A contrasting situation occurs when the Co/Pd multilay-

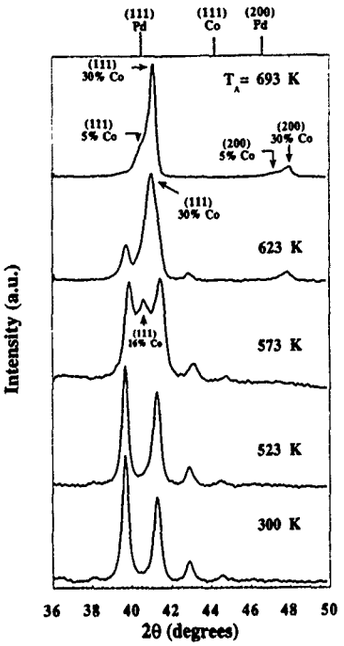

FIG. 2. X-ray spectra of samples annealed at different temperatures T_A. The peak positions corresponding to bulk Co and Pd are shown at the top. Alloys with different compositions have also been indexed.

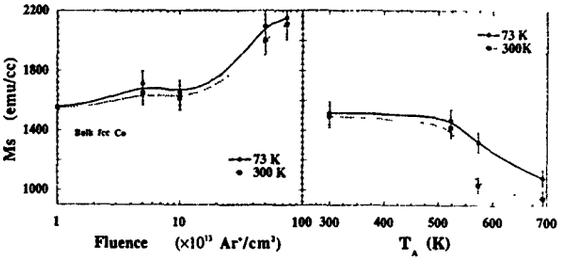

FIG. 3. Saturation magnetization in unit of emu/cm^3 of Co at 300 K (dotted curves) and 73 K (solid curves) as functions of fluences (left-hand side) and annealing temperatures (right-hand side).

ers have been thermally annealed at various annealing temperatures T_A. The x-ray-diffraction data of the as-prepared (T_A=300 K) and representative data of the annealed samples (T_A up to 693 K) of [Co(14 Å)/Pd(44 Å)]$_{18}$ are shown in Fig. 2. Discernible change of the diffraction are observed for $T_A \geq 523$ K; most notably a diminution of the satellite peak intensity and the appearance of additional diffraction peaks. It is useful to recall that Co and Pd form fcc Co-Pd alloys over the entire composition range. The lattice parameter of the alloy decreases monotonically from that of pure Co to that of pure Pd. At the top of Fig. 2 the locations of the diffraction peaks of Co(111) and Pd(111) are shown, and the (111) peak of a Co-Pd alloy falls between those of Co(111) and Pd(111) according to the composition. At T_A=573 K, in addition to the satellite peaks, a new peak, corresponding to $Co_{16}Pd_{84}$, appears. At T_A=623 K both the (111) and (200) peaks of $Co_{30}Pd_{70}$, in addition to the remanence of the satellite peaks, are observed. Finally, at T_A=693 K, only (111) and (200) peaks corresponding to predominantly $Co_{30}Pd_{70}$ and a small portion of Co_5Pd_{95} are observed. There are no satellite peaks remaining, and the layer structure has been completely destroyed. It may be noted that, if the Co and Pd atoms in [Co(14 Å)/Pd(44 Å)]$_{18}$ were mixed completely and uniformly, one would have obtained an alloy of $Co_{30}Pd_{70}$, which is very similar to the alloy composition found.

From the above results, it is clear that both ion implantation and thermal annealing can cause deterioration of the multilayers; however, the processes with which the layer structure and the interfaces are compromised are very different in the two cases. At low fluence, ion implantation causes local damages of the layer structure, while most of the layer structure and the structural coherence of the multilayer remain intact. On the other hand, thermal annealing is far more disruptive. It promotes interdiffusion of all the constituent atoms at the interfaces, very efficiently destroying the multilayers even at moderate annealing temperatures. Furthermore, due to the interdiffusion, the multilayer rapidly converges to the terminal and homogeneous alloy composition.

These conclusions made from structural studies are corroborated by the magnetic properties. It is useful first to recall the magnetic properties of Co_xPd_{100-x} alloys of which the magnetic ordering temperature T_C increases rapidly and monotonically with Co content. The values of T_C are less than 300 K for the alloys with low Co content ($x<10$).[6] The magnetic moment per atom of Co-Pd alloys also rises monotonically with Co content. However, because of the strong polarization effect on the Pd atoms by the nearby Co atoms (also known as the giant moments), these polarized Pd atoms contribute significantly to the magnetization.

The saturation magnetization M_s of the Co/Pd multilayers after ion implantation and thermal annealing are shown in Fig. 3. First of all, the as-prepared samples have a higher M_s than that of bulk fcc Co, owing to the well-known polarization effect of Pd. The enhanced magnetization has also been observed in other Co/Pd and Fe/Pd (Ref. 7) multilayers. Most remarkably, after ion implantation, there is further enhancement of M_s, and M_s has a weak temperature dependence; the values at 77 and 300 K are similar. This indicates that, as the interfaces are systematically disrupted by ion implantation, more Pd atoms are exposed and polarized by the displaced Co, hence a larger M_s. Furthermore, most of the magnetic species remain strongly coupled to share a high value of T_C. Quite the contrary, the thermally annealed samples show a decrease in M_s and a stronger temperature dependence in M_s. Both of these observations, which are consistent with another group's results,[8] are the results of the formation of Co-Pd alloys with relatively low Co contents, hence lower values of T_C.

In Fig. 4, the magnetic coercivity H_c for the implanted [Fig. 4(a)] and the annealed [Fig. 4(b)] samples are shown. We discuss the annealed samples first. Changes in H_c occur when the formation of the Co-Pd alloy appears at $T_A \geq 523$ K. Higher values of T_A result in large values of H_c, and H_c shows similar behaviors at the three temperatures (77, 150, and 300 K) measured. For the ion-implanted samples, H_c for the ion-implanted samples with higher fluences ($\geq 5\times10^{14}$

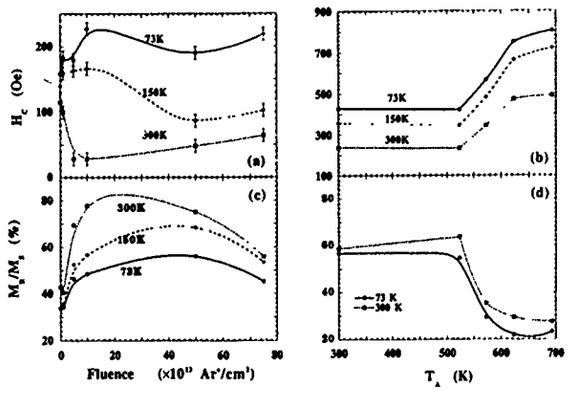

FIG. 4. In-plane coercivity H_c and squareness M_r/M_s at different temperatures as functions of fluences (left-hand side) and annealing temperatures (right-hand side).

ions/cm^2) has similar temperature dependencies as the annealed samples. The results for the low fluences are, however, more complex. In particular, the results of the implanted samples with fluences less than 1×10^{14} ions/cm^2 suggest the possibility of a phase(s) with low ordering temperature (<300 K). The precise nature of these possible phases, albeit of low sample content, has not been ascertained.

Finally, we turn to remanent magnetization M_r expressed as the squareness M_r/M_s shown in Figs. 4(c) and 4(d). After ion implantation with low fluence, the squareness becomes larger, suggesting an increase in the in-plane anisotropy. At high fluence, the squareness decreases due to the presence of Co-Pd alloy phases. In the annealed samples, the predominant evolution of the multilayer is toward the formation of Co-Pd alloys, which generally give rise to lower squareness.

In conclusion, we have observed via structural and magnetic properties the very different effects on the Co-Pd multilayer due to ion implantation and thermal annealing. Ion implantation causes local damage to the interfaces while maintaining the layer structure, whereas thermal annealing promotes massive interdiffusion toward the formation of Co-Pd alloys. Consequently, contrasting behaviors in saturation magnetization and other magnetic properties have been observed.

Sputtering pressure effects and temperature-dependent magnetism of Co/Pd multilayers

S. Y. Jeong,[a] Z. S. Shan, P. He, J. X. Shen, Y. B. Zhang, J. A. Woollam, and D. J. Sellmyer

Behlen Laboratory of Physics and Center for Materials Research and Analysis, University of Nebraska, Lincoln, Nebraska 68588-0113

The temperature dependence of the sputtering Ar pressure effects on magnetic properties and the coercivity mechanism of Co(2 Å)/Pd(13 Å) multilayers were studied as the sputtering Ar pressure varied from 3–15 mTorr and the temperature from 300 to 35 K. It is found that the roughness of the interfaces or film surface increases with increasing sputtering pressure, the anisotropy increases with decreasing temperature and increasing Ar pressure and shows a maximum at $P_{Ar}\approx 12$ mTorr, and the coercivity increases with Ar pressure and shows stronger temperature dependence at higher Ar pressure. The coercivity mechanism was analyzed in terms of the coercivity predicted by Kronmüller's theory [Phys. Status Solidi B **144**, 385 (1987)]. Wall pinning is found to be the main mechanism and the size of the pinning site increases slightly as the Ar pressure increases.

I. INTRODUCTION

Co/Pd multilayers have been studied intensively in the last decade for pure and applied reasons.[1–3] For the Co/Pd multilayers with nanoscale Co layer, the interfacial magnetism, which is strongly influenced by the preparation conditions, plays a crucial role in determining the magnetic behavior. Hashimoto *et al.*,[4] de Haan *et al.*,[5] Shin *et al.*,[6] and He *et al.*[7] have reported the Ar pressure effects on magnetic properties at room temperature. It is found that the coercivity increases with increasing Ar pressure P_{Ar} during deposition and the anisotropy increases monotonically with increasing P_{Ar} (up to $P_{Ar}\approx 56$ mTorr),[5] or shows a maximum at $P_{Ar}=10$ mTorr.[4,6]

In this article the temperature dependence of the sputtering pressure effects on magnetism was studied as the temperature varied from 300 to 35 K. The coercivity mechanism was investigated in terms of the initial magnetization curves and minor loops at different temperatures, and comparisons were made to Kronmüller's model.[8]

II. EXPERIMENT

[Co(2 Å)/Pd(13 Å)]×35 (35 is the number of bilayers) multilayers were deposited onto glass substrates by dc magnetron sputtering under pressure $P_{Ar}=3$, 6, 9, 12, and 15 mTorr. All five samples were fabricated in one vacuum run to insure identical preparation conditions except for the Ar pressure.

The structure properties were characterized with the x-ray diffraction and atomic force microscopy (AFM) and the magnetic properties were measured by an alternating gradient force magnetometer (AGFM) with the temperature changed from 300 to 35 K. The coercivity $H_c(T)$ and magnetization $M(T)$ data were obtained from the perpendicular hysteresis loops and the measured anisotropy $K_u'(T)$ data were determined from the area between the parallel and perpendicular magnetization curves.

III. RESULTS AND DISCUSSIONS

A. Structure properties

Figure 1 shows the small-angle x-ray-diffraction patterns. It is seen clearly that the amplitude of the diffraction peaks decreases with increasing sputtering Ar pressure and when the sputtering pressure is greater than 9 mTorr, the diffraction peaks become obscure. This is attributed to the roughness of the interfaces which increases as the sputtering pressure increases since the sputtered Co and Pd atoms experienced more collisions with Ar atoms and form larger clusters at the growing film surface.

Figure 2 shows the AFM pictures of samples sputtered at (a) $P_{Ar}=3$ mTorr and (b) 15 mTorr and it is found that the surface roughness in Fig. 2(b) is much larger than that in Fig. 2(a). If the surface roughness may be regarded as the accumulation of the roughness of all individual layers or interfaces, Fig. 2 indicates clearly that the interfaces have larger roughness when sputtered in the higher Ar pressure, which is consistent with the result in Fig. 1.

B. Temperature character of pressure effects on magnetic properties

The Ar pressure dependence of the anisotropy K_u ($K_u = K_u' + 2\pi M_s^2$) as the temperature varied from 300 to 35 K is demonstrated in Fig. 3. It is seen that K_u increases as the temperature decreases. As the pressure increases K_u first increases, then decreases and shows a small peak at $P_{Ar}=12$ mT for all temperatures. This behavior is qualitatively consistent with earlier work[4,6] except that our peaks are rather small; K_u shows larger Ar pressure dependence at lower temperature. The origin of such K_u behavior is attributed to the interfacial magnetism which strongly depends on the polarization of Pd atoms at the interfaces[9,10] and the morphology of interfaces. As the temperature decreases the induced Pd moment increases which enhances the K_u. Hashimoto and co-workers[4] have explained qualitatively the behavior of Ar pressure dependence of K_u in terms of the stress-induced anisotropy because the stress in the film changes from compressive to tensile as the Ar pressure increases. Recently Vic-

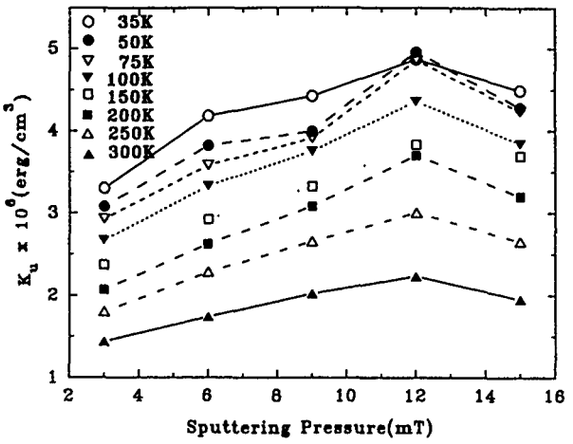

FIG. 3. Sputtering Ar pressure dependence of measured anisotropy K_u' at different temperatures.

tora and MacLaren[11] employed the symmetry-derived model based on summing $L(\mathbf{M}\cdot\mathbf{R})^2$ pair interactions (where $\mathbf{M}$ is the magnetization direction, $\mathbf{R}$ is the vector connecting the two atoms, and L is an interaction parameter) to calculate anisotropy for Co/Pd and Co/Pt multilayers. We intend to use this approach to calculate the K_u behavior quantitatively.

The sputtering pressure dependence of coercivity H_c as the temperature varied from 300 to 35 K is shown in Fig. 4(a). The coercivity increases monotonically with increasing P_{Ar} and shows stronger P_{Ar} dependence at the lower temperature. This behavior cannot be attributed fully to the change of K_u as shown in Fig. 3. In order to understand such behavior properly, we also need to consider the pinning effect of the domain-wall motion which is discussed in more detail in the following section.

The temperature dependence of H_c is shown in Fig. 4(b): H_c increases as the temperature decreases and shows stronger temperature dependence at higher P_{Ar}. The physical origins of this feature are discussed below.

C. Coercivity mechanism

In order to study the coercivity mechanism the initial curves and minor loops were measured at room and low temperature. All these curves show the typical domain-wall pinning feature: The magnetization is small at low applied field H_a and increases rapidly while H_a reaches a threshold value H_{th} which corresponds to the field required to exceed the pinning barrier. As the temperature decreases the thresh-

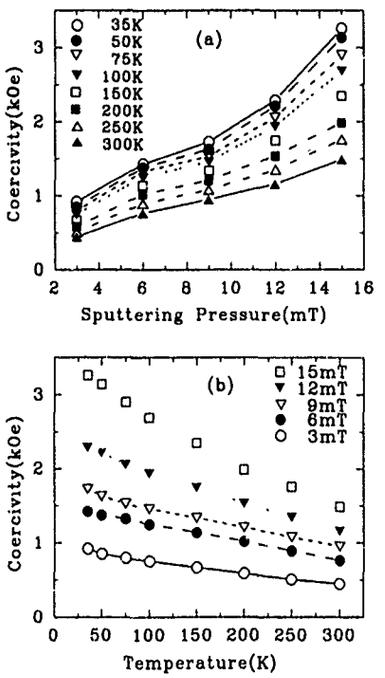

FIG. 4. (a) Sputtering Ar pressure dependence of coercivity at different temperature and (b) temperature dependence of coercivity at different sputtering Ar pressure

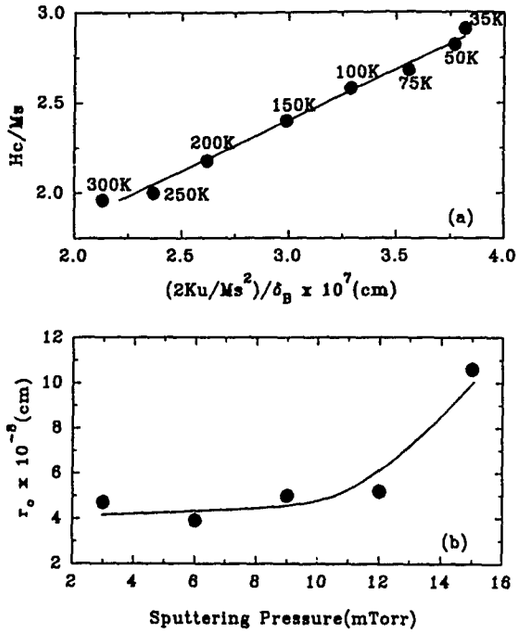

FIG. 5. (a) A linear fitting to the experimental data after Eq. (1) and the r_0 obtained is 4.7 Å. (b) The sputtering Ar pressure dependence of the estimated size of the pinning site.

old field H_{th} increases because of the decreasing thermal activation energy as predicted by Kirby *et al.*[12]

Kronmüller's formulas[8] were used to analyze the coercivity mechanism in more detail. If wall pinning is the dominant mechanism, the coercivity $H_c(T)$ is given by

$$H_c(T)=\kappa(r_0/\delta_B)(2K_u/M_s)-N_{\text{eff}}M_s \quad \text{for} \quad r_0 \ll \delta_B \qquad (1)$$

and

$$H_c(T)=\kappa'(\delta_B/r_0)(2K_u/M_s)-N_{\text{eff}}M_s \quad \text{for} \quad r_0 \gg \delta_B, \qquad (2)$$

where κ and κ' are both related to the exchange coupling constants and the anisotropy constants, r_0 is the size of the pinning site, and N_{eff} is a demagnetization factor. The wall width δ_B is given by $\pi(A/K)^{1/2}$, where A and K are exchange constant and anisotropy,[13] respectively.

Figure 5 is an example of the fitting curve based on Eq. (1) for the sample prepared at 3 mTorr Ar pressure. Similar fittings for all samples (P_{Ar}=6, 9, 12, and 15 mTorr) have been performed. The fact that the $[H_c/M_s, (2K_u/M_s^2)/\delta_B]$ experimental points measured at different temperatures are on a straight line implies that the domain-wall pinning is the dominant mechanism.

From the fits we could estimate the size of the pinning sites for each sample. The estimated sizes are 4.7, 3.9, 5.0, 5.2, and 10.6 Å for the samples prepared at P_{Ar}=3, 6, 9, 12, and 15 mTorr, respectively [see Fig. 5(b)]. The estimated values show that the size of the pinning site increases with increasing sputtering pressure. Equation (1) also tells us that $H_c(T)$ depends on the r_0K_u product. Although K_u decreases with increasing P_{Ar} for P_{Ar}>12 mTorr (as shown in Fig. 3), H_c still increases with increasing P_{Ar} for P_{Ar}>12 mTorr [as shown in Fig. 4(a)] because r_0 increases, and we have pointed out this feature earlier.

IV. CONCLUSIONS

The variation of the anisotropy and coercivity as a function of temperatures is closely related to the polarization of the Pd atoms at the interfaces and the film morphology which was controlled by the sputtering Ar pressure. The dominant mechanism for the coercivity is the wall pinning and the size of the pinning sites increase with increasing the sputtering pressure.

Magnetoelastic effect in Co/Pd multilayer films

Young-Suk Kim and Sung-Chul Shin
Department of Physics, Korea Advanced Institute of Science and Technology, Kusung-Dong, Yusung-Gu, Taejon 305-701, Korea

In situ measurements of the stress are reported, and the magnetoelastic contribution to the magnetic anisotropy is clarified, in Co/Pd multilayer films prepared by dc magnetron sputtering. The stress was varied between 2.36×10^{10} and 4.22×10^{10} dyn/cm^2 in the Co sublayer of the film with an abrupt drop of the stress in the Co sublayer thicker than about 5 Å. This abrupt change seems to be related with a structural transition of a coherent-to-incoherent matching at the interface with thickening the sublayer. The stress-induced anisotropy of the samples having perpendicular magnetic anisotropy is found to be 40%–80%, compared to Néel's surface anisotropy.

I. INTRODUCTION

Co-based multilayer films are of great interest today because of their novel properties and potential technical applications.[1,2] In particular, the perpendicular magnetic anisotropy observed in those materials has been attracting wide attention for the application of the materials to magnetic and magneto-optical recording. Co/Pd multilayer films have been reported to show the perpendicular magnetic anisotropy for the samples having a Co sublayer thinner than about 8 Å and Pd sublayer thicker than about 5 Å.[3–6] The perpendicular magnetic anisotropy in this system is generally believed to be related to the change in the magnetic anisotropy of the interfacial atoms as a consequence of the reduced symmetry in their surroundings, as Néel first suggested.[7] However, recent studies have indicated that the stress-induced magnetic anisotropy also plays a role, especially for the samples prepared by sputtering.[5] In this article, we report *in situ* measurements of the stress and clarify the magnetoelastic contribution to the magnetic anisotropy in Co/Pd multilayer films.

II. EXPERIMENT

Co/Pd multilayer films were prepared by dc magnetron sputtering from 2-in.-diam Co and Pd targets on 4-cm-long, 1.1-cm-wide, and 130-μm-thick glass substrates at the Ar sputtering pressure of 10 mTorr. The distance between the substrate and the sputtering source was 12.7 cm. An edge of the substrate was fixed by a cantilever holder. The multilayer structure was achieved by alternately exposing the substrate to two sputtering sources via a reciprocating shutter. Typical deposition rates of Co and Pd were 0.53 and 0.81 Å/s, respectively.

The stress of a multilayer film was measured *in situ* during the deposition using a homemade optical displacement detection system as depicted in Fig. 1. A displacement sensor, composed of 38 optical fibers of 50 μm core diameter, was installed behind the free end of the substrate. The back side of the substrate was coated by 1000-Å-thick Al to enhance the reflectivity. A change in the gap distance between the sensor and the substrate, caused by the stress of a deposited film, was detected by measuring a corresponding change in the reflectivity from the back side of the substrate. The sensitivity of the displacement sensor used in this study was 0.059 V/μm and it turned out to be good enough to detect the stress caused by a deposition of a monatomic layer of Co or Pd. The multilayer structure was examined by low- and high-angle x-ray diffractometry. The magnetization was measured by a vibrating sample magnetometer (VSM) and the magnetic anisotropy was measured using a torque magnetometer at an applied field of 10 kOe.

III. RESULTS AND DISCUSSION

All samples in this study developed low-angle x-ray-diffraction peaks irrespective of the sublayer thickness, which suggests the existence of the multilayer structure in those samples. High-angle x-ray diffraction studies revealed that the samples were polycrystalline grown along the [111] cubic orientation.

Figure 2 shows a typical results of *in situ* measurement of the gap distance between the substrate and the optical probe with the deposition time for the sample having 8-Å-thick Co sublayers and 9-Å-thick Pd sublayers. The positive slope for the Co sublayer implies the existence of a tensile stress in the layer, while, the negative slope for the Pd sublayer implies a compressive stress in the layer. This result is as expected, since the d spacing of the (111) matching plane of Co is 9.9% smaller than that of Pd; however, it is inter-

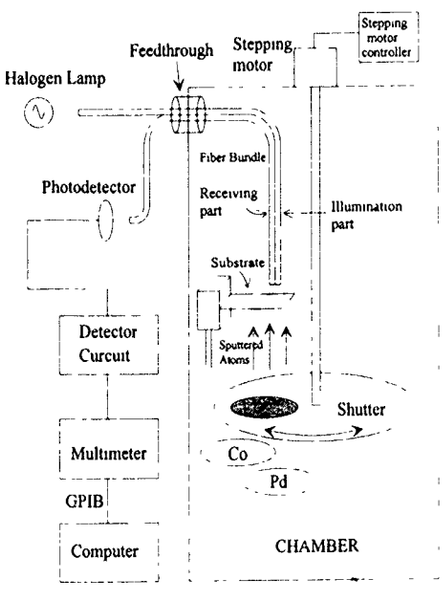

FIG. 1. Schematic configuration of an *in situ* stress measurement system.

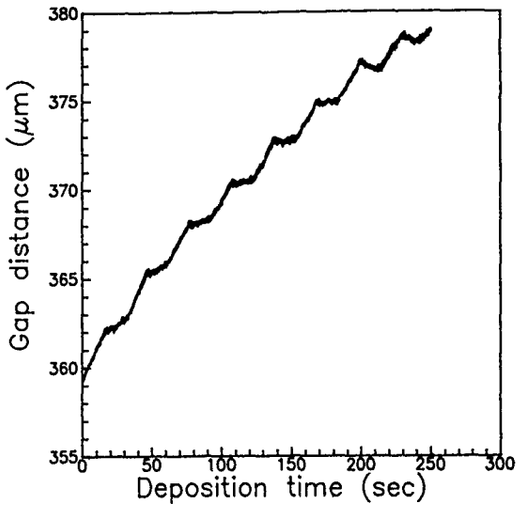

FIG. 2. A plot of the gap distance vs deposition time for the sample having 8-Å-thick Co and 9-Å-thick Pd layers.

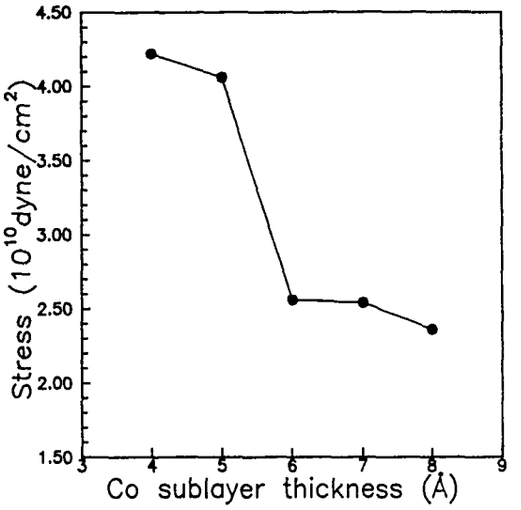

FIG. 4. A plot of the stress vs the Co sublayer thickness for a series of the samples having a constant Pd sublayer thickness of 9 Å.

esting to note that the slopes of the Co and Pd sublayers are changed with increasing sublayer thickness. To see the variation of the stress with the sublayer thickness, we calculate the stress existed in each sublayer using the well-known Stoney formula[8] as follows:

$$\sigma = \frac{E_s t_s}{3l^2(1-\nu_s)} \frac{\Delta d}{\Delta t_f}, \tag{1}$$

where E_s, ν_s, l, and t_s are Young's modulus, Poissons's ratio, and the length and thickness of a substrate, respectively, Δd is the change of the gap distance and Δt_f is the change of the film thickness. $E_s = 1.51\times10^{12}$ dyn/cm^2, $\nu_s = 0.3$, $l = 3$ cm, and $t_s = 130$ μm are used in the calculation.

Using Eq. (1) we plot the stress as a function of the sublayer of Co and Pd in Fig. 3. Since the Co sublayer was deposited first, the Co sublayers are expressed by the odd numbers and the Pd sublayers by the even numbers. The

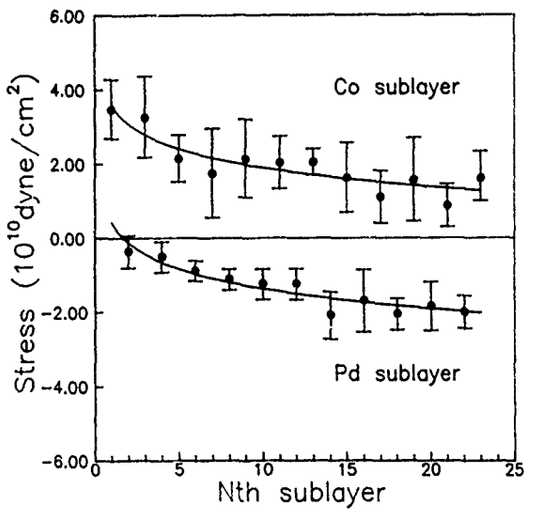

FIG. 3. A plot of the stress as a function of the Nth sublayer of Co and Pd.

error bar corresponds to the root-mean-square deviation of the mean stress of the Nth sublayer, which was obtained by taking the derivative at 100 points in each sublayer in Fig. 2. The stress in a multilayer film is mainly caused by two origins: an adhesion of the film to the substrate and the lattice mismatch between two dissimilar adjacent sublayers. The behavior of the stress with the sublayer thickness in Fig. 3 implies that an influence of the substrate yields a tensile stress with a maximum of 2.00×10^{10} dyn/cm^2 in the sublayer, possibly due to a smaller thermal-expansion coefficient of the glass substrate than the Co/Pd multilayer. This effect is monotonically decreased and seems to be negligible when the film is thicker than about 100 Å. Therefore, that a very small compressive stress observed in the first several Pd sublayers is not surprising; in this thickness range the tensile stress due to the substrate is appended to a compressive stress caused by the lattice mismatch. From Fig. 3 we note that the lattice mismatch between Co and Pd layers yields a 2.36×10^{10} dyn/cm^2 tensile stress for the Co sublayer and a 1.81×10^{10} dyn/cm^2 compressive stress for the Pd sublayer in this particular sample, which is larger than the stress of e-beam-evaporated samples.[9]

Interestingly enough, we have observed that the stress of the Co/Pd multilayer film was suddenly dropped with increasing the Co sublayer thickness. Figure 4 shows a plot of the stress versus the Co sublayer thickness for a series of the samples having a constant Pd sublayer thickness of 9 Å. A distinct drop in the stress can be seen when the Co sublayer thickness is larger than about 5 Å. Since the samples were prepared on the same glass substrates at the same sputtering conditions, the contribution other than the lattice mismatch to the stress of the film should be the same. Therefore, a sudden drop in the stress is believed to be related with a structural change from a coherent to incoherent interfacial matching between Co and Pd sublayers with increasing the Co sublayer thickness. The critical thickness for a coherency-incoherency transition observed in our sample agrees with a theoretical value of ~5 Å estimated by den

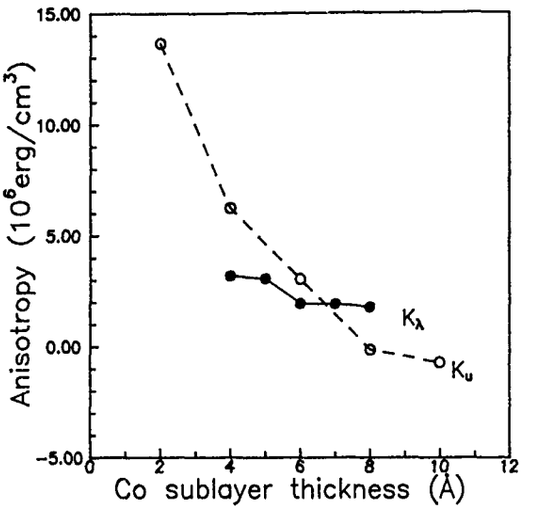

FIG. 5. A plot of the anisotropy energy K_u and the stress-induced anisotropy K_λ as a function of the Co sublayer thickness.

Broeder and co-workers.[1] The structural transition is under investigation by transmission x-ray diffractometry and will be published elsewhere.

In our system the perpendicular magnetic anisotropy exists for the samples having a Co sublayer thinner than about 8 Å as seen in Fig. 5. The anisotropy energy K_u associated with a multilayer can be described phenomenologically[4] as $K_u = 2K_s/t_{Co} + K_v$, where K_s is the interface anisotropy and K_v is the volume anisotropy. For a coherent multilayer K_s is only due to Néel's surface anisotropy and the strain-induced anisotropy is contained in K_v; however, for an incoherent case the misfit strain anisotropy may contribute to K_s.[1]

When the lattice mismatch is much larger than the magnetostriction coefficient as in Co/Pd multilayers the stress-induced magnetic anisotropy energy K_λ is given by[10]

$$K_\lambda = -\tfrac{3}{2}\lambda\sigma_{Co}, \tag{2}$$

where λ is the magnetostriction coefficient and σ_{Co} is the stress of the Co sublayer. Because of a negative λ for Co/Pd multilayers[11] the strained Co sublayer yields a positive perpendicular anisotropy energy. In Fig. 5 the stress-induced anisotropy K_λ is plotted, together with the magnetic anisotropy energy K_u. As seen in the figure, K_λ of $\sim 3.11\times10^6$ and $\sim 1.87\times10^6$ erg/cm^3 are obtained for the coherent and incoherent samples, respectively. The Néel surface anisotropy K_N in our samples, obtained from a plot of $K_u t_{Co}$ vs t_{Co} is estimated 0.16 erg/cm^2. The contribution of K_N to K_u for the samples showing perpendicular magnetic anisotropy is estimated to be between 2.7×10^6 and 8×10^6 erg/cm^3. Hence, the magnetoelastic contribution to the perpendicular magnetic anisotropy is 40%–80% in comparison with the contribution by Néel's surface anisotropy.

IV. CONCLUSIONS

We have investigated the effect of the stress on the magnetic anisotropy in Co/Pd multilayer films prepared by dc sputtering. *In situ* measurements of the stress have revealed that multilayers had a tensile stress of 2.36×10^{10}–4.22×10^{10} dyn/cm^2 in the Co sublayers. An abrupt reduction of the stress was observed when the Co sublayer thickness was larger than 5 Å, which is believed to be caused by a coherent-to-incoherent transition. It was found that for the perpendicular magnetic anisotropy of our samples, the magnetoelastic contribution due to the lattice mismatch is much comparable to the contribution by Néel's surface anisotropy.

Interface processing in multilayer films

R. J. Pollard, M. J. Wilson, and P. J. Grundy
Joule Physics Laboratory and Science Research Institute, University of Salford, Greater Manchester M5 4WT, United Kingdom

We have investigated the effect of ion modification of multilayer growth and ion etching of multilayer interfaces on perpendicular anisotropy and giant magnetoresistance in sputter deposited Co/Pt and Co/Cu multilayers. These two properties are thought to be particularly sensitive to the form of the interface profile in multilayers. We find that the ion-assisted deposition conditions used degrade both perpendicular anisotropy and GMR through interface smoothing and mixing. In contrast, thermal annealing and first experiments in ion etching show that GMR can be increased by smoothing of the Co/Cu interfaces.

INTRODUCTION

Co/Pt and Co/Cu MLs are believed to exhibit structure sensitive magnetic anisotropy[1–3] and giant magnetoresistance.[4] We have used such systems as models in preliminary investigations of the effect of ion beam-assisted sputter deposition, ion beam etching, and thermal annealing on these properties.

EXPERIMENT

The MLs were deposited in a UHV-compatible magnetron sputtering system equipped with dc magnetrons and a 3 cm Kaufman ion source. The Co, Pt, and Cu layers were deposited onto glass substrates by ion-assisted deposition, i.e., the ion beam (0–400 eV, 2 mA) on and irradiating the ML during growth, or by ion etching, i.e., with the deposition interrupted and the top surface of each Co layer irradiated with the ion beam for 10 s. The deposition rate was about 0.1 nm s^{-1}.

The magnetic hysteresis loops were measured in a VSM (Co/Cu MLs) or in a Kerr M/O loop plotter (Co/Pt MLs). Anisotropy (Co/Pt MLs) was investigated by torque magnetometry, and magnetoresistance (Co/Cu MLs) was measured by the standard four probe dc method. Some basic structural changes were inferred from x-ray diffraction measurements. All measurements were carried out at room temperature.

RESULTS AND DISCUSSION

Figure 1(a) shows the polar Kerr hysteresis loops for a series of three $15x$(0.4 nm Co/1.2 nm Pt) MLs deposited by ion-assisted growth. It can be seen that as the ion energy is increased the loops depart more and more from squareness and the coercivity of the MLs decreases. The shearing of the loops is reflected in the torque curves of Fig. 1(b), which show a gradual decrease in the torque amplitude with increasing ion energy. The negative slope at $\theta=0$ confirms the normal to the ML as the easy direction (θ is the angle between the normal to the ML and the field direction) for the 0 eV (no ion flux) and 100 eV MLs. However, for 200 eV the torque curve is clearly modified with the appearance of a change of slope near zero torque and $\theta=0$. These changes indicate that the effective perpendicular anisotropy decreases with increasing ion energy from a value of $\approx 6\times10^5$ J m^{-3} for the "unassisted" ML and that the easy direction of magnetization rotates from the normal to the ML towards the plane. A similar result has been obtained for ion beam etching of a series of $7x$(0.4 nm Co/1.2 nm Pt) MLs. Again, a decrease in torque and perpendicular anisotropy with increasing ion energy was observed.

Sputter deposited Co/Pt MLs with thicker ($\geq$0.8 nm) Co layers do not show such strong perpendicular anisotropy.[5,6] Figure 2(a) gives polar Kerr loops for a series of four 15

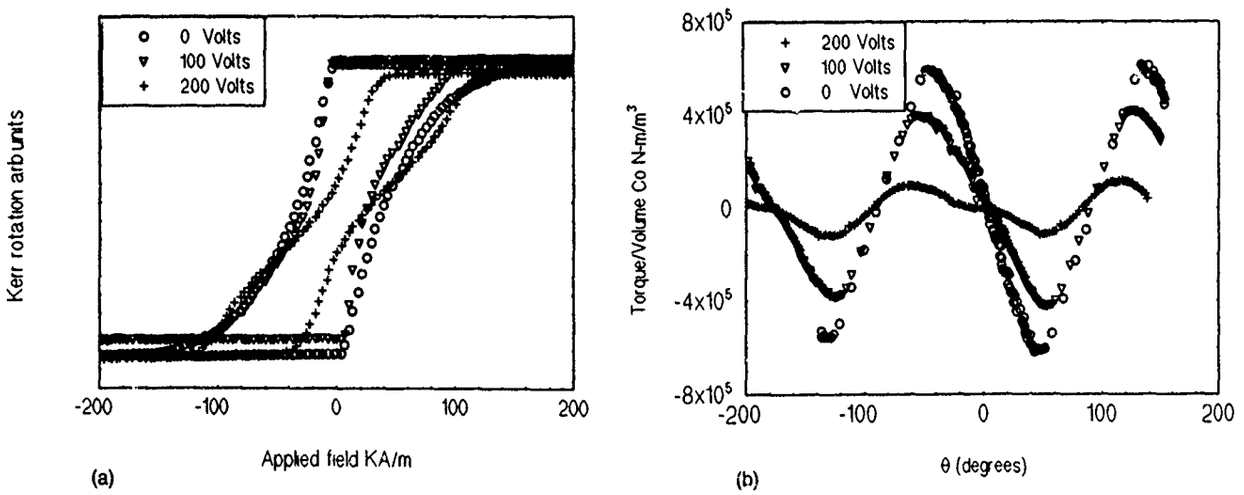

FIG. 1. Polar Kerr loops (a) and torque curves (b) for $15x$(0.4 nm Co/1.2 nm Pt) MLs for different beam energies/voltages in ion-assisted deposition.

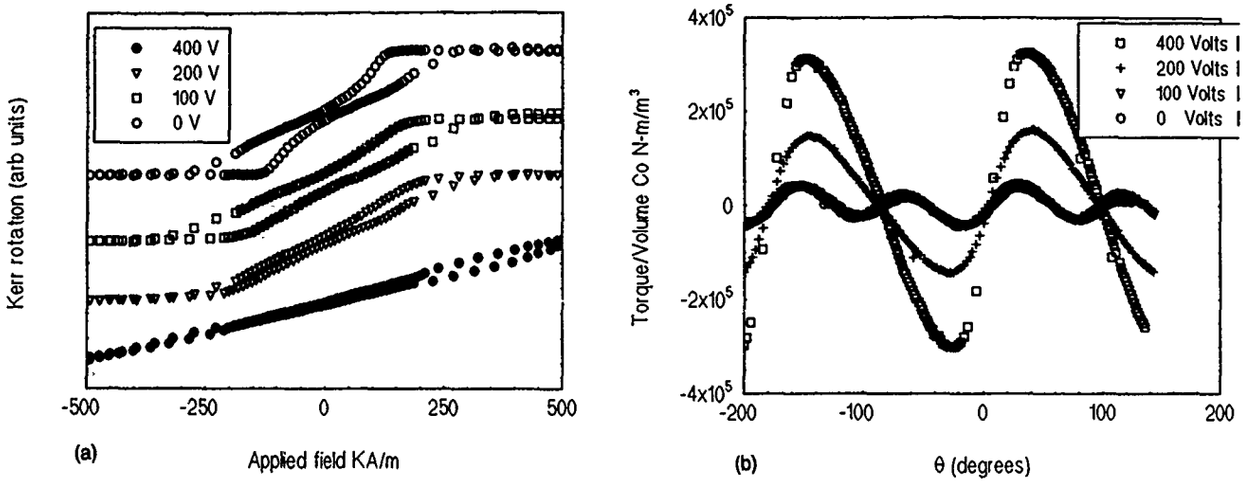

FIG. 2. As in Fig. 1 but for $15x$(1.2 nm Co/1.2 nm Pt) MLs.

×(1.2 nm Co/1.2 nm Pt) MLs deposited with ion assistance at 0, 100, 200, and 400 eV. These perpendicular loops change gradually with increasing shear and decreasing coercivity until at 400 eV the loop has the shape typical of a hard axis loop. The torque curves for these MLs, given in Fig. 2(b), change from two similar curves of small amplitude for 0 and 100 eV, which can be analyzed in terms of an easy cone of magnetization about the normal to the ML, which is isotropic in its plane, to curves for 200 and 400 eV for which the easy direction is clearly in the plane of the ML as signified by the positive slope of the torque curve at $\theta=0$.

X-ray diffraction confirmed the layered and textured structure of the low energy ion-assisted and etched MLs. Increasing the beam energy in ion-assisted deposition eventually destroys the layered structure as indicated by the ratio of the ⟨111⟩ maximum to the first satellite maximum, I_{111}/I_{sat}. For the 0, 100, 200, and 400 eV MLs described in Fig. 2, I_{111}/I_{sat} was measured as 1.7, 1.6, 2.3, and ∞, respectively.

Turning to the Co/Cu systems, Figs. 3(a) and 3(b) show the VSM hysteresis loops and magnetoresistance loops for four ion-assisted $20x$(1 nm Co/2 nm Cu) MLs. These MLs are structured for the second maximum in the GMR oscillation.[4,7] It can be seen in Fig. 3(a) that the ML deposited without ion assistance (0 eV) gave a sheared magnetic hysteresis loop having a lower remanence than MLs deposited with ion assistance suggesting some definite antiferromagnetic coupling between the Co layers in the 0 eV ML. Figure 3(b) shows a GMR of 15% for this ML. The figures also show that ion assistance in the deposition gradually destroys the properties of the ML; it reduces the amount of antiferromagnetic coupling in the ML and it eventually produces a much less sheared hysteresis loop at 200 eV, Fig. 3(a). There is a concomitant decrease in the GMR ratio to almost zero, Fig. 3(b).

Thermal annealing and x-ray measurements[8] show that the GMR in Co/Cu MLs is destroyed along with the layered structure at temperatures above about 300 °C. However, an

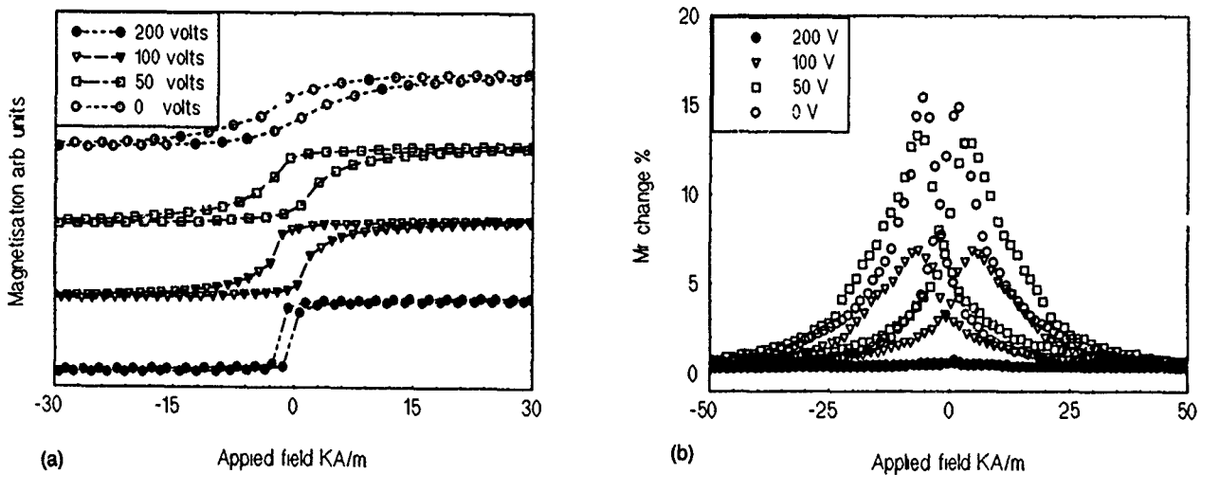

FIG. 3. VSM hysteresis (a) and GMR (b) loops for $20x$(1 nm Co/2 nm Cu) ion-assisted MLs.

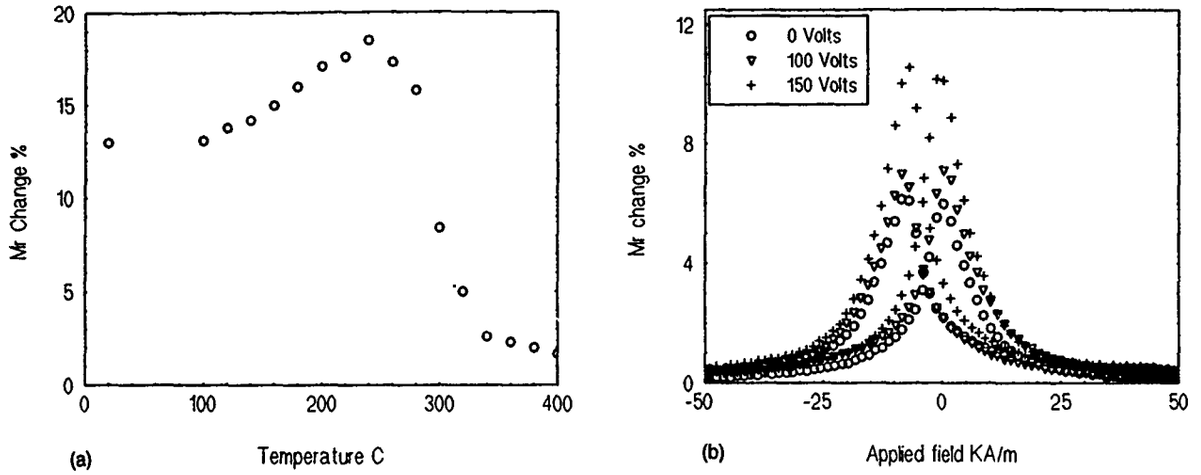

FIG. 4. GMR loops for (a) thermally annealed and (b) ion etched 16x(1 nm Co/2 nm Cu) MLs.

increase in GMR can be observed in annealing at lower temperatures. This is illustrated in Fig. 4(a) for a 16×(1 nm Co/2 nm Cu) ML where the GMR increases by about 50% up to 250 °C. Significantly, we have found that ion etching can also produce an improvement in GMR. Figure 4(b) shows GMR loops for a series of MLs having the structure 10×(1 nm Co/2 nm Cu) in which the Co surfaces have been ion etched at different energies. There is a clear improvement in GMR at energies up to 150 eV. We have some evidence that this effect is followed by a decrease at energies greater than 200 eV.

In the ion-assisted depositions the ratio of the ion to atom fluxes can be calculated as $j_i/j_a \approx 2$ and there is sufficient energy transferred in collisions of the ions with the condensing and condensed atoms to cause surface displacements and densification of the microstructure of the growing layers.[9] However, certainly at the higher energies, there is a possibility of atom mixing by the ion bombardment at any interface as the deposition progresses and this will encourage a less sharp compositional profile in the ML. No material loss from the MLs was detected up to ion energies of 200 eV and measurable sputtering of the growing ML is only expected at energies greater than 300 or 400 eV.

In ion etching, modification of the surface and near-surface regions of the interrupted structure can be expected. As the individual layers in the MLs discussed here are less than ten atomic layers thick, and some are of the order of two to three atomic layers, there is a possibility of modification and mixing at the interface below the treated surface. Monte Carlo simulations show that for the Co/Cu MLs, with 10 nm Co and 20 nm Cu layers, this effect is not significant for 100 eV ions, but at 200 eV mixing of Co into Cu occurs over a region ≈0.4 nm in width across the interface below the etched surface. In the Co/Pt MLs, considerable displacement of atoms from the 0.4-nm-thick Co layer into the underlying Pt layer is predicted at 100 eV, but in the case of the 1.2 nm Co layers, this is only significant at energies above 300 eV.

The effects in the ion treated Co/Pt MLs discussed here can be compared to those reported for Co/Pt MLs sputter-deposited in "thermalizing" conditions,[1] which result in rougher interfaces and coarser microstructures and stronger perpendicular anisotropy and larger coercivities. We can therefore reasonably interpret our results for the loss of perpendicular anisotropy in Co/Pt MLs in terms of surface smoothing at the lower ion energies and microstructural modification involving mixing and roughening of the interface at higher energies.

The progressive loss of GMR and antiferromagnetic coupling in the ion-assisted Co/Cu MLs may have been due to modification of the microstructure and texture of the layers and/or interface regions. The initial increase in GMR in the low energy ion etched MLs, and in the thermally annealed structures, followed by a loss at higher energies, suggests strongly that increased electron scattering was caused by interface/surface smoothing. We plan to investigate these suggested microstructural and interface changes by high resolution electron microscopy and x-ray reflectometry.

Anomalous interface magnetism in ultrathin Co films with in-plane anisotropy

F. O. Schumann, M. E. Buckley, and J. A. C. Bland
Cavendish Laboratory, Madingley Road, Cambridge CB3 OHE, United Kingdom

Using the magneto-optical Kerr effect, we have observed a striking sensitivity of the magnetic properties of ultrathin Co/Cu(001) films to submonolayer coverages of Cu. In particular large nonmonotonic changes of the coercive field H_c, the height of the *M-H* loop (magneto-optical signal), and the ratio S of remanent and saturation magnetizations are observed. With increasing Cu thickness the coercivity first sharply decreases, reaching a minimum at around 0.2 monolayer (ML) followed by a gradual increase. In contrast, the magneto-optical signal is found to peak strongly at the same Cu overlayer thickness of 0.2 ML, decaying in magnitude with further Cu coverage.

I. INTRODUCTION

It is now well established experimentally that nonmagnetic overlayers can drastically affect the magnetic properties of ultrathin magnetic films as reported by Przybylski *et al.*[1] and Weber *et al.*[2] More recently, Engel *et al.*[3] have shown the influence of ultrathin Cu, Ag, and Pd overlayers on the perpendicular magnetism of Co/Pd(111) films, where the coercive field exhibits a nonmonotonic dependence on the nonmagnetic overlayer thickness. It is therefore of interest to test the effect of a nonmagnetic overlayer in the ultrathin regime for a film with in-plane anisotropy. The Co/Cu(001) system displays in-plane anisotropy,[4–7] and upon coating with several monolayers (ML) of Cu, a reduction of the Curie temperature,[8] and of the out-of-plane anisotropy[9] and coercive field[10] are known to occur.

II. EXPERIMENT

The experiments were carried out in an ultrahigh vacuum chamber with a base pressure of 1.0×10^{-10} mbar, and a pressure of less than 5.0×10^{-10} mbar during Co and Cu deposition. Ar^+ sputtering (1 kV) and annealing up to 700 K resulted in a clean and well-ordered Cu(001) surface. Magneto-optical Kerr effect in the transverse geometry[4] has been employed for recording hysteresis loops, with the magnetic field aligned along the ⟨110⟩ easy axis.[4,6] Co and Cu films were grown with the sample at 300 K with typical deposition rates of 0.1 ML/min for Co and 0.05 ML/min for Cu (judged using the Auger peak heights and, for the Co, the sharp onset of ferromagnetic order as a guide).[10] All magnetic measurements were performed at 300 K.

III. RESULTS AND DISCUSSION

The thickness d_{Co} of the Co layers has been varied between 1 and 2 d_c, where d_c is the critical thickness at which long-range order occurs at 300 K. The absolute value of d_c is between 1 and 1.7 ML.[7–9,11,12]

In Fig. 1 we display several *M-H* loops of a $1.6d_c$ Co/Cu(001) film obtained during growth of the Cu overlayer. Clearly minute coverages reduce H_c drastically and change S, the ratio of remanent magnetization to saturation magnetization. Surprisingly, the squarest loop is obtained for a small Cu overlayer thickness of approximately 0.2 ML. A careful analysis of all *M-H* loops during this growth sequence reveals a nonmonotonic dependence M_{sat} (the loop amplitude) and H_c on Cu thickness d_{Cu} as shown in Fig. 2, and of S (not shown). In particular the coercivity exhibits a sharp minimum at the thickness at which S and M_{sat} peak.

For all Co thicknesses studied, qualitatively similar variations in each of these quantities are observed, except that the nonmonotonic behavior of S is less pronounced for thinner films, for which S is closer to unity than for the

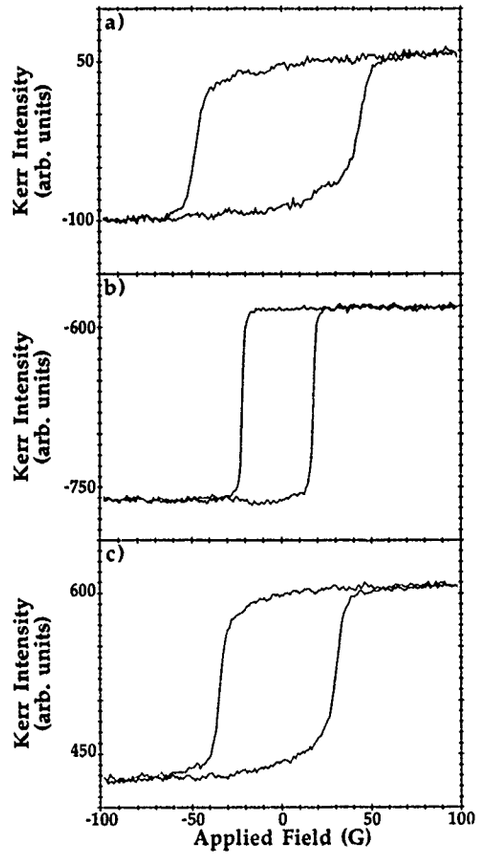

FIG. 1. Various *M-H* loops of a $1.6d_c$ thick Co/Cu(001) film during a Cu overlayer growth sequence, with Cu overlayer thickness d_{Cu} of 0.04, 0.16, and 0.36 ML for (a)–(c), respectively.

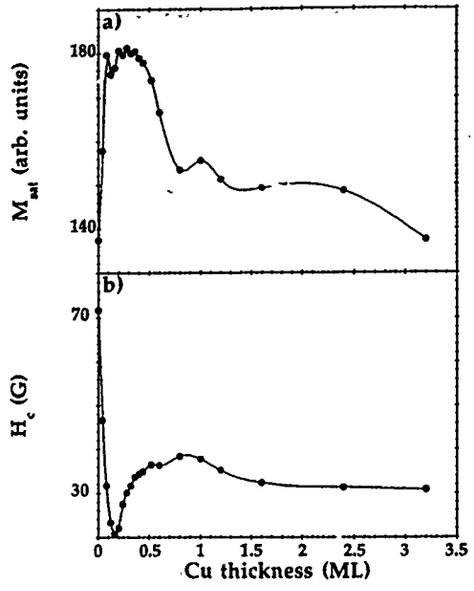

FIG. 2. The results of a careful analysis of the Cu overlayer growth sequence of a $1.6d_c$ thick Co/Cu(001) film are shown, revealing the nonmonotonic behavior of the saturation magneto-optical signal M_{sat} in (a), and the coercive field H_c in (b).

thicker Co films. We define the peak enhancement as follows:

$$\Delta = \frac{M_{sat}(d_{Cu}) - M_{sat}(0)}{M_{sat}(0)} \quad \text{with } d_{Cu} = 0.2 \text{ ML.} \qquad (1)$$

We can now summarize the main experimental findings for all the structures studied as follows: H_c always rapidly drops by roughly a factor of ~3, and Δ is always of the order of 20% upon the deposition of only 0.2 ML of Cu.

In Fig. 3 we show the thickness dependence of M_{sat} of a $1.5d_c$ thick Co/Cu(001) film. We notice again a nonlinear behavior in the submonolayer range as in Fig. 2. At higher coverages we see a noticeable drop of M_{sat} below the value for the uncovered Co/Cu(001) film, which is more pronounced than that which would be caused by optical attenuation through the Cu layer. A low-energy electron diffraction study of the energy dependence of the Bragg peak intensity

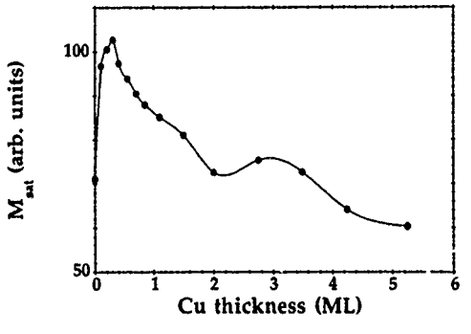

FIG. 3. The behavior of M_{sat} for a $1.5d_c$ thick Co/Cu(001) film. Note M_{sat} drops below the value for the uncovered film at high Cu coverages.

maxima for the (00) beam did not indicate strong changes in the perpendicular lattice parameter occurring upon Cu deposition.

The drop in H_c may indicate a drastic change in the magnetic anisotropy. A correlation between the change in perpendicular anisotropy and coercivity induced by an overlayer is reported by Engel *et al.*[3,13] for Cu-coated Co/Pd films. We would like to point out that Schneider *et al.*[8] report that the coercive field of films grown at 300 K is much higher than for those of identical thickness grown at 450 K. This observation is consistent with our data if we assume that the films grown at high temperatures correspond to the coated structures we have studied, as suggested by the observation by Kief *et al.*[14] that surface Cu segregation occurs at elevated temperatures.

The increase in magneto-optical signal with Cu deposition is surprising. We find that the degree of enhancement due to the 0.2 ML Cu overlayer is comparable with the increase in magnetic signal that would occur for an equivalent increase in the Co thickness. Schneider *et al.*[8] report a reduction of the Curie temperature T_C upon Cu deposition: therefore one might expect a reduction of M_{sat} upon Cu deposition. Since H_C and M_{sat} change with Cu overlayer thickness d_{Cu}, it is feasible that T_C could also be a general function of d_{Cu}, with the reported reduction[8] being the limiting behavior at higher Cu coverages. However, because T_C increases rapidly with Co thickness,[8,15] any effects due to a change in T_C should be more pronounced for films with a thickness of $1.1d_c$ than for those of $1.7d_c$; our findings show a similar behavior for all Co thicknesses. We can therefore rule out changes in the Curie temperature as a possible mechanism for the enhancement in loop amplitude we observe.

At present we cannot rule out the possibility that the deposition of small amounts of Cu acts like a "surfactant," improving the structural quality of the film. This is suggested by the almost perfectly square loop shown in Fig. 1(b) for 0.2 ML Cu coverage. However, further Cu deposition causes the loop to become less square, which contradicts this explanation at higher thicknesses. Also the peak enhancement is difficult to explain via surfactant effect. It is also possible that the Cu overlayer affects magnetic domain pinning or domain wall energies.

In our opinion, the most likely mechanism for the behavior we observe is that the evolving interface electronic structure influences the magnetic properties (anisotropy in particular). Recent calculations by Freeman[16] show that the presence of a Cu overlayer considerably influences the magnetism of fcc Co/Cu(001). The anomalous anisotropy behavior observed by Engel *et al.*[3,13] is believed to arise from the interface electronic structure, although we note that in this case the maximum effect is obtained for a nonmagnetic overlayer thickness of around 0.8 ML. In our view, the significance of the present work is that it implies that "anomalous" interface-induced changes in the magnetic properties may also occur for films with planar anisotropy, suggesting that a common mechanism may apply in both cases.

IV. SUMMARY

In summary, we have observed a nonmonotonic dependence of magnetic properties of ultrathin Co/Cu(001) films upon coating with submonolayers of Cu that may originate in the electronic structure of the interface. Most important, we report an enhancement of the magneto-optical signal upon deposition of 0.2 ML Cu. Surprisingly, these observations suggest that features analogous to the anomalous anisotropy in perpendicular Co/Pd(111) films[3,17] also occur in the in-plane Co/Cu(001) system. These results emphasize the importance of the interaction between the substrate and the magnetic layer, which can give rise to striking and largely unexplored effects in the submonolayer range.

The effect of substrates on the magnetic properties has been studied for Co and Fe films both on Al_2O_3 $(11\bar{2}0)$ and MgO (001) substrates by using ferromagnetic resonance techniques. For Fe(C01)/MgO(001) samples the thickness dependence of the magnetocrystalline constant and of the effective magnetization values have been determined from the in-plane angular variation of the resonance field H_0. Different reasons for the thickness dependencies of these parameters are discussed. For $Co(111)/Al_2O_3(11\bar{2}0)$ the angular variation of H_0 exhibits an uniaxial anisotropy, for which several causes are discussed. For $Co(11\bar{2}0)/MgO(100)$ a four-fold in-plane anisotropy was observed which is due to the twinned structure of these samples.

I. INTRODUCTION

Magnetic properties of thin films are affected to a large degree by interfacial effects arising from the interaction of the film with the substrate. Understanding these interface anisotropies in thin ferromagnetic layers is also very important for dealing with the more complex problem of magnetic multilayers and in particular with the analysis of exchange coupling. Recently, anisotropy measurements using the longitudinal Kerr effect were carried out on cobalt films grown by molecular beam epitaxy (MBE)[1] and on iron films prepared by rf sputtering techniques.[2] For the observed anisotropies possible sources for the film/substrate interaction were suggested. However, final conclusions can only be drawn after detailed investigations of the thickness and temperature dependences of the anisotropy have been carried out. It is well known that the ferromagnetic resonance (FMR) technique is a powerful tool for the study of magnetic anisotropies. Here we report the results of a FMR study of the in-plane anisotropy of Co and Fe films on Al_2O_3 $(11\bar{2}0)$ and MgO(001) substrates over wide temperature and thickness ranges.

II. EXPERIMENT

Cobalt films were grown by MBE techniques on $Al_2O_3(11\bar{2}0)$ and MgO(001) substrates. During film growth the substrate temperature was held constant at T_s=620 K for the sapphire substrate and at T_s=300 K for the magnesium oxide substrates. The sample preparation and the growth conditions are described in more detail in Ref. 3. Some films were exposed later to high temperatures (470 K) at a hydrogen atmosphere of about 100 mm Hg. For one sample the effect of the substrate temperature on the anisotropy was also examined.

The Fe films were grown by rf sputtering on MgC(001) substrates at 300 K in a 5×10^{-1} Pa pure Ar (99.999%) plasma with a growth rate of 0.1 Å/s. Further details are provided in Ref. 4. In order to prevent oxidation, the iron films were covered by a protective gold layer of 40 Å thickness.

The structural properties of films were studied by out-of-plane and in-plane x-ray scattering experiments. It should be noted that the structural quality of our rf sputtered films come close to the quality of the MBE grown epitaxial films.[4] The epitaxial relation of bcc Fe(100) on fcc MgO(100) follows the 45° epitaxy expected from the bulk lattice constants, i.e., the Fe[100] in-plane axis is parallel to the MgO[110] axis. Thin Co films on Al_2O_3 $(11\bar{2}0)$ substrates grow in a fcc or hcp structure depending on the film thickness with either the (111)-axis or (0001) pointing perpendicular to the film plane. Co films on MgO(100) substrates grow in the hcp structure with the $(11\bar{2}0)$ plane parallel to the film plane.

FMR experiments were carried out at 9.4 GHz in the temperature range from 20 to 400 K. The angular dependencies of the spectra were observed with both the dc magnetic field and the high frequency field in the film plane.

III. RESULTS

A. Fe/MgO

The results of the FMR measurements were analyzed using the standard formalism (see, e.g., Ref. 5). Magnetic free energy was taken consisting of a Zeeman $F_Z=-MH\sin\theta\cos(\phi-\phi_H)$, a demagnetization $F_D=2\pi M^2\cos^2\theta$, and a magnetocrystalline anisotropy term

$$F_C=\tfrac{1}{4}K_1(\sin^2 2\theta+\sin^4\theta\sin^2 2\phi), \quad (1)$$

where $\theta(\theta_H)$ and $\phi(\phi_H)$ are the angles of the magnetization M (magnetic field H) with respect to the film normal and to the x axis in the film plane (xy plane), respectively. In our geometry $\theta_H=\pi/2$.

By fitting the four-fold angular dependence of the resonance field position H_0, the $4\pi M$ value and the cubic anisotropy constant K_1 were determined. In Fig. 1 K_1 is plotted as a function of the reciprocal film thickness L^{-1} and in Fig.

 0021-3979/94/76(10)/6096/3/$6.00 © 1994 American Institute of Physics

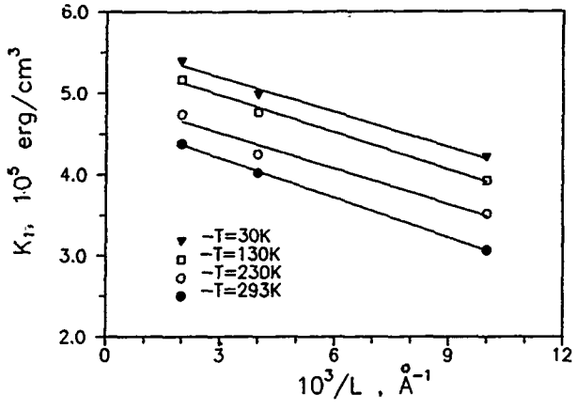

FIG. 1. The anisotropy constant K_1 for Fe(001) on MgO(001) plotted as a function of reciprocal Fe film thickness and for different temperatures.

2 $4\pi M$ is plotted as a function of temperature and for the different film thicknesses. These data clearly show a thickness dependence of K_1 and of $4\pi M$.

The thickness dependence of K_1 may be caused by the epitaxial misfit between film and substrate. If the epitaxial stress is located within a few atomic layers near the interface, we expect K_1 to vary inversely proportional with the film thickness because K_1 represents the volume density of the anisotropy energy. X-ray scans from these films revealed structural features which are consistent with this interpretation.[4]

The thickness dependence of $4\pi M$ comes as a surprise, at least for the thickness range studied here. However, it should be stressed that our FMR experiments cannot distinguish between an apparent decrease and a real reduction of the saturation moment due to interface effects. These possibilities shall be discussed in the following.

An apparent renormalization of the saturation moment could be caused by epitaxial misfit stresses. In this case a term accounting for the magnetostriction effects should be included in the expression for the free energy. The angular dependence of this contribution is similar to that for the demagnetization term. Therefore, in the expression for the free energy the effective value $4\pi M_{\text{eff}}$ should be used. Evaluating the contribution from the magnetostriction effect to $4\pi M_{\text{eff}}$, the correct sign is recovered, but the magnitude is far from being able to explain the reduction.

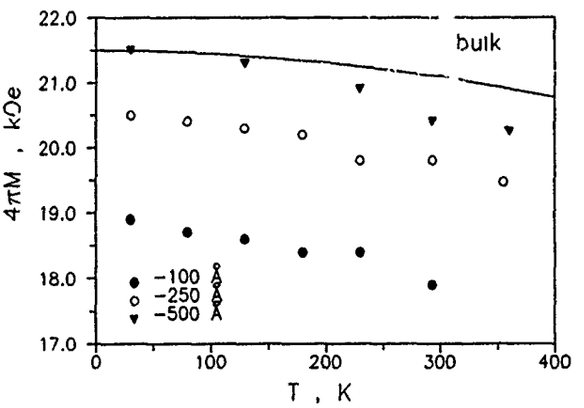

FIG. 2. The temperature dependence of the $4\pi M$ value plotted for all studied samples.

A more important contribution to the apparent reduction of $4\pi M_{\text{eff}}$ may come from the axial crystal field generated by interfaces. This uniaxial anisotropy field leads to perpendicular anisotropy of thin films.[7] Estimates show that this reason is partly responsible for the apparent reduction of $4\pi M_{\text{eff}}$ as observed by FMR.

At this point we would like to discuss the possibilities for a real reduction of the net magnetic moment. Early observations of moment reductions in rather thick films[8] could be discarded because of oxide formations on film surfaces resulting in "dead layers" (see. e.g., Ref. 9). However, this seems not to be the case here because of the use of a protective gold layer. From a theoretical point of view, band structure calculations lead, in general, to moment enhancements at (inter)surfaces due to band narrowing effects (see, e.g., Refs. 10 and 11). However, in these calculations, possible quantum fluctuation effects of the local moments cannot be incorporated. They are important at real interfaces resulting from random anisotropy fields and changes of the sign of the exchange coupling. In our case, for instance, antiferromagnetic (super)exchange interaction between Fe spins via oxygen ions at the Fe/MgO interface can be expected. Then the ground state would not correspond to a fully saturated ferromagnetic moment of the film. Strong frustrations of the exchange coupling may even lead to some canting of the spins near the surface or interface ("surface magnetic reconstruction"[12,13]).

B. Co/ Al_2O_3

FMR measurements on the angular variation of the resonance field H_0 showed a uniaxial in-plane anisotropy, which can be described by the free energy:

$$F_C = K_1 \sin^2\theta + K_2 - \sin^4\theta (K_u/2) \sin^2\theta \cos 2\phi. \quad (2)$$

Figure 3 shows the temperature dependence of the in-plane uniaxial anisotropy field $H_u = K_u/M$ for two samples with t_{Co}=120 Å and t_{Co}=350 Å. For the t_{Co}=120 Å thick sample the H_u value increases with decreasing temperature, whereas for the sample with t_{Co}=350 Å, H_u is reduced as compared to the thinner sample and is nearly temperature independent. After annealing the thin sample in a hydrogen atmosphere, the H_u value drops and approaches the H_u value for the thick sample. Moreover, we noticed that lowering the substrate temperature during film growth has the effect of decreasing the H_u and its temperature dependence seems to disappear.

From these observations at least two contributions to the uniaxial anisotropy can be inferred. The temperature dependent part may be caused by strains arising from the difference in thermal expansion coefficients of the substrate and the film. This part depends on the growth temperature and decreases after annealing at temperatures lower than the growth temperature. The temperature independent part may be due to internal oxidation of Co atoms along the oxygen

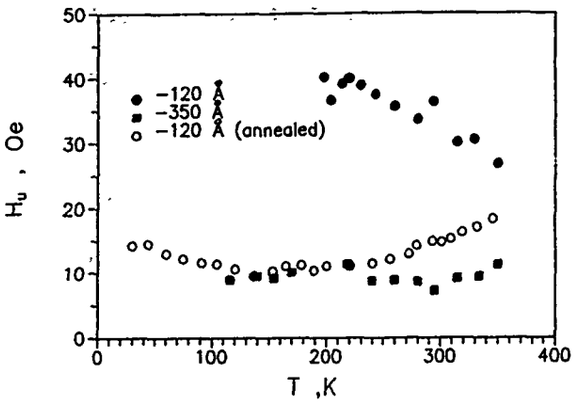

FIG. 3. The temperature dependence of the in-plane uniaxial anisotropy field $H_u=K_u/M$ shown for two samples of Co(111)/ $Al_2O_3(11\bar{2}0)$ with film thicknesses t_{Co}=120 Å and t_{Co}=350 Å. In addition, the data for the thinner sample are shown before and after annealing.

chains on the Al_2O_3 $(11\bar{2}0)$ surface as was suggested in Ref. 2, or due to the existence of an array of steps on the surface of the substrate which creates uniaxial in-plane anisotropy, as observed by Heinrich *et al.*[14]

C. Co/MgO

The in-plane angular variation of the FMR resonance field clearly exhibits a four-fold anisotropy for Co on MgO(001) similar to anisotropies usually observed for cubic crystals in the (100) plane. In contrast to Fe, the Co films have hcp $(11\bar{2}0)$ orientation with the c axis in the film plane. By surface x-ray scattering methods it was established that the Co films on MgO exhibit a twinned structure with the c-axis oriented parallel to the MgO[100] and MgO[010] directions. This twin structure, in turn, causes an apparent four-fold structural and hence a four-fold magnetic in-plane anisotropy. It can be supposed that the strong exchange interaction provides the coupled uniform motion of moments of different crystal domains, thus generating a single FMR-resonance line. For the anisotropy contributions of the two crystallographic domains the averaged magnetocrystalline term can be written as:

$$F_C=-\tfrac{1}{2}(K_1+2K_2)\sin^2\theta+\tfrac{3}{8}K_2\sin^4\theta + \tfrac{1}{8}K_2\sin^4\theta\cos 4\phi. \quad (3)$$

Here K_1 and K_2 are the first- and second-order uniaxial magnetocrystalline anisotropy constants. In this case the values measured in FMR are $H_i=4\pi M+H_{A1}+H_{A2}/2$ and H_{A2} ($H_{A1}=K_1/M$ and $H_{A2}=K_2/M$). If for $4\pi M$ the bulk value is assumed, a negative value for H_{A1} is obtained, indicating that $4\pi M$ is reduced. This reduction is most likely due to the reasons already discussed above for the case of Fe/MgO.

IV. CONCLUSIONS

FMR measurements of MBE grown Co films and of rf sputtered Fe films on the Al_2O_3 $(11\bar{2}0)$ and MgO (001) substrates have been performed over a wide temperature range and for several film thicknesses. For all studied systems, film/substrate interactions were detected. The particular anisotropy observed depends on the specific substrate material chosen and on the preparation conditions such as substrate temperature during growth. Thus, for iron films on the MgO(001) substrates, a reduction of the $4\pi M_{\text{eff}}$ value in comparison to the bulk saturation moment was observed with decreasing thickness. It was argued that this effect may possibly be caused by surface contributions to the out-of-plane axial anisotropy. An additional contribution may come form an interface reduction of the saturation moment. In the case of Co/Al_2O_3 samples with the Co fcc [111] axis perpendicular to the film plane a strong and unexpected uniaxial in-plane anisotropy was observed. This anisotropy probably arises in part from the difference of the thermal expansion coefficients of the film and the substrate and in part from the oxidation of Co along oxygen chains on the $Al_2O_3(11\bar{2}0)$ surface or from step arrangement on the surface of the substrate. Finally, for Co films on MgO(001) substrates a four-fold in-plane anisotropy was observed due to the twinned hcp structure of the film and a decrease of the $4\pi M_{\text{eff}}$ value was obtained resembling the Fe/MgO system.

The relationship between the microstructure and magnetic properties of sputtered Co/Pt multilayer films (abstract)

Y. H. Kim, Amanda K. Petford-Long, and J. P. Jakubovics
Department of Materials, University of Oxford, Parks Road, Oxford OX1 3PH, United Kingdom

Co/Pd multilayer films (MLFs) are of interest because of their potential application as high-density magneto-optical recording media. Co/Pd MLFs with varying Co and Pd layer thicknesses were grown by sputter-deposition onto (100) Si wafers. X-ray diffraction and high resolution electron microscopy were used to study the microstructure of the films, and Lorentz microscopy was used to analyze their magnetic domain structure. The films show an fcc crystal structure with a compromised lattice parameter and a strong (111) crystallographic texture in the growth direction. The compromised interplanar spacing parallel to the surface increased with decreasing thickness ratio (t_{Co}/t_{Pd}), and the columnar grain size decreased with increasing Pd layer thickness. Films with t_{Co}=0.35 nm and t_{Pd}=2.8 nm (columnar grain diameter 20 nm) showed promising magnetic properties, namely a high perpendicular magnetic anisotropy (1.85×10^5 J m^{-3}), with a perpendicular coercivity of 98.7 kA m^{-1}, a perpendicular remanence ratio of 99%, and a perpendicular coercivity ratio of 88%. The magnetic domains were uniform and of a narrow stripe type, confirming the perpendicular easy axis of magnetization. The Curie temperature was found to be about 430 °C. Films of pure Co and Pd, grown for comparison, also showed columnar grain structure with grain-sizes of the same order as those seen in the MLFs. In addition the Pd films showed a (111) textured fcc structure.

Magnetic anisotropies of ultrathin transition-metal films are inherently related to their structural properties. In ultrathin films the large fraction of atoms located at the film interface generates strong interface anisotropies, whereas elastic strain fields caused by the forced registry of atoms at the substrate/film interface induce magnetoelastic anisotropy contributions.[1–3] So far the experimental confirmation of the transition from these thin-film properties to bulk anisotropy properties, characterized by a dominating magnetocrystalline anisotropy, has not yet been presented. Magnetic anisotropies reflect, depending on their origin, both the crystallographic symmetry and the symmetry of the film geometry. For a clear separation between magnetoelastic, magnetocrystalline and Néel-type interface anisotropy contributions, the film symmetry and thickness must be chosen such that the respective different anisotropy contributions appear with different symmetries and film thickness dependencies. This is the case for (110)-oriented fcc Co films. In the present study we use the Brillouin light-scattering technique for the determination of the anisotropy contributions. An analysis of the spin-wave frequency measured as a function of the in-plane direction of the external field and the film thickness yields information about all relevant anisotropies. The samples used were molecular-beam-epitaxy grown in ultrahigh vacuum. Onto a Cu (110) single-crystal substrate a wedge-type sample and two staircase-shaped samples with distinct thicknesses in the range of 8–110 Å were grown. To obtain symmetric Co/Cu interfaces the Co layers were covered with a 12 Å Cu layer. Finally, a 25-Å-thick Au protective layer was deposited. Low-energy electron-diffraction studies were used to obtain the structural data of the films. All relevant anisotropy contributions—the magnetocrystalline anisotropy, and the uniaxial in-plane and out-of-plane anisotropy contributions—were determined. Three different anisotropy regimes are observed as a function of the Co layer thickness d_{Co}. This thickness regime up to 13 Å is dominated by the magnetoelastic anisotropy contributions as a result of the pseudomorphic film growth of the Co layer. For Co layer thicknesses larger than 13 Å we find a reduction of the magnetoelastic anisotropy contributions. This is structurally correlated to an anisotropic relaxation of the in-plane Co lattice constant. In the regime of $d_{Co}>50$ Å we observe a thickness-independent value for the magnetocrystalline anisotropy contribution $K_1=-8.5\times10^5$ erg/cm^3. This anisotropy contribution is largely suppressed for $d_{Co}<50$ Å. This finding might either indicate a breakdown of the usually postulated linear superposition principle of magnetic anisotropy contributions to the free anisotropy energy, or it might point to a subtle modification of the electronic band structure. At the onset of the magnetocrystalline anisotropy we find a change in the easy magnetization direction from ⟨001⟩ for thin Co films to ⟨111⟩ for thicker ones. For a more detailed discussion see Ref. 4.

Nature of half-metallic ferromagnets: Transport studies

J. S. Moodera and D. M. Mootoo
Francis Bitter National Magnet Laboratory, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139-4307

The half-metallic ferromagnetic compounds due to the absence of states at E_F for minority spin electrons, as predicted by band theory, should exhibit unique features in their transport properties. Transport measurements conducted as a function of T and H for NiMnSb and PtMnSb thin films show interesting behavior. In $H=0$, the resistivity versus T shows the absence of the T^2 dependence at low temperature found in ferromagnets such as Fe, Ni, etc. The Hall constant increases significantly below about 100 K for both compounds; NiMnSb shows a factor of seven increase. Transverse magnetoresistance changes sign between 295 and 4.2 K. Transport data seem to imply a drop in the carrier density and a large increase in their mobility at low temperatures, which is consistent with zero density of states for minority spins at E_F, but additional measurements are needed to clarify theoretical understanding.

I. INTRODUCTION

The prediction of an energy gap for the minority spin carriers at the Fermi level (E_F) in certain Heusler alloys has not yet been verified.[1] Such materials have been called as half-metallic ferromagnets, in that only majority spin carriers occupy the Fermi level, leading to 100% polarized conduction electrons. Among several compounds which may be classified as HMF, NiMnSb, and PtMnSb are the two compounds that have been studied the most.[2–4] However, very limited transport measurements have been carried out. The study on polycrystal and single-crystal bulk samples of NiMnSb and PtMnSb by Otto *et al.*[3] covers the resistivity and Hall-effect measurements in the whole temperature range, from the ferromagnetic Curie temperature to the liquid-helium range. However, detailed temperature variation of ρ at low T is lacking. For normal ferromagnets such as Fe, Ni, and Co near liquid-helium temperatures, ρ varies as T^2 due to spin flip scattering of charge carriers by magnons.[5,6] In the case of an HMF material the absence of spin-down states at E_F is expected to change the character of spin scattering, leading to the absence of spin flip scattering for the majority spin carriers, with ρ vs T not showing T^2 dependence at low temperatures. The ultimate test of the theoretical prediction is the direct measurement of spin polarization of conduction electrons which can be performed by spin-polarized tunneling technique. In order to carry out tunneling, thin films are orders of magnitude better than single crystals for preparing planar tunnel junctions. In addition, careful transport measurements can be performed with relative ease and sensitivity. In this paper we concentrate on the magnetotransport properties of thin films of NiMnSb and PtMnSb compounds.

II. EXPERIMENTAL

Thin films of NiMnSb and PtMnSb were prepared by three-source coevaporation on glass substrates held at 450–500 °C. After annealing these films at the deposition temperatures for 20 min, they were cooled to room temperature by turning off the heater. Films were analyzed by x-ray diffraction, EDX, and Auger depth profiling to confirm the formation of correct phase and chemical composition. Film surfaces showed nonstoichiometry down to several tens of Å and beyond that, 1:1:1 ratio of the three elements were observed within the accuracy of the Auger analysis. In order to prepare tunnel junctions over these films the surface was cleaned by Ar ions at shallow incident angle and immediately covered with Al_2O_3 by sputtering onto these films using a sapphire target. Aluminum thin films, 40 Å thick, served as the top electrode. Tunnel junction preparation was carried out in a modified ion milling system. Optimum conditions for obtaining useful junctions are yet to be found.

Magnetotransport measurements of these films were carried out in the temperature range of 300–1.1 K and applied magnetic field up to 20 T, using a water-cooled Bitter magnet. Results of these measurements are presented below.

III. RESULTS AND DISCUSSION

For both NiMnSb and PtMnSb the resistivity decreased with temperature as shown in Fig. 1. For these films ρ at 300 K is higher than that reported by Otto *et al.*[3] for single crystals of NiMnSb and PtMnSb. In the case of NiMnSb, ρ decreases more rapidly below about 100 K, whereas PtMnSb shows a nearly uniform drop in ρ. Detailed low-temperature variation of resistance for both compounds is shown in Fig. 2. Below ~15 K the resistance decreased *linearly* with temperature. This is different from the T^2 dependence of ρ observed for normal ferromagnets such as Fe, Ni, and Co in this temperature range,[5] and also observed by us for a pure Fe film prepared under similar conditions as used for NiMnSb and PtMnSb films.

Transverse magnetoresistance of both PtMnSb and NiMnSb films was negative at 295 K, all the way to 20 T. At liquid-helium temperatures it changed to a positive value for

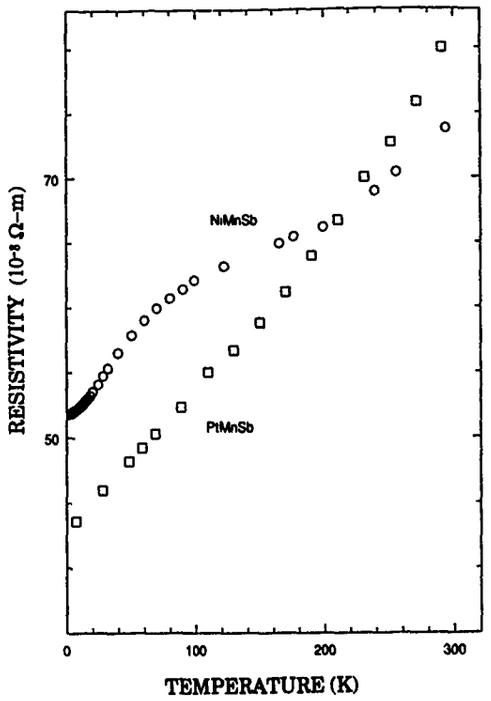

FIG. 1. Temperature variation of resistivity for NiMnSb and PtMnSb compound thin films. Note the rapid drop in resistivity below ~100 K for NiMnSb.

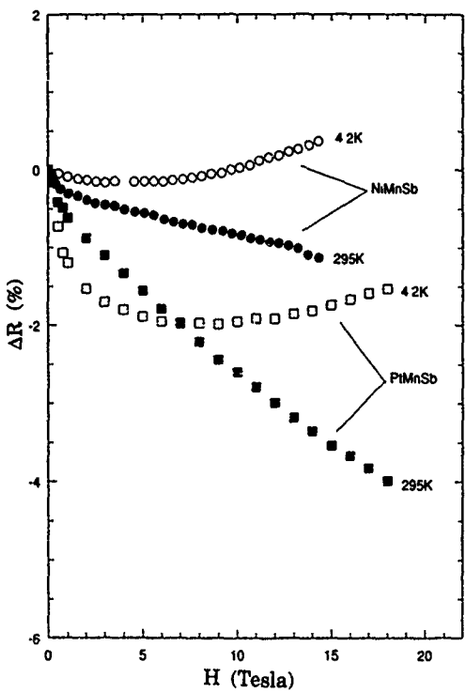

FIG. 3. Transverse magnetoresistance of NiMnSb and PtMnSb in high applied magnetic fields.

NiMnSb, the change occurring below ~50 K. However, in the case of PtMnSb, at low temperatures, magnetoresistance started out negative and then increased with increasing H beyond ~7–8 T. These results are shown in Fig. 3. Both films showed a decrease in resistance from 0 to ~1 tesla at all temperatures, expected for a ferromagnetic films in a field due to the buildup of magnetization. PtMnSb has higher values of ΔR compared to NiMnSb.

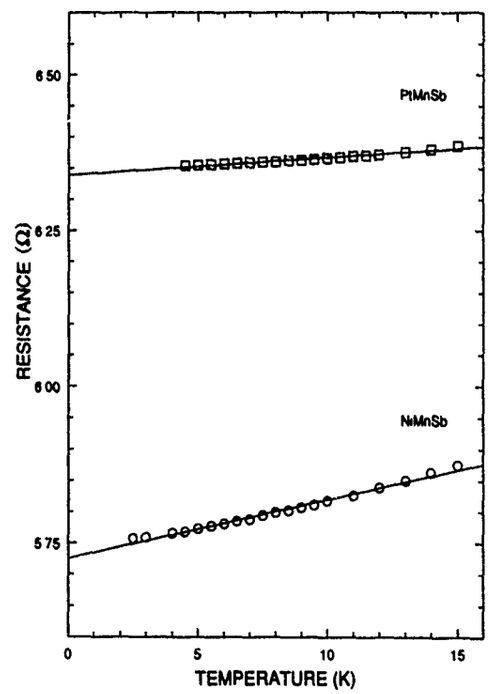

FIG. 2. Detailed temperature dependence of resistance for NiMnSb and PtMnSb compound thin films at low temperatures, showing linear dependence. Lines through the data points are linear fits.

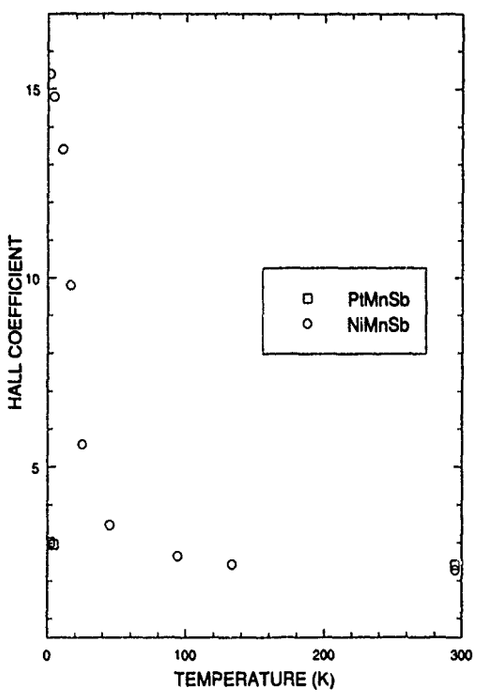

FIG. 4. Hall coefficient (in units of 10^{-10} m^3 A^{-1} S^{-1}) variation as a function of temperature for NiMnSb and PtMnSb films.

The Hall effect, as expected for a ferromagnetic material, showed two components as a function of applied magnetic field. In fields up to ~1 T, a large anomalous Hall voltage was observed and beyond which the ordinary Hall voltage (positive) increased linearly with H. The anomalous part decreased as T decreased, consistent with an increase in the film magnetization. Ordinary Hall constant (R_0) plotted in Fig. 4 as a function of T shows a small increase down to ~100 K, below which it increases significantly by about 20% for PtMnSb and by a factor of 7 in the case of NiMnSb. Similar behavior was observed earlier by Otto *et al.*[3] in polycrystalline bulk samples.

The transport properties of the above HMF compounds thus show unique features. There are no theoretical models to explain this behavior. The temperature variation of ρ is interesting, particularly the linear dependence of ρ vs T. According to theoretical prediction, if there are no spin-down states at E_F, then spin flip scattering for spin-up charge carriers due to magnons is forbidden. This will lead to the absence of T^2 dependence of ρ and to an increase in the mobility of the charge carriers. Since the Curie temperature of PtMnSb and NiMnSb are 582 and 730 K, respectively,[2] one may not expect many magnons at near-helium temperatures. This means absence of T^2 dependence of ρ does not provide conclusive proof for the absence of spin-down states at E_F. In addition, scattering processes such as electron-phonon, electron-electron, etc., can give rise to nontrivial ρ-T dependence. However, ordinary Hall coefficient increase by a large amount as T decreases shows significant changes in the carrier concentration and mobility. Caution should be exercised in the above interpretation since in NiMnSb, for example, the Fermi surface consists of three hole sheets and parts of it are electron-like.[1] In any case, a factor of seven increase in R_0 for NiMnSb indicates a decrease in the carrier density at low temperature. The mobility also has to increase considerably in order to explain the drop in the resistivity in the same temperature region. Between 4.2 and 295 K the saturation magnetization does not change more than 5%–6% for NMS. Within limits, the above *ad hoc* interpretation of the Hall and resistivity data appears to be consistent with the prediction of a gap for minority spin carriers at E_F. Although HMF is not quite like a semiconductor, transport behavior of our films is somewhat similar to that seen in doped or narrow-gap semiconductors. If the minority spin gap is much smaller than the predicted 0.5 eV in NiMnSb, then its effects can be realized only at lower temperatures where thermal activation across the gap becomes negligible. Presence of small quantities of other phases, below the detection limit of powder x-ray diffraction, can also dilute the HMF effect in these materials. Negative magnetoresistance at higher temperatures for NiMnSb may be interpreted as due to inelastic s-d scattering, which reduces to negligible values at low temperatures, which in turn is due to reduced thermal fluctuations and to the absence of spin-down states at E_F. This tentative explanation again depends on the presence of an energy gap for minority spin carriers. In PtMnSb the corresponding energy gap is even smaller[1] and hence the effects are smaller. The effect seen in the transport measurements can also result from a structural phase transition below room temperature. The above conjectures need more support from further studies on these compounds. For instance, thermal conductivity, specific heat, and MOKE measurements as a function of temperature and magnetic field will certainly shed more light onto the nature of these compounds. In addition, structural studies below room temperature are necessary.

IV. CONCLUSIONS

In summary, NiMnSb and PtMnSb compound thin films show interesting temperature changes of resistivity and Hall coefficient. This behavior appears to be consistent with the band structure calculation for these half-metallic compounds. However, study of other properties is needed to confirm the above observation.

Magnetoresistance and magnetic properties of NiFe/oxide/Co junctions prepared by magnetron sputtering

T. S. Plaskett and P. P. Freitas[a)]
INESC, R. Alves Redol 9-1, 1000 Lisbon, Portugal

N. P. Barradas, M. F. da Silva, and J. C. Soares
INETI, EN10, 2685 Sacavem, Portugal

NiFe/oxide/Co junctions were fabricated by magnetron sputtering for studies of polarized electron transport across the insulating barrier. Al_2O_3, Al-Al_2O_3, and MgO insulating barriers were prepared with junction resistances from 0.5 to 116 Ω. The *I-V* characteristics at room temperature are linear. For low barrier resistance, the magnetoresistance of the structure is dominated by the anisotropic magnetoresistance of the ferromagnetic electrodes. For the higher barrier resistances, a different magnetoresistance effect is observed, which is tentatively related to tunneling or spin-valve effects across the insulating junction.

I. INTRODUCTION

Ferromagnetic/insulator/ferromagnetic junctions have been studied in the past[1-3] in order to clarify the effect of spin polarization on the tunneling current across the insulating barrier. These experiments were carried out at low temperatures in the tunneling regime of the *I-V* curve. A change in the junction zero-bias conductance was observed, which depended on the relative magnetic state of the bottom and top electrodes. Due to the relative size of electrode and junction resistances, the magnetoresistance (MR) of the ferromagnetic electrode was neglected.

Recently,[4] work has been reported on NiFe/Al-Al_2O_3/Co junctions. These authors claim spin-tunneling effects at room temperature, although it is not clear how the MR of the ferromagnetic electrodes was avoided.

In this paper we describe a study of NiFe/oxide/Co structures, where three types of oxide barriers were prepared, reactively sputtered Al_2O_3 and MgO, and thermally oxidized Al-Al_2O_3. A systematic study of junction resistance, *I-V* characteristics, oxide structure, and magnetoresistance behavior is reported. We find that when junction resistance is of the order of the electrode resistance, electrode MR dominates. For junction resistance much larger than electrode resistance, the observed magnetoresistance is ascribed to tunneling across the oxide.

II. EXPERIMENTAL METHOD

The samples were prepared by magnetron sputtering in a system with a base pressure of 1×10^{-7} Torr. The ferromagnetic and insulating layers were deposited through metallic masks to produce the cross pattern shown in Fig. 1(a). The junction has an active area of 1 mm^2, and the oxide layer is deposited through a circular mask with a diameter of 5 mm in order to prevent shorts between the top and bottom electrodes. The ferromagnetic electrodes were deposited at a rate of 1 Å/s in a magnetic field of 100 Oe to induce an easy-axis direction along the $Ni_{81}Fe_{19}$ and Co bars.

The insulating oxide layers were prepared by thermal oxidation of a metallic Al layer, and by reactive rf sputtering of Al_2O_3 or MgO in a mixed Ar/O_2 atmosphere, containing 2%–10% O_2 by volume, from metallic Al and Mg targets. The reactive sputtering of the oxide layers was done at power densities of 1 W/cm^2, rates of 0.1–0.2 Å/s, at an Ar pressure of 1.5 mTorr. In the thermal oxidation method, a thin layer of Al was deposited on top of the NiFe electrode. The sample was brought to atmosphere and oxidized in air for 36–100 h to produce an Al-Al_2O_3 layer. The Co layer was then deposited. The oxide thickness was varied from 25 to 300 Å, and electrode thickness was either 400 or 1500 Å.

The oxidation process was studied by Rutherford backscattering (RBS). For this purpose a thin Si⟨100⟩/NiFe(50 Å)/$Al_2O_3(t)$/Co(50 Å) structure was prepared without breaking vacuum. Figure 2 shows the oxygen content, obtained by RBS, for a series of samples with various Al_2O_3 thicknesses.

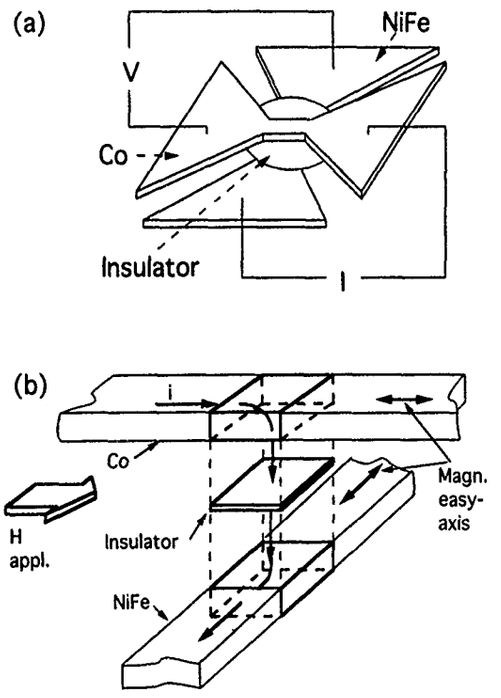

FIG. 1. (a) Schematic diagram of the ferromagnet/insulator/ferromagnet cross structure; (b) enlarged view of the junction area.

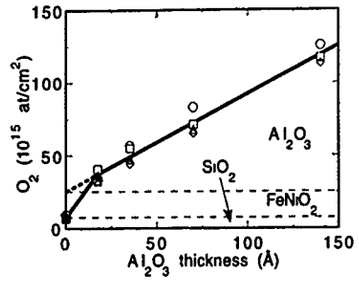

FIG. 2. Oxygen content determined by RBS analysis, for the reactively rf-sputtered Al_2O_3 junctions. The symbols represent different angles of incidence of the beam from 0° to 75°.

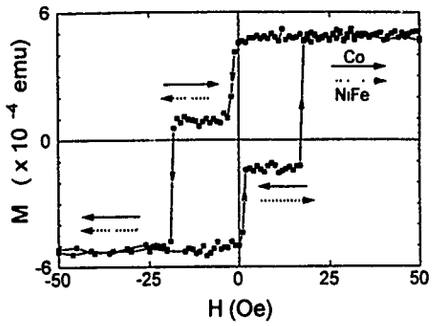

FIG. 3. Magnetization hysteresis loop for a NiFe/Al-Al_2O_3/Co structure with the field applied parallel to the Co easy axis (long axis of the bar). The arrows show the relative orientation of the NiFe and Co magnetizations.

The oxygen content is proportional to the oxide thickness, and the slope indicates an Al_2O_3 stoichiometry. The extrapolation to the origin corresponds to a NiFe oxide layer of 20 Å. The measured O_2 content at the origin is due to the SiO_2 native layer on the substrate. The main conclusion is that during the initial growth of the Al_2O_3 layer, the NiFe is being oxidized.

The main problem with these thin oxide layers is the existence of pinholes, leading to a low junction resistance of a few ohms. Also, the junction resistance sometimes decreases significantly at current densities as low as 0.1 A/cm^2. This occurs through irreversible dielectric breakdown taking place for fields of the order of 2×10^5 V/cm.

III. RESULTS AND DISCUSSION

Table I summarizes the oxide type and thicknesses studied, and the measured junction and electrode resistances. The junction resistance includes both insulator and electrode resistances. The electrode resistance in the junction area was measured using the same geometry as shown in Fig. 1, but without the oxide layer. A simple calculation of this resistance shows that most of the current in the junction area is in-plane. Notice that high junction resistances were observed only for MgO barriers. In this case, junction resistance is about 800 times higher than electrode resistance. For the Al oxides, most junction resistances are of the order of the electrode resistance.

TABLE I. Oxide types, thicknesses, junction resistance, and electrode resistance in the junction area.

	Junction		Electrodes	
Insulator	t (Å)	R (Ω)	t(each) (Å)	R(total) (Ω)
Al_2O_3	100	0.4	1000	
	400	20	400	0.75
Al-Al_2O_3	40	1.0	400	0.75
	60	1.4	400	0.75
	100	0.9	400	0.75
	200	0.4	400	0.75
MgO	150	116	1500	0.15
	100	0.4	1500	0.15

One signature used to indicate tunneling is a nonlinear behavior of the I-V curve. This has been shown at low temperatures for Fe/Ge/Co,[1] and Ni/NiO/(Ni,Fe,Co) junctions. Our I-V characteristics at room temperature are linear over four orders of magnitude, and therefore give no evidence for tunneling across the oxides.

Another signature for tunneling across an insulating barrier comes from the magnetoresistance measurement. Slonzceski's theory for spin tunneling across an insulating barrier[5] predicts that the magnetoresistance is a function of the cosine of the angle between the magnetizations in both electrode layers. In Fig. 1(b) we show the junction structure under study. The easy axis on both electrodes are at 90° to each other, such that we will always have one of the layers in a hard direction when the field is applied along one of the electrode bars. With this structure, one of the magnetizations reverses by rotation, therefore producing a configuration where the angle between the two magnetizations varies from 0° to 180°.

Figure 3 shows the hysteresis loop for a NiFe/Al-Al_2O_3/Co structure where the electrode thickness is 400 Å, oxide thickness is 40 Å, and the junction resistance is 1.0 Ω. The applied field is parallel to the Co easy axis. The NiFe is in a hard-axis direction and should start reversing at a 4 or 5 Oe positive field. This is not observed. The curve is shifted giving rise to 100% remanence at $H=0$. This may indicate a ferromagnetic 2–3 Oe pinhole coupling. Between −5 and −20 Oe the magnetizations of the Co and NiFe layers are antiparallel.

Figures 4(a)–4(d) show the magnetoresistance behavior for the same sample, for different orientations of the applied field, either parallel to the Co easy axis (a), parallel to the NiFe easy axis (b), or at ±45° to the Co easy axis (c) and (d). The main conclusion of these results is that the observed MR comes from the anisotropic magnetoresistance produced by the in-plane current component in each electrode [see Fig. 1(b)]. In Fig. 4(a) the Co reverses by domain-wall motion leading to no AMR. On the other hand, the NiFe is perpendicular to the in-plane current component at saturation, and becomes parallel at near-zero field, leading to the observed positive AMR. In Fig. 4(b) the NiFe now reverses by domain-wall motion (no AMR), and the Co rotates from perpendicular to the in-plane current at saturation to parallel to

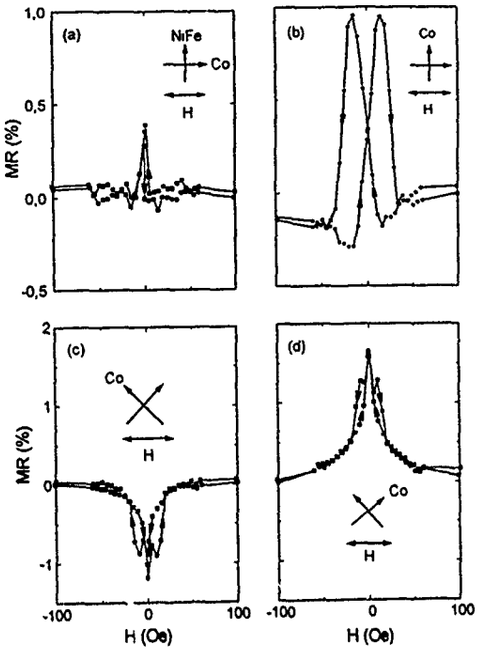

FIG. 4. Magnetoresistance for the same structure shown in Fig. 3, but with the magnetic field applied along different orientations. The angular dependence of the MR comes from the anisotropic magnetoresistance of the ferromagnetic electrodes. Junction resistance is of same order as electrode resistance.

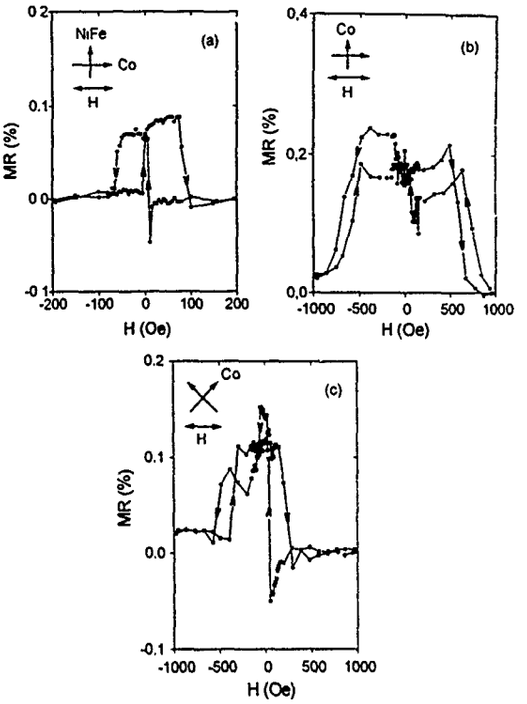

FIG. 5. Magnetoresistance for a NiFe/MgO/Co structure, where the junction resistance is much larger than electrode resistance. No AMR is observed.

the in-plane current at zero field. The definite proof of AMR is the negative magnetoresistance found in Fig. 4(c), where both the NiFe and Co at zero field have magnetization components perpendicular to the current. This result is not unexpected since in this sample the junction resistance is 1.0 Ω, which is of the order of the electrode resistance in the junction area.

On the other hand, on one of the NiFe/MgO/Co samples, the junction resistance is about 800 times larger than the electrode resistance, and it is now possible to probe the junction MR. In this case, the voltage across the electrode arms comes mainly from the junction. Figure 5 shows the measured MR signal, for an electrode thickness of 1500 Å and oxide thickness of 150 Å. Contrary to the sharp positive and negative MR peaks shown in Fig. 4, which are characteristic from electrode AMR, Fig. 5 shows essentially positive MR for all orientations. In Fig. 5(a) plateaus occur in the MR at low fields, when the magnetizations of the electrodes are antiparallel. This geometry, and the measured hysteresis loop is similar to that described in Fig. 3. These MR results are characteristic of tunneling or spin-valve effects.[3,4]

The details of Figs. 5(b) and 5(c) are not yet fully understood, and are being investigated with respect to the possible exchange coupling between MgO and the NiFe or Co layers, and the formation of magnetic oxide compounds at the interfaces. When dielectric breakdown occurred in this same sample, and junction resistance dropped to 3.5 Ω, the electrode AMR became comparable to the junction signal. Again, we emphasize that the MgO junctions show linear I-V curves at room temperature. This may indicate that the observed MR has a different origin than tunneling.

The main conclusion of this study is that further work is needed in order to produce stable, high-resistive junctions, with high dielectric breakdown. Only in this case can the junction contribution to the perpendicular MR be measured. Whether tunneling effects across insulating layers can be observed at room temperature, remains an open question.

Changes in resistivity behavior of metallic glass $Fe_{70}Ni_{12}B_{16}Si_2$ due to molybdenum substitution for nickel

A. K. Bhatnagar[a] and B. Seshu
School of Physics, University of Hyderabad, Hyderabad 500134, India

The changes in the resistivity behavior of metallic glass $Fe_{70}Ni_{12-x}Mo_xB_{16}Si_2$ are reported as a function of Mo substitution (x=0, 2, 4, and 6) for Ni at temperatures between 300 and 1.5 K.

The temperature dependence of the resistivity of many magnetic and nonmagnetic metallic glasses below room temperature results from a number of scattering mechanisms, and localization and Coulomb interaction effects in the highly disordered structures. Metallic glasses with Fe-rich composition based on $Fe_{80}B_{20}$ and $Fe_{80}B_{20-x}Si_x$, which are ferromagnetic, normally show a positive temperature coefficient of resistivity (TCR) at room temperature, and their resistivity exhibits a minimum in its value usually at a temperature (T_{min}) below 20 K. Addition of Ni or Co for Fe in such systems does not shift T_{min} very much but addition of Cr or Mn does change the resistivity substantially as far as T_{min} is concerned. It is known that a substitution of Mo, a nonmagnetic metal, reduces the Curie temperature (T_C) of $Fe_{80}B_{20}$ (Ref. 1) and $(Fe_{1-x}Mo_x)_{75}P_{16}B_6Al_3$ (Ref. 2) appreciably, the effect of Mo being more drastic in the latter glass. On the other hand, substitution of Mo in a metallic glass like $Fe_{70}Ni_{12}B_{16}Si_2$ does not change T_C and magnetic properties as much as in the above two mentioned metallic glasses.[3] The similarity of magnetic properties of Cr and Mo substituted Fe-B-Si glasses has motivated us to investigate whether a similarity in the resistivity behavior also exists in these two types of glasses. We present measurements of the resistivity of the metallic glass system $Fe_{70}Ni_{12-x}Mo_xB_{16}Si_2$. These glasses remain ferromagnetic at room temperature (RT) and below even for x=6. We compare the results with those reported for Cr substitution in ferromagnetic glasses and discuss them qualitatively.

$Fe_{70}Ni_{12-x}Mo_xB_{16}Si_2$ samples (S0, S2, S4, and S6, corresponding to x=0, 2, 4, and 6, respectively) were prepared at Allied Signal. The ribbons were 0.5 cm wide and 20 μm thick. Glassy structure was confirmed by x-ray diffraction and differential scanning calorimetry. The resistance was measured between 300 and 1.5 K using the four-probe dc method. The temperature was changed quasicontinuously with a 5–10 K/h drift in temperature. The samples were enclosed in a double can, one in high vacuum with an inner can for the samples having 0.1 Torr of He gas for good thermal contact. Changes in the resistance with an accuracy of better than two parts in 10^5 were detected. The accuracy in the room-temperature resistivity is determined by geometrical factors. Curie temperature (T_C) determined by a vibrating sample magnetometer as well as by differential scanning calorimetry are in good agreement with each other.

The normalized resistivity $r(T)=\rho(T)/\rho_0$, where ρ_0 is the resistivity at the ice point, is plotted in Figs. 1 and 2 as a function of temperature. Table I lists room-temperature resistivities ρ(RT), temperature coefficient of resistivity (TCR) defined as $[\rho^{-1}(d\rho/dT)]$, assuming linear T dependence of ρ near RT, and Curie temperatures (T_C) for the samples. The resistivity increases with the addition of Mo, the initial increase being about 30% for x=2 after which the change is about 5 $\mu\Omega$ cm/Mo at. %. The TCR, the magnitude of which is typical of most metallic glasses, decreases with increasing room-temperature resistivity, hence with Mo concentration. This is expected from Mooij's correlation.[4] Although samples S4 and S6 have ρ(RT) higher than 150 $\mu\Omega$ cm, the TCRs for these samples are still positive at 300 K.

The temperature dependence of normalized resistivity $r(T)$ (Figs. 1 and 2) exhibits substantial changes as the Mo concentration increases. Sample S0 behaves typically as other iron-rich metallic glasses like $Fe_{80}B_{20}$, with almost linear behavior near 300 K. A minimum in resistivity is observed at 15 K, and below this temperature the resistivity ratio shows a negative TCR. For S2 the temperature dependence becomes less pronounced, and exhibits a resistivity minimum at about 45 K. However, the resistivity minimum is much broader than that for S0. Higher Mo concentration changes the resistivity behavior significantly. The minimum shifts to much higher temperatures. T_{min} values for S4 and S6 are 195 and 232 K, respectively. Because T_{min} for S6 is close to room temperature, its negative TCR range is much

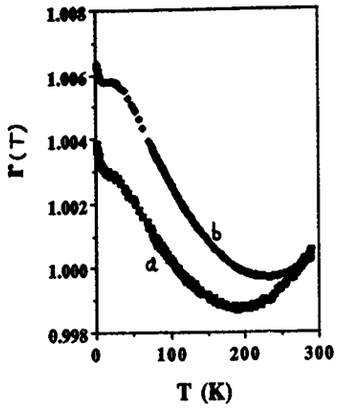

FIG. 2. Normalized resistivity $r(T)$ vs temperature T: (a) $Fe_{70}Ni_8Mo_4B_{16}Si_2$ (sample S4) and (b) $Fe_{70}Ni_6Mo_6B_{16}Si_2$ (sample S6).

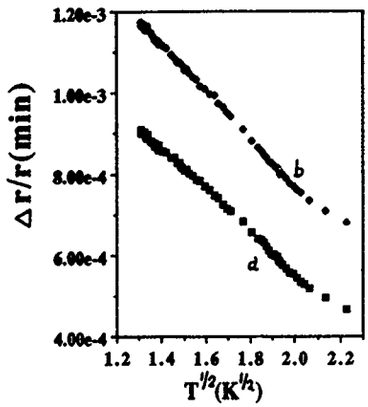

FIG. 3. $\Delta r/r(\min)$ vs $T^{1/2}$ for samples (a) $Fe_{70}Ni_{12}B_{16}Si_2$, and (b) $Fe_{70}Ni_{10}Mo_2B_{16}Si_2$ for $T<T_{min}$.

larger than for the other samples. The total change in resistivity from RT to $T=T_{min}$ for S0 is about 5% while this change is less than 1% for other samples. These figures also show that $r(T)$ of both samples S4 and S6 exhibits a weak maximum followed by another weak minimum at lower temperature. The broad resistivity minimum for S2 may be considered as the precursor to the development of a second minimum. Similar results have been reported for glassy $Fe_{80-x}Cr_xB_{20}$ (Ref. 5) and $Fe_{80-x}Mo_xB_{20}$ (Ref. 1) although it has been reported that T_{min} for glassy $Fe_{80-x}Mo_xB_{20}$ (Ref. 6) increases with x up to $x=4$ but then reduces for $x=6$ while we find that, for our sample S6, T_{min} is larger than that for S4. We speculate that this difference may be due to the presence of Ni in this glass. A reasonable linear correlation between T_{min} and ρ(RT), and T_{min} and T_C within experimental uncertainty is observed. These correlations indicate the possible importance of roles played by the structural disorder and the magnetic property of the samples in addition to other physical mechanisms in determining the behavior of their minimum in resistivity. The temperature at which a local maximum in resistivity is observed for S4 and S6 is practically the same for both samples, while the temperature T_{min2}, at which the second resistivity minimum is observed, decreases slightly with increasing Mo concentration. Values of T_{min} and T_{min2} are listed in Table I. Errors in these values are determined by the flatness of the resistivity variation near these temperatures.

For discussion purposes we shall divide temperature intervals as follows: (1) $T>T_{min}$, (2) $T<T_{min2}$, and (3) $T_{max}<T<T_{min}$. For $T>T_{min}$, the resistivity ratio $r(T)$ can be fitted to a second-order polynomial in T with a linear coefficient of the order of 10^{-4} K^{-1}, and a quadratic coefficient of the order of 10^{-7} K^{-2} between 200 and 300 K indicating the possibility of a contribution from magnetic scattering to the total resistivity.[7] For lower temperatures but above T_{min}, a quadratic fit in T adequately describes $r(T)$ which may include the T^2 magnetic scattering term[7] in addition to the T^2 contribution as predicted by Ziman's theory.[8] Data for S4 and S6 samples were also fitted to the second-order polynomial in T for $T>T_{min}$ which resulted in a linear term with a negative coefficient of about 5×10^{-5} (K^{-1}) and a positive quadratic term of the order of 10^{-7} (K^{-2}). The T^2 term, we believe, is due to the magnetic scattering[7] since the Ziman theory predicts a linear T dependence near RT. The negative linear term is most probably the contribution due to the incipient localization effect as expected from Mooij's correlation with ρ(RT). In the negative TCR region, it is controversial as to whether the increase in $\rho(T)$ of ferromagnetic glasses is due to a "Kondo-type effect," structural disorder induced two level states, or weak localization and Coulomb interaction effects. Numerous reports indicate that the temperature dependence of resistivity of many magnetic and nonmagnetic metallic glasses can be fitted to $T^{1/2}$ reasonably well below T, at which minimum in resistivity is observed, with negative slope as predicted by Coulomb interaction theories.[9] To check whether our samples show the similar trend, we have plotted, in Figs. 3 and 4, $\Delta r/r(\min)=[\rho(T)-\rho(\min)]/\rho(\min)$ vs $T^{1/2}$ for $T<T_{min}$ for S0 and S2, and $T<T_{min2}$ for S4 and S6. It is seen that it exhibits a linear behavior, and that the slopes for all of these samples are approximately constant (-5×10^{-4} $K^{1/2}$). A similar observation was reported for $Fe_{80-x}Cr_xB_{20}$ samples for $x<20$.[5] According to the Coulomb interaction theory,[9] the major contribution to the resistivity arises from the diffusion channel which predicts an additional term to the conductivity, which in absence of spin-orbit interaction is given by[5]

$$\sigma_D(H,T)=\frac{1.3}{\sqrt{2}}\frac{e^2}{4\pi^2\hbar}\left(\frac{k_BT}{\hbar D}\right)^{1/2}\times\left\{\frac{4}{3}+\lambda^{J=1}(F)\left[\frac{3}{2}+\frac{g_3(h)^2}{1.3}\right]\right\},$$

where

6	161	1.38×10^{-5}	232±2	20±2	10±2	476

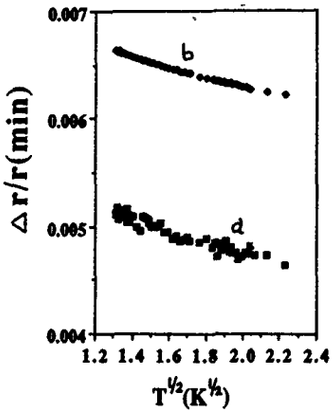

FIG. 4. $\Delta r/r(\min)$ vs $T^{1/2}$ for samples (a) $Fe_{70}Ni_8Mo_4B_{15}Si_2$, and (b) $Fe_{70}Ni_6Mo_6B_{16}Si_2$ for $T<T_{min2}$.

$$\lambda^{j=1}(F)=\frac{32}{3F}\left[1+\frac{3F}{4}-\left(1+\frac{F}{2}\right)^{3/2}\right]$$

is a measure of the electron-phonon interaction. The function $g_3(h)$, where $h=g\mu_B H/k_B T$, has the asymptotic form $0.056h^2$ for $h\ll 1$ and $(h^{1/2}-1.3)$ for $h\gg 1$. Various constants have the usual meaning. We have calculated an upper limit for D, the diffusion constant, from this expression by taking the limit $\lambda^{j=1}=0$ and find it to be $\sim 3.5\times10^{-5}$ and 7.8×10^{-5} m^2/s for S0 and S6 samples. These are typical values (within a factor of 2) reported for other metallic glasses. Hence, the assumption that the temperature dependence of the resistivity of $Fe_{70}Ni_{12-x}Mo_xB_{16}Si_2$ at temperatures below 10 K is dominated by the Coulomb interaction effects seems to be a reasonable one.

We have also plotted $\Delta r/r(\min)$ vs $T^{1/2}$ for S4 and S6 in the region $T_{max}<T<T_{min}$ in Fig. 5 since these samples show two minima in $\rho(T)$. It is clearly seen that $\Delta r/r(\min)$ shows

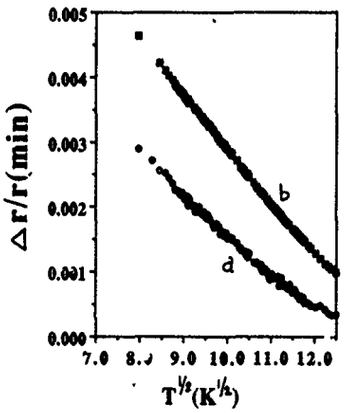

FIG. 5. $\Delta r/r(\min)$ vs $T^{1/2}$ for samples (a) $Fe_{70}Ni_8Mo_4B_{16}Si_2$, and (b) $Fe_{70}Ni_6Mo_6B_{16}Si_2$ for $T_{max}<T<T_{min}$.

a linear dependence on $-T^{1/2}$ in this temperature interval also. We also find that $\Delta r/r(\min)$ for these samples can be fitted to an expression $(a-b\ln T)$ equally well in this temperature interval which is predicted by either two-level tunneling or Kondo-type magnetic scattering,[10] however, the coefficient b is about one order of magnitude greater than that found for $Fe_{80}B_{20-x}C_x$ and similar metallic glasses.[7] The slope of $\Delta r/r(\min)$ vs $T^{1/2}$ in this temperature range is only about one and a half times larger than that found below T_{min2}. Whether this $T^{1/2}$ temperature dependence is due to Coulomb interaction effects or not is difficult to conclude at this time although one would expect these effects not to be appreciable at such large temperatures. Most probably, the higher-temperature region has resistivity contributions from other mechanisms, e.g., magnetic scattering, localization effects, etc., as well, and one needs to do additional measurements like the magnetic field dependence of $r(T)$ to get a better understanding.

Thus, the resistivity behavior of $Fe_{70}Ni_{12-x}Mo_xB_{16}Si_2$ is similar to that of Fe-Cr-B metallic glasses,[3] i.e., the temperature dependence of resistivity shows two minima as Mo concentration is increased. Since it is very difficult to make high concentration Mo amorphous samples, it is difficult to determine whether T_{min} (observed at larger temperatures) would start decreasing for large Mo concentration samples or not. Similarity of Mössbauer spectra of Mo and Cr substituted Fe-B-Si/Fe-Ni-B-Si and Fe-B-Cr samples, the fast decrease in Curie temperature with concentration, and the similar behavior of resistivity indicates that Mo in these glasses induces an "interaction" similar to that of Cr. It has been suggested[2] that this interaction is an "antiferromagnetic" type based on the observations of the fast decrease of Curie temperature of $(Fe_{1-x}Mo_x)_{75}P_{16}B_6Al_3$ with increasing Mo concentration, and the similarity of Mössbauer spectra of $Fe_{80-x}M_xB_{20}$ (M=Cr, Mo). A more detailed analysis and measurements of the magnetic field dependence of the resistivity minima and maximum need to be done in order to fully elucidate the role of Mo in this metallic glass system. Such measurements are in progress.

We thank Dr. V. R. V. Ramanan for providing samples. This work was supported at the University of Hyderabad by the Department of Atomic Energy (India), and at Texas A & M by the Robert A. Welch Foundation (A-0514).

We report the results of dc magnetization and electrical resistivity studies of a single-domain $Al_{70}Ni_{15}Co_{15}$ decagonal quasicrystal. The temperature dependence and anisotropy of the electrical resistivity are in excellent agreement with previous results for a similar sample. The magnetic properties were determined by superconducting quantum interference device magnetometry over the temperature range 1.8–300 K for magnetic fields between 10 Oe and 10 kOe. The magnetic behavior can be characterized by a weak ferromagnetic component $M_0(H)$ which saturates in moderate fields ($H \approx 1$ kOe) and a differential susceptibility, $\chi_0 = \Delta M/\Delta H$, obtainable from the high-field data. The observed magnetization $M = \chi_0 H + M_0$ is slightly anisotropic and essentially temperature independent below room temperature. For H parallel to the quasicrystal axis, we observe $\chi_{0\parallel} = 7.1 \times 10^{-7}$ emu/g and $M_{0\parallel} = 2.0 \times 10^{-3}$ emu/g. For H perpendicular to the quasicrystal axes, we obtain $\chi_{0\perp} = 8.2 \times 10^{-7}$ emu/g and $M_{0\perp} = 1.7 \times 10^{-3}$ emu/g. An anisotropic and weak superconducting transition was observed at $T = 3.2$ K, corresponding to a superconducting volume fraction of only $\sim 10^{-3}$.

Although a great deal of experimental effort has been directed at understanding the unusual nature of quasicrystalline materials,[1] only recently, with the discovery of the two-dimensional decagonal quasicrystals,[2,3] has it been possible to make a direct comparison between properties in the quasicrystalline and periodic directions of the same material. The decagonal quasicrystalline material $Al_{70}Ni_{15}Co_{15}$ was recently[4] shown to exhibit appreciable transport anisotropy. In this work, we verify the transport properties observed in Ref. 4 and present the results of dc magnetic measurements; the magnetic data indicate a weak anisotropy in the conduction electron susceptibility and the presence of small quantities of both ferromagnetic and superconducting inclusions in the single-domain $Al_{70}Ni_{15}Co_{15}$ quasicrystal studied.

The single-grain crystal used in this study ($\sim 0.6 \times 0.6 \times 3$ mm^3) was prepared and characterized in a similar manner to that used for specimens previously described.[5] The temperature dependence of the anisotropic resistivity was determined from conventional four-terminal measurements with careful placement of voltage and current leads. The magnetic data were obtained at temperatures in the range 1.8–300 K using a Quantum Design model MPMS superconducting quantum interference device (SQUID) magnetometer. Because of the small signal from the ~7 mg quasicrystal, a custom sample holder was employed which utilized a cancellation of Pauli paramagnetic and Langevin core diamagnetic contributions, resulting in an extremely low background signal. For example, at $T = 50$ K with $H = 10$ kOe, a background moment of only $\sim 1 \times 10^{-6}$ emu was obtained, compared to the quasicrystal moment of $\sim 6 \times 10^{-5}$ emu (i.e., only a 1–2% typical correction). A point-by-point subtraction of the sample holder background was used for all data to avoid possible nonlinearities in the background response. For the observed susceptibilities, demagnetization effects were negligible.

Figures 1 and 2 both define the geometries used in this study and show the results of the electrical resistivity measurements. The resistivity in the periodic direction (perpendicular to the quasicrystal axes) of Fig. 1 exhibits the positive temperature coefficient expected for delocalized electronic states in a metal. However, in the quasiperiodic

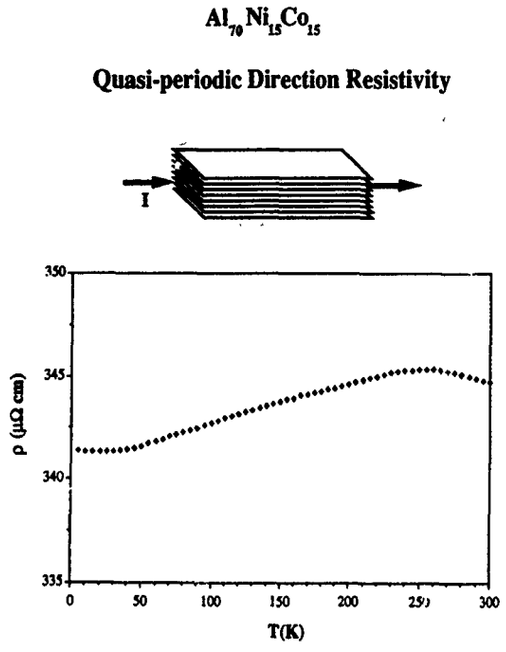

FIG. 2. The resistivity in the quasicrystalline direction as a function of temperature for a single-domain specimen of the decagonal quasicrystal $Al_{70}Ni_{15}Co_{15}$.

direction, Fig. 2, we observe the resistivity to increase with decreasing temperature between ~250 and 300 K, and then decrease before levelling off at low temperatures. As mentioned above, this result is in good agreement with a previous study[4] using the Montgomery method, where such nonmetallic behavior was argued to be consistent with phonon-assisted tunneling of carriers in extended states.

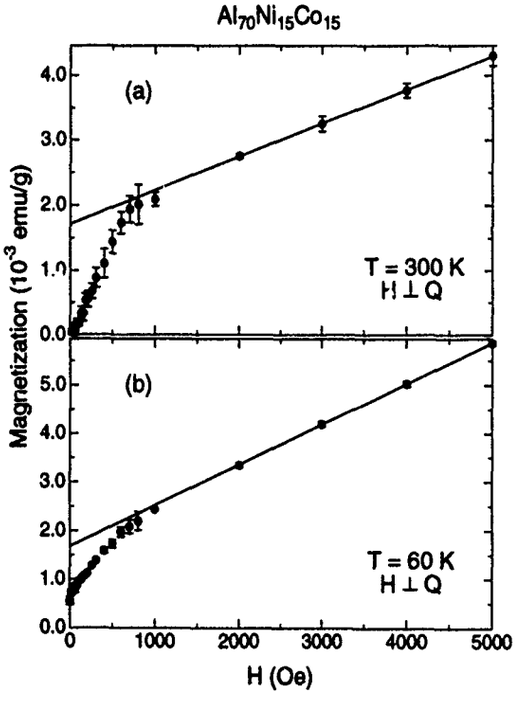

FIG. 3. Isothermal magnetization at (a)$T=300$ K and (b)$T=60$ K as a function of magnetic field applied parallel to the periodic direction of $Al_{70}Ni_{15}Co_{15}$.

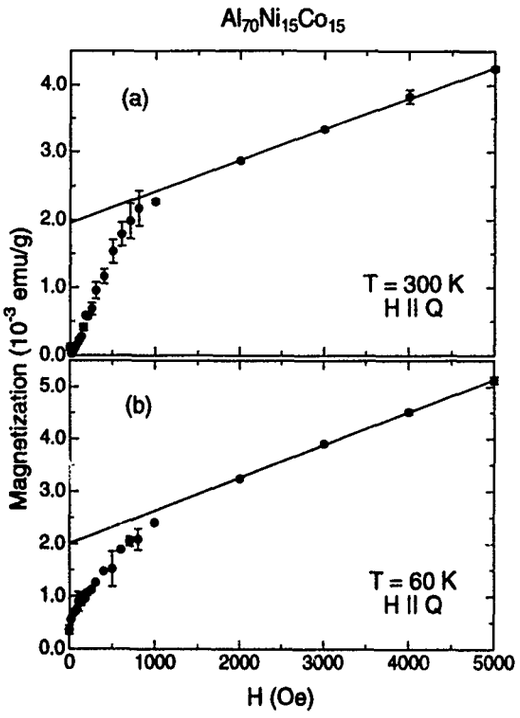

FIG. 4. Isothermal magnetization at (a) $T=300$ K and (b) $T=60$ K as a function of magnetic field applied parallel to the quasicrystalline direction of $Al_{70}Ni_{15}Co_{15}$.

In Figs. 3(a) and 3(b) are shown isothermal magnetization data as a function of the external magnetic field, taken with the field perpendicular to the quasicrystalline axes, for $T=300$ and 60 K, respectively. Similar data are shown in Fig. 4 for the magnetic field applied parallel to a quasicrystalline axis. The nonlinear behavior may be characterized by a ferromagnetic component which saturates in moderate fields ($H\approx 1$ kOe) followed by the more usual linear increase in magnetization with field at higher fields. Several observations are in order. First, the overall behavior is nearly isotropic and essentially temperature independent. Such temperature-independent behavior implies that whatever is responsible for the ferromagnetic component (whether it be clusters, inclusions, or paramagnons) cannot be attributed to extremely small nanoclusters, which would be expected to exhibit superparamagnetic behavior above some blocking temperature. Second, the ferromagnetic component exhibits remanence at 60 K [note the y intercept of the data in Figs. 3(b) and 4(b)], which disappears at room temperature. The lines in Figs. 3 and 4 are linear fits to the high-field region where the ferromagnetic component has presumably saturated. The intercepts of these lines with the magnetization axes provide the saturated moment of the ferromagnetic component, with temperature-independent values of $M_{0\perp}=(1.7\pm0.1)\times10^{-3}$ emu/g for H perpendicular to the quasicrystal axes and $M_{0\parallel}=(2.0\pm0.1)\times10^{-3}$ emu/g for H parallel to the quasicrystal axis. If the anisotropy in M_0 is attributed to shape anisotropy of the possible inclusions or

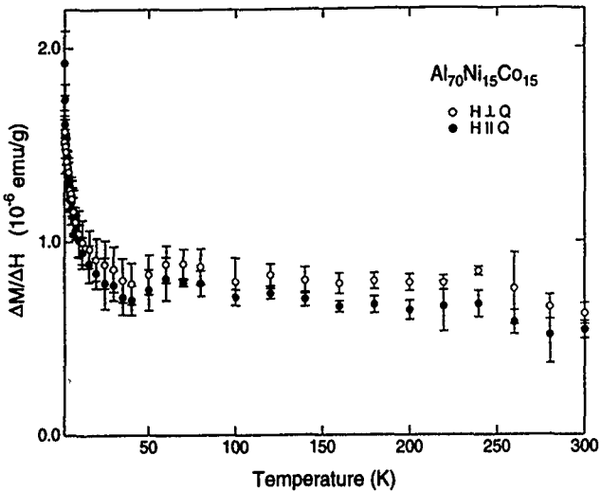

FIG. 5. High-field differential susceptibility, $\chi_0 \equiv \Delta M/\Delta H$, as a function of temperature for magnetic fields applied both perpendicular (open circles, $H \perp Q$) and parallel (filled circles, $H \| Q$) to the quasicrystalline direction of $Al_{70}Ni_{15}Co_{15}$.

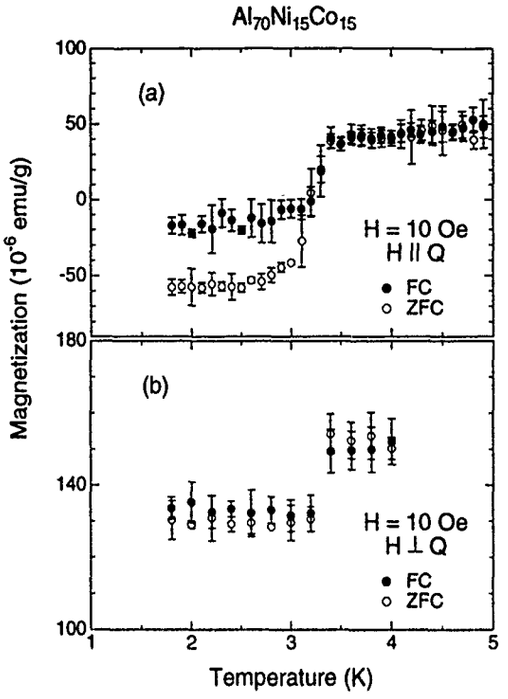

FIG. 6. Magnetization as a function of temperature in a field $H=10$ Oe applied (a) parallel to the quasicrystalline direction and (b) perpendicular to the quasicrystalline direction for $Al_{70}Ni_{15}Co_{15}$. Both zero-field cooled (ZFC) and field-cooled (FC) data are shown.

clusters, this would imply (for ferromagnetism) that their shape is prolate with the shorter axis perpendicular to the quasicrystal direction, a reasonable result. We point out, however, that the observed values of M_0 correspond to only about $1\times10^{-3}\mu_B$ per formula unit of $Al_{70}Ni_{15}Co_{15}$, a rather small ferromagnetic component.

To obtain the underlying field-independent susceptibility (the slope of the lines in the high-field regions of Figs. 3 and 4), magnetization data were taken as a function of temperature between 1.8 and 300 K for applied fields $H=5$ and 10 kOe. The intrinsic susceptibility was then defined by $\chi_0 \equiv \Delta M/\Delta H$. The results are shown in Fig. 5. The data are essentially temperature independent between about 30 and 250 K, with a Curie-like impurity tail at low temperatures. The Curie-like term corresponds, for example, to only $\sim 2\times10^{-3}$ free Co^{2+} moments per formula unit of $Al_{70}Ni_{15}Co_{15}$. A small but persistent anisotropy in the value of χ_0 is observable in Fig. 5. The average values of the data for temperatures between 30 and 250 K are $\chi_{0\perp}=8.2\times10^{-7}$ emu/g and $\chi_{0\|}=7.1\times10^{-7}$ emu/g. Such values are appreciably higher than that reported[4] for $Al_{65}Cu_{15}Co_{20}$, where $\chi_0 \approx -1\times10^{-7}$ emu/g; that small value was attributed to a nearly *sp*-like band at the Fermi energy. The larger value for $Al_{70}Ni_{15}Co_{15}$ is somewhat unexpected, given the similar transport properties of the two materials. If one estimates a contribution to χ_0 due to core diamagnetism of $\chi_{\text{core}} \approx -1.5\times10^{-7}$,[6] the bare density of states from the resulting χ_0 value is $N(E_F) \approx 160$ states eV^{-1} per formula unit of $Al_{70}Ni_{15}Co_{15}$, or $N(E_F) \approx 1.6$ states eV^{-1} $atom^{-1}$. However, this may be an overestimate, since we have neglected any possible Van Vleck paramagnetism (e.g., due to Co^{3+}), which is difficult to determine.

Finally, in Fig. 6, we show magnetization data as a function of temperature taken under both zero-field-cooled (ZFC) and field-cooled (FC) conditions in a field of $H=10$ Oe. A weak superconducting transition is observable at $T=3.2$ K; the strength of the signal corresponds to a superconducting volume fraction of only $-4\pi\chi_v \approx 10^{-3}$. One candidate for superconductivity in this temperature regime would be inclusions of amorphous aluminum. The signal for $H \| Q$ (Q is the quasicrystalline direction) is about five times larger than for $H \perp Q$. Such behavior is opposite of that expected for demagnetization effects due to prolate inclusions parallel to the quasicrystalline planes; however, for small inclusions, penetration depth effects may dominate shape anisotropy.

In summary, we have reported electrical resistivity and dc magnetization measurements on a single-domain decagonal quasicrystal of $Al_{70}Ni_{15}Co_{15}$. The anisotropic resistivity was in good agreement with earlier measurements. Weak superconducting, Curie-like, and ferromagnetic contributions were observed, presumably due to defects. A dominant temperature-independent susceptibility of $\sim 7\times10^{-7}$ emu/g, with $\sim 10\%$ anisotropy, was observed.

Mössbauer effect investigation of the pentagonal approximant phase in the Fe-Nb system

R. A. Dunlap, J. Kyriakidis, and M. Yewondwossen
Department of Physics, Dalhousie University, Halifax, Nova Scotia B3H 3J5, Canada

The formation of the pentagonal Frank–Kasper phase (μ phase) in the $Fe_{50+x}Nb_{50-x}$ system near $x=0$ has been investigated. The effects of composition and heat treatment on the phase diagram of this system have been studied. Only the as-cast $x=0$ alloy was found to consist of a pure μ phase. X-ray diffraction patterns indicate the existence of a phase with a high degree of structural order but considerable chemical disorder. A Mössbauer spectrum of the μ-phase material exhibits a room-temperature quadrupole split doublet with $\Delta=0.209$ mm/s and an isomer shift $\delta=-0.289$ mm/s relative to α-Fe. A shell model analysis of the spectrum indicates a structure with a high degree of order. Results are discussed in terms of measurements on related icosahedral and decagonal phase materials.

I. INTRODUCTION

Mössbauer effect studies of quasicrystals have been important for an understanding of the microstructure of these novel materials. A recent review of these studies has been presented by Dunlap and Lawther.[1] A number of methods for the interpretation of Mössbauer spectra of quasicrystalline materials have been presented in the literature and the information which can be obtained from these measurements depends crucially on the techniques applied to their analysis. The comparison of results from quasicrystalline materials and those of related crystalline phases has been important in understanding the relationship of Mössbauer spectral parameters and microstructural details. In the present work we have considered Mössbauer measurements of the pentagonal approximant phase in the Fe-Nb system. These results will be interpreted in the context of results for related quasicrystalline materials.

II. EXPERIMENTAL METHODS

Samples of $Fe_{50+x}Nb_{50-x}$ were prepared by melting high-purity elemental components in an argon arc furnace for compositions with $x=0,2$. Materials were studied as-cast and after annealing for four days at 1000 °C and water quenching. Room-temperature Cu K_α x-ray diffraction patterns were made of all samples using a Siemens D500 scanning diffractometer. Room-temperature ^{57}Fe Mössbauer effect studies were performed using a constant acceleration Wissell System II spectrometer and a $Pd^{57}Co$ source. The intrinsic linewidth of the spectrometer for ^{57}Fe is 0.23 mm/s (FWHM).

III. RESULTS

All alloys studied here showed the presence of the pentagonal μ phase. However, only the as-cast $x=0$ sample was free from the presence of impurity phases. This analysis is consistent with the phase formation studies of the Fe-Nb system reported by Raman.[2] Further investigations presented in the present manuscript are confined to the single-phase sample.

X-ray diffraction peaks for the μ phase were well defined with a typical linewidth of $\Delta(2\theta)\leq 0.2°$ (FWHM), indicating a high degree of structural order. The peak locations and relative intensities obtained in this work along with those calculated for the μ phase (W_6Fe_7 structure) with $a=4.928$ Å and $c=26.83$ Å are given in Table I. The peak locations are in excellent agreement with the calculated values[3] for the lattice parameters as indicated above. The anomalies in the measured intensities for some of the diffraction peaks are an indication of the presence of substantial chemical disorder on the lattice sites.

The room-temperature ^{57}Fe Mössbauer effect spectrum of the pentagonal phase of Fe-Nb is illustrated in Fig. 1. This spectrum shows the existence of a symmetric quadrupole split doublet. Although the individual lines cannot be resolved, the shape and width of the absorption peak indicate that it is not a singlet. A fit to this spectrum using a Lorentzian doublet yields the mean quadrupole parameters as indicated in Table II. The linewidth of the component lines, 0.29 mm/s, is slightly greater than the intrinsic linewidth of the spectrometer but is substantially less than that found for similar fits to spectra of quasicrystalline materials; typically

about 0.36 mm/s.[1] This excess linewidth is, presumably, the result of local disorder in the structure as evidenced by the anomalous x-ray peak intensities and which produces a corresponding distribution of local Fe environments. This behavior can be accounted for in the analysis of the Mössbauer effect spectrum by fitting the data to a shell model distribution of quadrupole splittings of the form[1,4]

$$P(\Delta)=\left(\frac{\Delta}{\sigma}\right)^{n}\exp\left(-\frac{\Delta^{2}}{2\sigma}\right), \qquad (1)$$

where n and σ are fitted parameters. The symmetric nature of the spectrum indicates the lack of correlation between isomer shift and quadrupole splitting distributions. A detailed computer analysis confirms this assumption. The results of the shell model analysis for this spectrum are given in Table III and the calculated $P(\Delta)$ is illustrated in Fig. 2.

IV. DISCUSSION AND CONCLUSIONS

The existence of a decagonal[9] and icosahedral[10] phase in the Fe-Nb system has been demonstrated by electron diffraction studies of rapidly quenched samples; although single-phase materials have not yet been prepared. Table I compares the mean quadrupole parameters of the pentagonal Fe-Nb phase with several other icosahedral and decagonal materials. The mean quadrupole splitting of Fe-Nb is somewhat less than in Al-based icosahedral[5] and decagonal[7] alloys where Fe atoms are believed to exist in a highly anisotropic environment analogous to the transition metal site environments in the outer shell of the MacKay icosahedra of a cubic approximant phase (e.g., α-AlMnSi) or in the sites of a two-dimensional Penrose tiling, respectively. On the other hand, the quadrupole splitting of Fe-Nb is much greater than that in typical Ti-based icosahedral alloys.[11,12] where the Fe atoms are believed to reside in highly symmetric sites at the center of an icosahedral cluster.

The negative isomer shift observed in this alloy is indicative of an anomalously high electron density at the Fe probe sites. This is expected on the basis of the presence of a large concentration of early transition metal (M) atoms in the alloy. The value of δ observed here is consistent with measurements of dilute MFe alloys and near neighbor effects of dilute M impurities in Fe (see Ref. 13 and references therein).

The parameters obtained from shell model fits to several quasicrystalline alloys are compared with the data for pentagonal Fe-Nb in Table III. The present results are anomalous in two respects; an unusually large value of the parameter n and an unusually low value of the parameter σ, when compared with all results for quasicrystalline alloys reported to date.[1] The relationship of these parameters to the detail of the microstructure has been discussed by Dunlap *et al.*[8] Specifically, n near unity and a large value of σ are characteristic of a highly disordered (e.g., amorphous) structure, while increasing values of n (and correspondingly smaller values of σ) are characteristic of an increase in the degree of microstructural order. This inverse correlation between the values of n and σ is characteristic of the relationship between the shell model and the distribution of local Fe environments in the material and is illustrated for typical data for quasicrystalline and related materials in Fig. 3. Typically quasicrystalline materials have values of n in the range of 1–2, with more highly ordered materials (as evidenced from other ex-

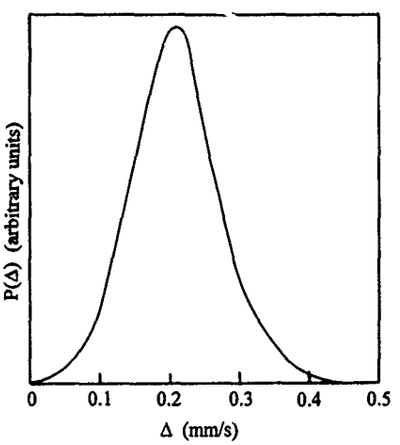

FIG. 2. Quadrupole splitting distribution, $P(\Delta)$, for the spectrum of Fig. 1 as obtained from the shell model.

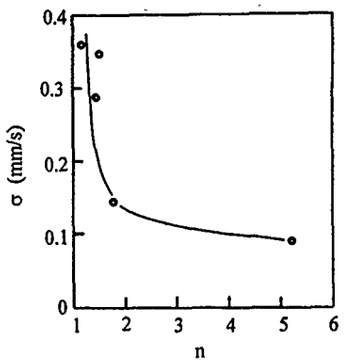

FIG. 3. Relationship between the shell model fitting parameters n and σ for several quasicrystalline and related materials.

perimental techniques) giving $n \approx 2$. The value of $n=5.2$ obtained in the present work for pentagonal Fe-Nb indicates a much greater degree of order in this crystalline approximant phase than in similar quasicrystalline phases. This, presumably, is indicative of the existence of translational symmetry in the approximant phase which is lacking in the quasicrystalline phase. In more specific terms, n is related to the number of independent distortion vectors d, which are necessary to describe the structure as $n=d-1$. The present studies clearly point to the differences which exist between the microstructure of quasicrystals and their crystalline approximants.

Short period oscillations in the Kerr effect of 4*d*- and 5*d*-transition metal wedges on Co films (invited) (abstract)

A. Carl and D. Weller
IBM Almaden Research Center, San Jose, California 95120-6099

We report a novel type of short period oscillations in electron-beam evaporated Co films covered with wedge-shaped films of Pt, Au, and Pd. Oscillatory behavior, with periods in the range 2–3 Å, is observed both in the saturation polar Kerr angle and in the high field susceptibility, as a function of the wedge position (see Fig. 1). The structures of the type buffer/Co/X wedge/Y cap were made by high vacuum evaporation using fused silica as substrates. They consist of a 200 Å Pt buffer layer, a thin Co layer revealing a perpendicular easy magnetization axis, a transition metal wedge (X) with thickness in the range 0–25 Å, and a thin Cu or Au cap (Y) layer. The presence of oscillations depends critically on the choice of the cap-layer Y. They are distinctly different from long and short range period oscillations observed in magnetic sandwich or multilayer structures, since there is only one magnetic film involved. The present results will be discussed in the framework of spin polarized quantum well states.

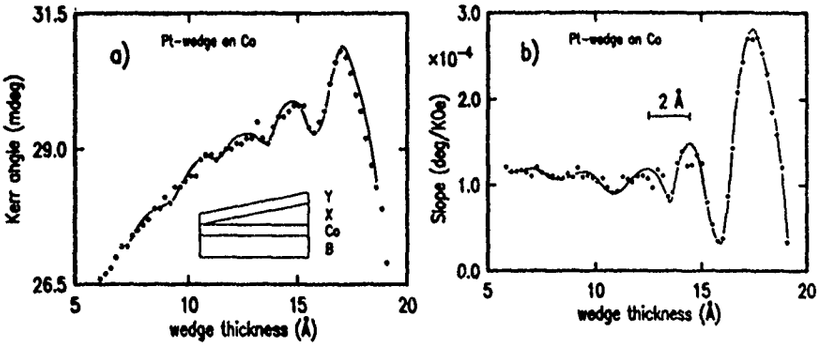

FIG. 1. Oscillatory behavior as a function of the wedge position.

Magnetoresistance of CuNiCo ternary alloys (abstract)

R. S. Beach, D. Rao, and A. E. Berkowitz
Center for Magnetic Recording Research, University of California, San Diego, La Jolla, California 92093

Magnetoresistance (MR) measurements on four film samples of the ternary alloy CuNiCo were performed at room temperature in fields $H \leq 20$ kOe. Following growth by sputtering onto thermally oxidized Si substrates, the films (100–200 nm thick) were annealed between 1 and 6 h at temperatures $T_A = 200$, 350, 500, and 700 °C. The samples display anisotropic magnetoresistances (AMR) for $H < 100$ Oe of up to 3% at room temperature for $Cu_{20}Ni_{53}Co_{27}$ ($T_A = 350$ °C). Despite the fact that in the bulk these alloys tend to phase separate into Co rich and Co poor regions, we find evidence for giant magnetoresistance (i.e., an isotopic negative component to the MR) in only one sample, $Cu_{51}Ni_{17}Co_{31}$, after a 6 h, 700 °C anneal. In the as-deposited condition, samples $Cu_{20}Ni_{53}Co_{27}$ and $Cu_{13}N_{41}Co_{46}$ display a pronounced asymmetry between the resistance decrease for H applied perpendicular to the current I and the corresponding increase for H parallel to I which substantially exceeds the 1:2 ratio in bulk materials or the 1:1 ratio expected for a thin film. The large observed values of AMR (more evident in samples with low Cu concentrations) are likely linked to AMR in binary CuCo alloys, which are known to exhibit large AMR.[1] The disparity between the MR for H parallel and perpendicular to the current we attribute to magnetic anisotropy induced during fabrication.

Enhancement of the localized behavior in $CeNi_{0.8}Pt_{0.2}$ Kondo compound replacing Ce by magnetic ions (Pr,Nd)

J. C. Gómez Sal

The substitution of Ce by magnetic ions such as Pr or Nd in the $CeNi_{0.8}Pt_{0.2}$ Kondo ferromagnetic compound not only favors the magnetic interactions increasing the Curie temperatures, but also disturbs the coherence of the Kondo lattice state leading to a decrease of the Kondo temperatures and an increase of the Ce intrinsic magnetic moment. These effects have been studied by resistivity, magnetization, and neutron diffraction.

$CeNi_xPt_{1-x}$ is among the cerium-based compounds one of the systems which presents a clear relationship between the cerium state and the cell volume.[1] The orthorhombic CrB-type structure is kept through the whole series from CePt to CeNi. The variation of the cell volume gives rise to changes in the magnetic properties according to the rule "the $4f$-sd conduction-band hybridization increases with decreasing cell volume." The substitution of Ce ions by nonmagnetic Y or La strongly supports this fact.[2] A mostly localized Ce^{3+} behavior is observed for the larger volume compounds (CePt or $Ce_{1-y}La_yNi_xPt_{1-x}$) while CeNi or $Ce_{1-y}Y_yNi_{0.8}Pt_{0.2}$, with smaller volumes, show an enhanced Pauli paramagnetism or Kondo impurity behavior. From CePt, the compounds are Kondo ferromagnets with T_K (Kondo temperature) increasing with the decreasing volume. $CeNi_{0.8}Pt_{0.2}$ is the compound with the largest T_c (Curie temperature) but close to the crossover between the localized and delocalized regime, according to the Doniach diagram.[3]

Recent specific-heat measurements[4] give electronic coefficients γ with a maximum ($\gamma \approx 200$ mJ/K^2 mol) for $CeNi_{0.8}Pt_{0.2}$. The description of C_{mag} and the relative variation of T_K and γ along the series could be interpreted in the framework of an $S=1/2$ resonant level model extended to Kondo lattices using a mean field approach as developed by Bredl, Steglich, and Schotte.[5] Neutron-diffraction studies[6] allowed us a direct estimation of the Ce intrinsic magnetic moment. As can be seen in Fig. 1, the magnetic moment is much smaller than that of the free Ce^{3+} ion ($2.14\mu_B$) and it progressively reduces with the Ni concentration as a consequence of the enhancement of the hybridization, showing the increasing importance of Kondo interactions with the volume decrease. It is worth to mention that the diluted (La or Y) compounds have magnetic moments according to the corresponding volume effects (see Fig. 1).

The substitution of Ce by magnetic atoms such as Pr or Nd must not only produce a decrease of the volume but also have a direct influence on the magnetic interactions. We present here the resistivity, magnetization, and neutron-diffraction studies performed in two diluted compounds: $Ce_{0.9}Pr_{0.1}Ni_{0.8}Pt_{0.2}$ and $Ce_{0.9}Nd_{0.1}Ni_{0.8}Pt_{0.2}$, referred to as (Pr) and (Nd) henceforth. These experiments are compared with the results from the "nondiluted compound" $CeNi_{0.8}Pt_{0.2}$, referred to as (Ce). Resistivity, magnetization, and neutron-diffraction experiments were performed at the Universidad de Cantabria, at the Laboratoire Louis Néel (Grenoble), and on the D1B diffractometer of the ILL (Grenoble), respectively.

We have not observed drastic changes in the general shape of resistivity due to the Pr or Nd substitution (Fig. 2).

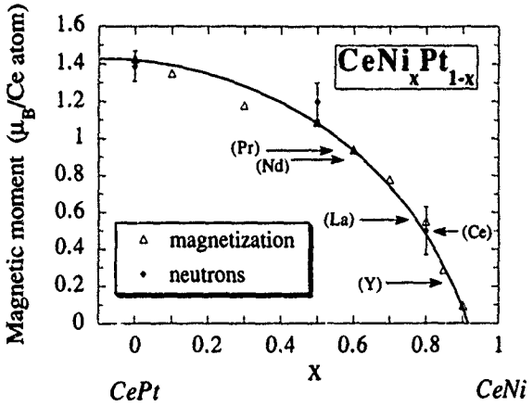

FIG. 1. Magnetic moment of the Ce atoms as a function of the Ni content in the $CeNi_xPt_{1-x}$ series. The moments of the diluted compounds have been situated with arrows pointing to the solid line used as a visual guide.

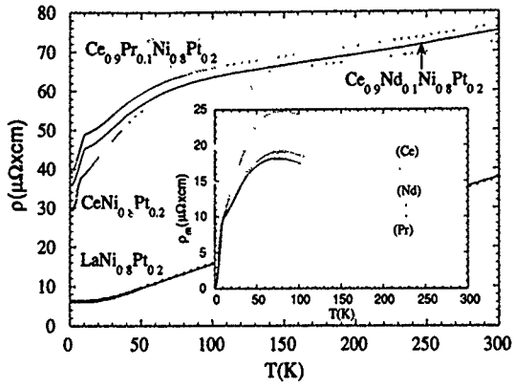

FIG. 2. Thermal variation of the electrical resistivity. Insert: magnetic contribution to the resistivity ρ_m.

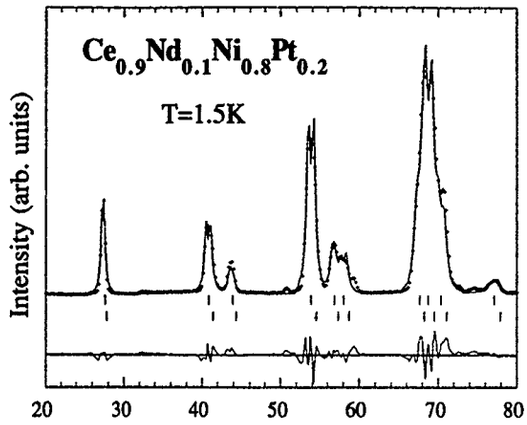

FIG. 4. Rietveld refinements of the neutron-diffraction patterns for $Ce_{0.9}Nd_{0.1}Ni_{0.8}Pt_{0.2}$ at 1.5 K. Vertical marks correspond to the reflexion of the two crystalline observed phases. $Ce_{0.9}Pr_{0.1}Ni_{0.8}Pt_{0.2}$ presents a similar pattern.

The magnetic contributions, obtained by subtraction of the isomorphous $LaNi_{0.8}Pt_{0.2}$ resistivity and a constant residual resistivity term, present a broad maximum attributed to the crystal-field effects which are quite strong in these low-symmetry compounds. The position of the maximum, which is related to the crystal-field-level scheme, does not seem to be very sensitive to the introduction of these small concentrations of Pr and Nd. The negative slope of ρ_{mag} at high temperatures is related to Kondo interactions, being slightly reduced by Nd or Pr substitutions. The Curie temperatures 10.2 and 9.8 K, deduced from the kinks in (Pr) and (Nd) respectively, are slightly higher than that of $CeNi_{0.8}Pt_{0.2}$ (8.6 K) and they coincide with those obtained from the Arrot plots of the magnetization measurements.

The magnetization curves at 1.5 K for the three compounds are presented in Fig. 3. They are characteristic of a ferromagnetic behavior but the (Pr) and (Nd) curves present a notably larger magnetization. At 80 kOe they are far from saturation. The extrapolated values of M ($H=0$, $T=1.5$ K) are 0.28, 0.35, and $0.34\mu_B$/formula for (Ce), (Pr), and (Nd), respectively, thus showing the enhancement of the effective magnetic moment on the rare-earth site. The reciprocal susceptibilities follow a Curie–Weiss law with averaged effective magnetic moments very close to the Ce^{3+} free-ion value and leading to paramagnetic Curie temperatures. $\theta_p=-49$, -40 K, and -43 K, for (Ce), (Pr), and (Nd), respectively.

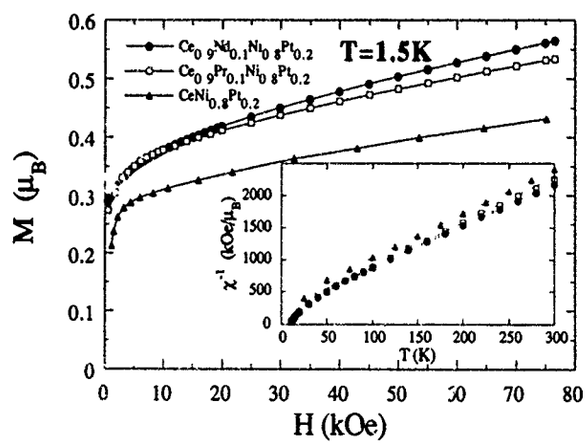

FIG. 3. Magnetization curves at 1.5 K. Insert: thermal dependence of the reciprocal susceptibility.

The neutron-diffraction patterns (Fig. 4), present the same characteristics of the rest of the series and previous diluted compounds.[6] All of these compounds, prepared in a cold crucible induction furnace and annealed for a few days, present a splitting on the peaks corresponding to the CrB structure. The only way to interpret such diagrams is to consider a kind of spinodal segregation of phases of the same structure with slight differences in the cell parameters. With these hypotheses the Rietveld refinements give quite accurate fits, assuming that Pr or Nd atoms are randomly distributed in the same ($4c$) site occupied by Ce atoms. The obtained crystallographic data are presented in Table I. As expected, we find a slightly smaller volume for (Pr) or (Nd).

The diagrams obtained at 1.5 K (in the ordered range) do not present supplementary new peaks, but only an increase of the intensity of some of them. The magnetic peaks are the same as those detected in other magnetic compounds of this system,[6] corresponding to the same collinear ferromagnetic structure, with the magnetic moments in the c direction. Due to the weak magnetic contributions, the determination of the magnetic structure has been performed from the difference diagrams (1.5–15 K) using the Rietveld method.[7]

The magnetic intensities are noticeably higher for (Pr) or (Nd) than for $CeNi_{0.8}Pt_{0.2}$. In order to estimate the Ce magnetic moment value, we have considered an average magnetic moment $\langle\mu\rangle=0.9\mu_{Ce}+0.1\mu_{(Pr\text{ or }Nd)}$ in each rare-earth ($4c$) site, taking $\mu_{Pr}=3.20\mu_B$ and $\mu_{Nd}=3.27\mu_B$ which correspond to the free-ion values $\mu=g_J J\mu_B$. Then, the only parameter to be fitted is the μ_{Ce} value. The magnetic rare-earth form factors were taken from Ref. 8. The obtained values must be considered just as an estimate which gives a minimum limit for the cerium intrinsic moment, because we have not considered the crystal-field effects on Nd and Pr. For example, in the isomorphous NdNi compound, the crystal field reduces the Nd magnetic moment to $2.7\mu_B$.[9] We obtain $0.92\pm0.05\mu_B$ for (Pr) and $0.89\pm0.05\mu_B$ for (Nd). These val-

TABLE I. Crystallographic and magnetic data.

	V (Å^3)	Phase %	Average V (Å^3)	R_{Bragg} (%)	T_c (K)	μ (μ_B/Ce atom)	R_{mag} (%)
	178.7	52.0		4.8			
(Ce)	----------		175.2	----------	8.6	0.50(5)	18.2
	171.3	48.0		6.6			
	178.1	42.7		4.8			
(Pr)	----------		174.7	----------	10.2	0.92(5)	12.2
	172.2	57.3		4.9			
	178.7	44.1		4.9			
(Nd)	----------		174.4	----------	9.8	0.89(5)	19.6
	171.3	55.9		5.6			

ues are much larger than that found for $CeNi_{0.8}Pt_{0.2}$ ($0.5\pm0.05\mu_B$). These moments are indicated by arrows over the general trend presented in Fig. 1.

From all of these data we can deduce that the introduction of 10% of Pr and Nd atoms in the $CeNi_{0.8}Pt_{0.2}$ Kondo ferromagnet enhances the exchange Ruderman–Kittel–Kasuya–Yoshida interactions leading to a noticeably increase of the Curie temperatures and very slight modifications of the crystal-field scheme.

If we only take into account the very small volume decrease caused by the Pr or Nd introduction, it should be expected an enhancement of the hybridization; however, it is clear from our results that the Kondo interactions are reduced. The experimental results that support this assertion are: (i) the decrease of the absolute value the paramagnetic Curie temperatures, which are related to T_K; (ii) the higher values of the magnetization, at 80 kOe for (Pr) and (Nd) (see Fig. 3); (iii) above all, the noticeable increase of the Ce intrinsic magnetic moments found in (Pr) and (Nd) by neutron diffraction (see Table I).

Figure 1 has been used to illustrate the effects of the different dilutions. On one hand, the substitution of Ce by nonmagnetic ions, $Ce_{0.8}La_{0.2}Ni_{0.8}Pt_{0.2}$ and $Ce_{0.8}Y_{0.1}Ni_{0.8}Pt_{0.2}$, leads to magnetic moments higher and lower than that of $CeNi_{0.8}Pt_{0.2}$, according to the volume effects. And, on the other hand, the Ce magnetic moment changes appearing with the introduction of Pr and Nd magnetic ions are opposite to those expected by pure volume effects.

The present results show that the dilution of Ce by magnetic atoms disturbs the coherence of the Kondo lattice state increasing the magnetic interactions and favoring the tendency to a localized behavior of the Ce ions. This is not the case of Y nonmagnetic dilutions for which a clear tendency to the delocalized behavior was observed. This means that the Kondo lattice behavior needs to be understood not only as a consequence of the large $4f$-sd conduction-band hybridization but also as a cooperative phenomenon of coherence between the Ce magnetic ions.

Low-temperature phase diagram of YbBiPt

R. Movshovich, A. Lacerda, P. C. Canfield,[a] J. D. Thompson, and Z. Fisk[b]
Los Alamos National Laboratory, Los Alamos, New Mexico 87545

Resistivity measurements are reported on the cubic heavy-fermion compound YbBiPt at ambient and hydrostatic pressures to ≈19 kbar and in magnetic fields to 1 T. The phase transition at T_c=0.4 K is identified by a sharp rise in resistivity. That feature is used to build low-temperature H-T and P-T phase diagrams. The phase boundary in the H-T plane follows the weak-coupling BCS expression remarkably well from T_c to $T_c/4$, while small hydrostatic pressure of ≈1 kbar suppresses the low-temperature phase entirely. These effects of hydrostatic pressure and magnetic field on the phase transition are consistent with an spin-density-wave (SDW) formation in a very heavy electron band at T=0.4 K. Outside of the SDW phase at low temperature, hydrostatic pressure increases the T^2 coefficient of resistivity, signaling an increase in heavy-fermion correlations with hydrostatic pressure. The residual resistivity decreases with pressure, contrary to trends in other Yb heavy-fermion compounds.

Interest in the compound YbBiPt has been sparked by the very large coefficient of the linear-in-temperature contribution to the heat capacity, γ=8 J/mol K^2, that develops at low temperatures.[1] If a substantial part of that heat capacity is due to the heavy-fermion nature of the ground state, that value of γ makes YbBiPt the "heaviest" fermion compound known to date. Inelastic neutron scattering[2] suggests that some fraction of this large γ may be due to the existence of low-lying crystal-field excitations; however, separation of these and intrinsic heavy-fermion contributions has not been possible. The heat capacity data also revealed a phase transition at 0.4 K as a small, but rather sharp, peak in the C vs T curve. It is the nature of that transition that is the subject of this article, together with the clues it may provide to the properties of the ground state of the system. To address these questions we have studied the electrical resistivity as a function of pressure and applied magnetic fields and we argue that these results are consistent with the development of a spin-density wave (SDW) below 0.4 K in a heavy-mass band of conduction electrons.

Single-crystal samples of YbBiPt were grown from an excess Bi flux.[3] X-ray diffraction confirms the samples to be face-centered cubic with the half-Heusler structure at room temperature. Neutron diffraction shows no evidence for a structural transition to 27 K.[2] Resistance measurements were made in standard four-probe and Montgomery[4] configurations. Pressure was generated in a self-clamping Be-Cu cell with Fluorinert FC-75 as the hydrostatic pressure medium. The pressure at low temperatures was established from the shift in the superconducting transition of a piece of high-purity lead mounted near the sample.

Results of four-probe ac resistivity measurements under hydrostatic pressure below ≈4 kbar are displayed in Fig. 1 for the rod-shaped sample in which the current flow was close to being parallel to the (100) crystallographic direction. Data for P=0 kbar curve show a sharp kink at T=0.4 K. The rise in resistivity below T_c suggests a decrease in the number of conduction electrons that could arise from partial gapping of the Fermi surface. Combination of this effect and the magnetic nature of the transition[1] suggests SDW as a candidate for the nature of T=0.4 K transition. The curve at P=0.78 kbar displays similar behavior, with the transition temperature shifted very slightly downward; however, application of 1.20 kbar suppresses any resistive signature for the low-temperature phase transition. The inset in Fig. 1 shows the P-T phase diagram, with data points identified from the kinks in the resistivity curves, as in Fig. 1, as function of pressure. The point at P=0.84 kbar is obtained from a curve not shown in the Fig. 1. The dashed line represents the approximate pressure above which there is no resistive signature for a phase transition. The dotted line through the data points corresponds to the pressure dependence of the transition temperature of $(dT_c/dP)_{P\to 0}$=−14 mK/kbar. The behavior of the transition temperature is highly nonlinear, and

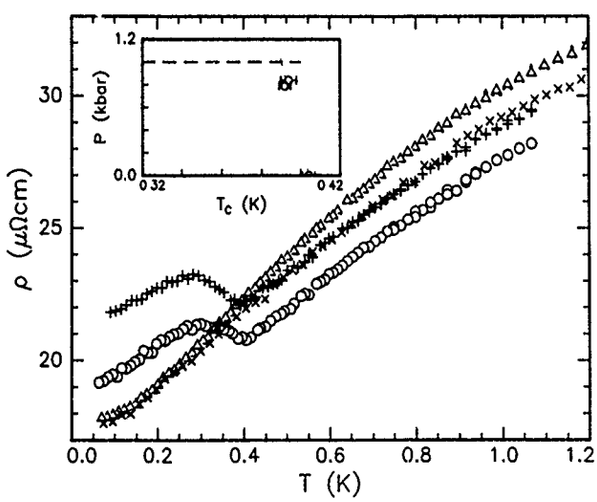

FIG. 1. Resistivity of a single-crystal rod-shaped sample of YbBiPt under hydrostatic pressure: (○) 0 kbar; (+) 0.78 kbar; (×) 1.20 kbar; (△) 3.92 kbar. Inset: transition temperature T_c vs applied hydrostatic pressure, obtained from the kinks in curves shown in the main body of the figure. Dashed line: approximate pressure that suppresses the low-temperature phase. Dotted line passes through the data points, with a slope $(dT_c/dP)_{P\to 0}$=−14 mK/kbar. The low-temperature phase is suppressed by pressure between 0.84 and 1.20 kbar.

very strong. Hydrostatic pressure has been an important tool for investigating the SDW transition in Cr. The transition temperature is suppressed rapidly by pressure, at the rate of $(dT_N/dP)_{P\to 0}=-5.1$ K/kbar.[5] Such a strong dependence on pressure is seen as a consequence of the delicate Fermi surface nesting that results in a SDW transition. The high sensitivity to relatively small pressure on the order of 1 kbar is consistent with the 0.4 K transition in YbBiPt being due to a Fermi surface instability. Extending the analogy with Cr,[6] analysis of data similar that of Fig. 1 for $P=0$ kbar (Ref. 7) results in a value for a weak-coupling SDW gap of $\Delta(T=0)/k_BT_c=1.65\pm0.15$. This is close to the minimum value of 1.764 for the two-band model of itinerant antiferromagnetism.[8] For comparison, in Cr it was found[6] that $\Delta(T=0)/k_BT_N=2.3$.

To further investigate this transition we performed a series of resistance measurements in a magnetic field. The two samples used were of a "Montgomery type," thin square platelets, each oriented to have one pair of long edges along the magnetic field. Both samples displayed anisotropic resistivity,[7] and the direction of the largest increase in V/I was longitudinal for one of the samples and transverse for the other. One reason for choosing such a geometry was the expectation that magnetic field might reorient the SDW domains with different order parameters, as was demonstrated for Cr,[9] and produce a single-domain sample. In one of the samples we indeed observed a small downward kink in V/I, in the direction which had a larger resistivity at zero field, while sweeping temperature at a fixed field of 2.5 kG. This would imply that reversal of the direction of the larger resistivity has taken place. However, temperature sweeps in fields greater than 2 kG are increasingly difficult since the phase boundary of the low-temperature phase becomes rather independent of temperature, as described below.

Figure 2(a) displays results of temperature sweeps for one of the samples described above in which the excitation current was transverse to magnetic field. The phase transition temperature is easily identified by sharp kink in V/I. Figure 2(b) shows V/I at 350 mK for the same sample but with the current flow parallel to the applied field. We identify the sharp kink at 2.1 ± 0.1 kG in the derivative with respect to H as the transition magnetic field for that temperature. This identification is consistent with the results of the temperature sweep at 2 kG, which gives a transition temperature of 350 ± 10 mK. Similar identifications were then made for magnetic field sweeps at 100 and 200 mK.

Figure 3 displays the resulting magnetic-field temperature phase diagram for the low-temperature phase of YbBiPt. The solid curve is the functional dependence of the BCS energy gap scaled to pass through the points $T_c=0.4K$, $H=0$ on the x axis and $T=0$, $H=3.1$ kG on the y axis. The curve fits the data very well, indicating the weak-coupling nature of the transition in the whole temperature range studied. In contrast to Cr, in which T_N is independent of magnetic fields up to $H=16$ T,[10] YbBiPt follows mean field behavior expected of an itinerant antiferromagnetism.

We now turn our attention to the resistive behavior of YbBiPt at pressures sufficiently high that evidence for a phase transition is not found. Figure 4 shows the

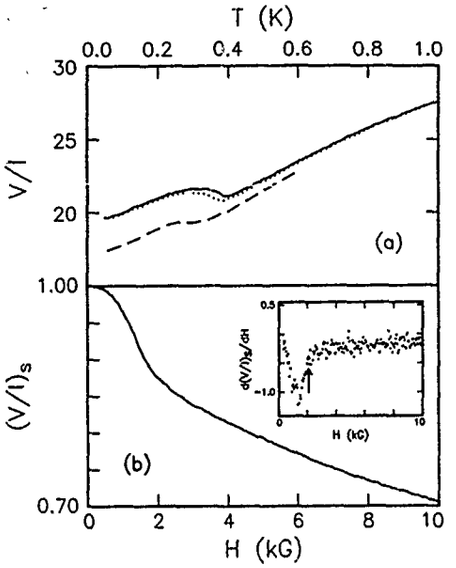

FIG. 2. (a) Temperature sweeps at constant magnetic field: (solid line) $H=0$ kG; (dotted line) $H=1$ kG; (dashed line) $H=2$ kG. Kinks in V/I curves are taken as signaling transition temperatures for given fields. (b) Magnetic-field sweep at a constant temperature of $T=350$ mK, $(V/I)_s=(V/I)/[V/I(H=0)]$. Inset: derivative of the curve shown in (b). The sharp kink indicated by the arrow at a field $H=2.1\pm0.01$ kG represents the phase transition at $T=350$ mK.

temperature-dependent resistivity at pressures between ≈4 and 19 kbar. Data for all curves can be fit very well by $\rho(T)=\rho_0+AT^2$ below $T=300$ mK, as expected for a Fermi liquid. In this Fermi liquid regime $\sqrt{A}$ was shown[11] to be proportional to γ for a large number of Ce and U heavy-fermion compounds. The inset in Fig. 4 shows A as a function of pressure and indicates an increase in the heavy-fermion correlations with pressure. Similar systematics with pressure are observed in other Yb heavy-fermion compounds.[12] The decrease of the residual resistivity ρ_0 with

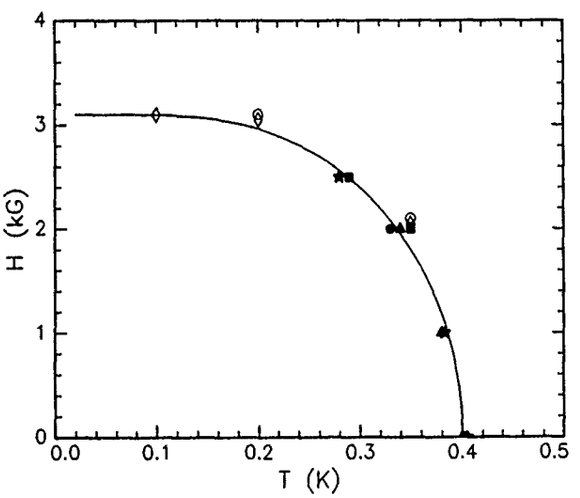

FIG. 3. Magnetic-field temperature phase diagram for the low-temperature phase of YbBiPt. The solid and open symbols are results of the temperature and magnetic field sweeps, respectively. The solid line is a BCS curve fixed by the points $H,T=0$ and $H=0$, T_c.

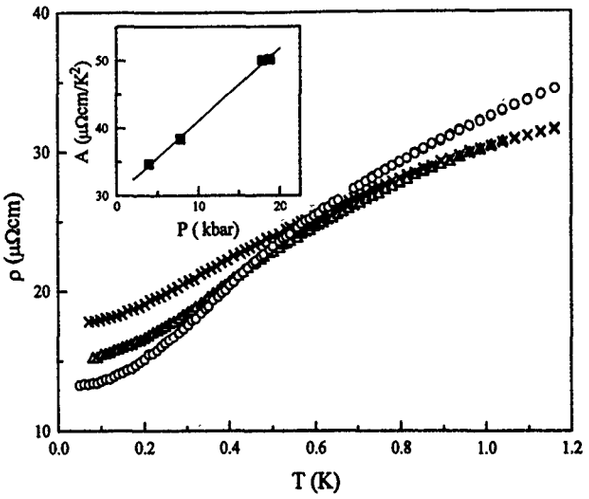

FIG. 4. Resistivity of YbBiPt in the high-pressure phase: (O) 18.79 kbar; (△) 7.83 kbar; (×) 3.92 kbar. Inset: T^2 coefficient of $\rho(T)$ vs pressure; straight line is a guide to the eye.

pressure, however, is rather anomalous. In other Yb compounds the residual resistivity increases with pressure, possibly reflecting its Kondo hole origin.[13] The decrease of ρ_0 with pressure in YbBiPt may be due to purely band-structure effects. The REBiPt series (RE is an element of the rare-earth series) exhibits a systematic progression from small gap semiconductor in Nd to metallic behavior in Yb,[14] as the RE series is traversed from the left- to right-hand side, i.e., as the size of the RE ion diminishes. Pressure would reduce the volume of the unit cell of YbBiPt even further, possibly increasing the carrier density and reducing resistivity.

In summary, the phase boundary in the H-T plane of the low-temperature state of YbBiPt follows the weak coupling BCS-like expression expected of an SDW transition. This identification is supported further by the extreme pressure dependence of the transition temperature, with the low-temperature phase being suppressed by pressures of ≈1 kbar. Above that pressure-induced transition, the heavy-fermion nature of YbBiPt appears to be enhanced further with increased pressure. We suggest that investigating YbBiPt at higher pressures yet may yield interesting information on a transition regime between heavy-fermion and antiferromagnetic behaviors.

We want to thank Dr. Günter Sparn for help with constructing apparatus and Dohn Arms for writing some of the software. We also acknowledge Dr. S. A. Trugman, Dr. Ward Beyerman, Dr. H. R. Ott, Dr. L. P. Gorkov, and Dr. A. J. Millis for stimulating discussions. Special thanks go to Dr. Alexander Balatsky for numerous discussions of data. Work at Los Alamos was performed under the auspices of the U.S. Department of Energy.

Quadrupolar effects in $PrCu_2Si_2$

As part of a systematic study of the crystal-field (CF) potential in RCu_2Si_2 compounds (R=Ce, Pr, Nd, Tb, Ho, Er) using inelastic neutron scattering, the CF level scheme and potential in the antiferromagnet $PrCu_2Si_2$ both above and below T_N has been determined. There have been recent speculations that the quadrupole moment of $PrCu_2Si_2$ has been quenched by the quadrupolar Kondo effect. Using the CF potential derived from the results, the quadrupole moment Q_2 of $PrCu_2Si_2$ has been calculated and it has been compared to the other members of the RCu_2Si_2 series. The temperature dependence of the quadrupole moment of $PrCu_2Si_2$ is significantly weaker than all the other compounds, e.g., it is approximately five times smaller than in $HoCu_2Si_2$. Therefore, it is the CF potential which is responsible for quenching Q_2 at low temperature rather than a quadrupolar Kondo effect. Furthermore, the CF Schottky contribution to C/T vs T^2 is approximately linear above T_N and explains the anomalously high linear term in the specific heat. However, the evolution of the CF potential across the rare-earth series provides evidence of an enhanced hybridization contribution to the CF potential of $PrCu_2Si_2$, intermediate between the heavy fermion $CeCu_2Si_2$ and the other rare-earth compounds.

I. INTRODUCTION

There has been considerable interest in f-electron systems, particularly uranium alloys such as $U_{0.2}Y_{0.8}Pd_3$ (Refs. 1 and 2) and $UCu_{3.5}Pd_{1.5}$,[3] displaying non-Fermi liquid scaling of their thermodynamic properties at low temperatures. One possible microscopic mechanism to explain these observations is the $N=2$ multichannel Kondo effect produced by orbital scattering of the conduction electrons.[4] This quadrupolar Kondo effect is expected to quench the local quadrupole moment of the f electrons just as the single-channel Kondo effect screens the local magnetic moment and suppresses magnetic ordering. It has recently been proposed that anomalies in the thermodynamic and structural properties of $PrCu_2Si_2$ and related isostructural compounds might also be evidence of quadrupolar Kondo interactions.[5,6] The extrapolation of C/T vs T^2, measured in the paramagnetic phase of $PrCu_2Si_2$ (T_N=21 K), to T=0 appears to give evidence for a large electronic contribution to the specific heat with γ=225 mJ mol^{-1} K^{-2}.[6] Since there is no evidence of conventional Kondo-like behavior in the magnetic susceptibility or resistivity, there has been speculation that quadrupolar Kondo scattering is responsible for the high γ. This suggestion is given further weight by the absence of a c/a lattice anomaly at low temperatures, comparable to those seen in all the other RCu_2Si_2 (R denotes rare earth) compounds, implying that the Pr^{3+} quadrupole moment has been quenched.

When the anomalous properties of $PrCu_2Si_2$ were first reported, it was pointed out that a knowledge of the crystal-field (CF) potential is essential to assess the validity of these ideas.[6] Apart from making a substantial contribution to the thermodynamic properties, the CF also determines the f-electron wave functions, in the absence of strong hybridization, and consequently the quadrupole moment. We have been conducting a systematic investigation of the magnetic properties of RCu_2Si_2 compounds using neutron diffraction and inelastic neutron scattering.[7–10] Inelastic neutron scattering (INS) is the most reliable method of determining the CF potential in intermetallic compounds since it measures directly the energies and dipole matrix elements of transitions between CF levels. One aim of our work is to measure the CF potential across the rare-earth series in order to determine whether the CF in the heavy-fermion compound $CeCu_2Si_2$ is anomalous compared to the "normal" rare-earth compounds. We have now established the CF parameters for R=Ce, Pr, Nd, Tb, Ho, and Er and discuss some of the consequences of these results here with particular reference to the praseodymium compound. Full details of this work will be published in Ref. 9.

II. EXPERIMENTAL RESULTS

The samples were prepared by arc melting stoichiometric quantities of the constituent elements, with no measurable weight loss. After annealing at 700 °C, nearly all peaks observed in neutron-diffraction measurements could be indexed with the $ThCr_2Si_2$-type structure and only a few very weak reflections in the light rare earths indicated minor contamination by other phases. The INS measurements were performed at the pulsed spallation neutron source ISIS (Rutherford Appleton Laboratory, U.K.) on the time-of-flight chopper spectrometer HET, using incident energies between 10 and 60 meV, and on the high-resolution inverse geometry spectrometer IRIS to resolve low-energy transitions.

The rare-earth ions in RCu_2Si_2 occupy sites with tetragonal point group symmetry. In the paramagnetic phase, the appropriate CF Hamiltonian is

$$H_{CF}=B_2^0O_2^0+B_4^0O_4^0+B_4^4O_4^4+B_6^0O_6^0+B_6^4O_6^4 \quad (1)$$

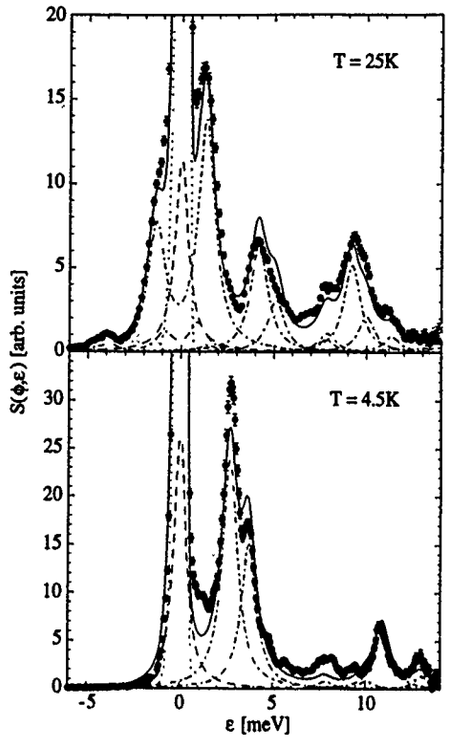

FIG. 1. Neutron inelastic scattering from $PrCu_2Si_2$ measured at 4.5 and 25 K on HET with an incident energy of 15 meV integrated over scattering angles of 9°–29°. The solid line is the profile of the crystal-field model described in the text including Lorentzian broadening and, at 4.5 K, a molecular field. The dashed line is the quasielastic scattering, the dashed-dotted lines are the inelastic transitions, and the dotted line is the elastic nuclear scattering.

where O_n^m are the Steven's operator equivalents and B_n^m are the phenomenological CF parameters. The influence of antiferromagnetic ordering on the excitation spectrum has been taken into account in the molecular-field approximation. An example of the HET spectra on $PrCu_2Si_2$, measured both above and below T_N, with an incident energy of 15 meV and summed over scattering angles from 9° to 29°, is shown in Fig. 1. The spectra taken at 136°, where the nuclear scattering is strongest, show that the phonon contribution in this energy range is negligible at low angles, so the observed peaks are all magnetic.

The solid lines in Fig. 1 are the results of a profile refinement of the CF model after establishing the approximate CF parameters using a comprehensive stepwise search. The resulting parameters are $B_2^0=-(6.28\pm0.15)\times10^{-2}$ meV, $B_4^0=(1.48\pm0.15)\times10^{-3}$ meV, $B_6^0=(5.27\pm0.07)\times10^{-5}$ meV, $B_4^4=(2.24\pm0.06)\times10^{-2}$ meV, and $B_6^4=-(3.80\pm0.03)\times10^{-4}$ meV, and the corresponding level scheme in the paramagnetic phase is shown in Fig. 2. The INS spectrum measured at 4.5 K shows that the molecular field H_{mf} changes the level splittings, energies, and transition probabilities significantly in the antiferromagnetic state. Nevertheless, it was fitted using the same CF parameters as in the paramagnetic phase with $H_{mf}=(10.4\pm0.6)$ T. Therefore, the CF model describes the measured profiles reasonably well both above and below T_N with some discrepancies due probably to the use of a common linewidth for all the transitions and to the neglect of

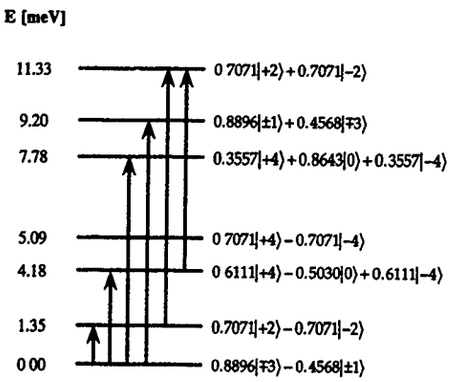

FIG. 2. Energy-level scheme for $PrCu_2Si_2$ in the paramagnetic phase with the crystal-field parameters given in the text. The arrows mark the dipole-allowed transitions.

dispersion in the antiferromagnetic state. We have performed similar analyses for the other rare-earth compounds. In each case, the CF potential was determined without ambiguity with the possible exception of $TbCu_2Si_2$ where the transitions are not well enough resolved to guarantee a unique solution.

III. DISCUSSION

As we stated in Sec. I it has been proposed that $PrCu_2Si_2$ shows unconventional (quadrupolar Kondo) heavy-fermion behavior.[5] One immediate result of our CF analysis is to explain the apparently high value of γ. The calculated CF contribution, consisting of a number of overlapping Schottky peaks, is approximately linear in C/T vs T^2 for about 20 K above T_N and extrapolates to the value 282 mJ mol^{-1} K^{-2} at $T=0$. Once this Schottky contribution has been subtracted, C/T is close to zero within the uncertainties of this analysis so there is no evidence of an enhanced electronic contribution to the specific heat. A second result is to explain the absence of the lattice anomaly at low temperatures. Figure 3 shows the calculated temperature dependence of the quadrupole moments $Q_2=\frac{1}{2}\alpha_J\langle O_2^0\rangle$ of RCu_2Si_2 using the measured CF parameters. Q_2 is proportional to the size of the lattice anomaly assuming the magnetoelastic coupling is linear in

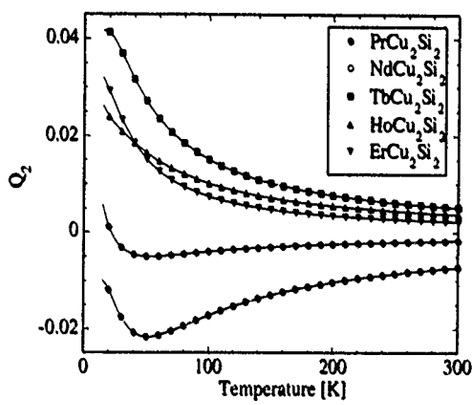

FIG. 3. Temperature dependence of the quadrupole moment Q_2 of RCu_2Si_2 compounds (R=Pr,Nd,Tb,Ho,Er).

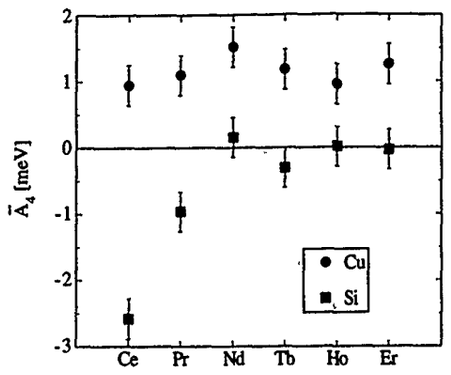

FIG. 4. Superposition model parameters $\tilde{A}_4$(Cu) and $\tilde{A}_4$(Si) for RCu_2Si_2 compounds (R=Pr,Nd,Tb,Ho,Er) assuming A_4^4 and A_6^4 are positive.

the tetragonal strain.[11] Although the absolute value of Q_2 in $PrCu_2Si_2$ at room temperature is slightly greater than the heavy rare earths, its temperature dependence is much weaker. For example, its variation between 300 and 20 K is five times weaker than in $HoCu_2Si_2$ making any attendant lattice anomaly difficult to see. Since the quadrupole moment of the CF ground state in $PrCu_2Si_2$ is relatively small, the increase in Q_2 is suppressed as the excited CF levels are depopulated. Therefore, it is the CF potential which reduces Q_2 at low temperature, not a quadrupolar Kondo effect. Nevertheless, the size of T_N indicates that orbital exchange contributions may be necessary to explain the scale of magnetic interactions in $PrCu_2Si_2$.[10,12]

Analyzing the CF potential in the framework of the superposition model (SM) allows a direct comparison of the different ligand contributions in the RCu_2Si_2 compounds. A detailed discussion of the use of this model is given in Refs. 7 and 8. Here we discuss briefly the systematics of this analysis across the rare-earth series. There is an ambiguity about the relative signs of B_4^4 and B_6^4 but both solutions show a systematic evolution of the two ligand contributions, $\tilde{A}_4$(Cu) and $\tilde{A}_4$(Si), to the CF potential with a substantial increase in the magnitude of the silicon term and a smaller decrease in the magnitude of the copper term. We discuss in Ref. 7 our reasons for favouring positive values of A_4^4 and A_6^4 and show these results in Fig. 4 ($B_n^m = \theta_n A_n^m \langle r^n \rangle$ where θ_n are the Steven's factors and $\langle r^n \rangle$ are the $4f$ radial integrals). In $NdCu_2Si_2$ and the heavy rare earths, the silicon contribution is small in comparison with the copper contribution which is nearly constant across the series. However, a large negative silicon contribution has developed in $CeCu_2Si_2$ indicating an enhanced hybridization between the rare-earth $4f$ electrons and the Si s-p orbitals. The SM analysis does therefore show evidence of the same hybridization in $PrCu_2Si_2$ but on a substantially reduced scale.

IV. CONCLUSION

Our solution of the CF potential of $PrCu_2Si_2$ shows that the anomalous thermodynamic and structural properties observed in earlier investigations can be understood in the framework of a conventional f-electron system split by the crystal field. Both the enhanced linear term in the specific heat and the apparent quenching of the Pr^{3+} quadrupole moment are reproduced by our CF model. However, the expanded radial wave functions of the f electrons, compared to the heavier rare earths, are reflected in an enhanced hybridization contribution to the CF potential by the silicon ligands as earlier observed in $CeCu_2Si_2$.

Mixed valence in a generalized Hubbard model

A. N. Kocharian[a] and G. R. Reich
Physics Department, Union College, Schenectady, New York 12308

A generalized Hubbard model involving two kinds of spinless fermions with different masses is proposed to explain the properties of mixed-valence compounds. An equivalence between the proposed model and an effective anisotropic antiferromagnetic Heisenberg model with external field is established in the strong-interaction limit. The ground-state energy and partition function are obtained analytically using generalized mean field theory which, for bipartite lattices, allows the system to be reduced to an equivalent two-site problem. The analytic behavior of the valence and compressibility under variation of pressure and the phase diagram in the ground state and at finite temperature are investigated. The conditions for a first-order transition depending on the position of the f band are obtained, taking into account the effect of local hybridization between the s and f states. The known anomalies in the behavior of n_f and χ in mixed-valence systems are interpreted in analogy with the magnetization and susceptibility in the corresponding pseudospin model.

Many phenomena in heavy-fermion compounds, high-T_c superconductors, quantum crystals, etc. have been modeled either with a single-band Hubbard model[1] or a spinless Falicov–Kimball (FK) (or closely related) model.[2–4] These models are also often used to explain phase diagram anomalies and interesting valence behavior in mixed-valence compounds under change of temperature and pressure (see, e.g., Ref. 5). Aside from some details of electron structure these two models can be studied together as particular cases of a more general model (GM),

$$H_{\mathrm{GM}}=-t_1\sum_{\langle ij\rangle} c_{i\uparrow}^{+}c_{j\uparrow}-t_2\sum_{\langle ij\rangle} c_{i\downarrow}^{+}c_{j\downarrow}+U\sum_{i} c_{i\uparrow}^{+}c_{i\uparrow}c_{i\downarrow}^{+}c_{i\downarrow}$$

$$-\frac{H}{2}\sum_{i}(c_{i\uparrow}^{+}c_{i\uparrow}-c_{i\downarrow}^{+}c_{i\downarrow}), \tag{1}$$

which includes hopping terms and intrasite repulsion ($U>0$) for two different kinds of particles. For $t_1=t_2$ it is, of course, a Hubbard model with an applied magnetic field. Although Eq. (1) is written in the language of electron creation operators with spin indices, an equivalent Hamiltonian could be written using band or orbital indices, as in the FK model. In other words, the $c_{\uparrow}^{+}, c_{\downarrow}^{+}$ operators in Eq. (1) can be replaced with creation operators f^{+}, a^{+} representing spinless fermions in the f and s bands. The field strength H in this case represents the energy difference between the centers of the two bands, which in mixed-valence materials can be changed with pressure. For $t_1=0$, this is equivalent to the FK model. In the strong interaction limit $U\to\infty$ the GM reveals some interesting relations between the two models, and helps to explain the connections between such phenomena as superfluity and excitonic insulators, antiferromagnetism (or charge-density waves) and valence-density waves, ferromagnetism, and pure integer valency. In addition, viewed as a generalization of the FK model there are significant advantages to using Eq. (1) for describing mixed-valence compounds. In the pure FK model, for example, mixed-valence states can appear only as a spatially periodic lattice of ions,[4] with $n_f=0$ or 1, a kind of orbital antiferromagnetism. The generalized model, however, also permits a liquidlike state of uniform, noninteger valence, as has been seen experimentally,[5] and it correctly predicts the first-order transitions seen in those materials under change of temperature and pressure.

It is convenient to rewrite the GM Hamiltonian, replacing the creation operators by Hubbard operators[1] so that $c_{i\sigma}^{+}=X_i^{\sigma 0}+\sigma X_i^{2-\sigma}$ and the Hamiltonian takes the symmetrized form $H_{\mathrm{GM}}=\Sigma_{i,\Delta}H(i,i+\Delta)+H(i+\Delta,i)$, where Δ is summed over the lattice vectors, and $H(i,j)$ can be written in terms of two-site operators as follows:

$$\begin{aligned}H(i,j)=&-t_1(X_i^{\uparrow 0}X_j^{0\uparrow}+X_i^{2\downarrow}X_j^{\downarrow 2})-t_2(X_i^{\downarrow 0}X_j^{0\downarrow}+X_i^{2\uparrow}X_j^{\uparrow 2})\\&-t_1(X_i^{\uparrow 0}X_j^{\downarrow 2}+X_i^{2\downarrow}X_j^{0\uparrow})+t_2(X_i^{\downarrow 0}X_j^{\uparrow 2}+X_i^{2\uparrow}X_j^{0\downarrow})\\&+U/2(X_i^{22}+X_j^{22})-H/4(X_i^{\uparrow\uparrow}+X_j^{\uparrow\uparrow}-X_i^{\downarrow\downarrow}-X_j^{\downarrow\downarrow}).\end{aligned} \tag{2}$$

While the first two terms in Eq. (2) represent simple hopping, the second two are interconfiguration fluctuation terms and can be removed by a suitable unitary transformation as in Ref. 6. In the strong interaction limit the transformed Hamiltonian can be expanded to any order in powers of $t_{1,2}/U$. Projecting the transformed Hamiltonian onto the subspace of singly occupied states, exactly at half-filling ($n_{\uparrow}+n_{\downarrow}=1$) gives, to lowest order, an effective Hamiltonian

$$H_{\mathrm{eff}}=-\frac{t_1^2+t_2^2}{2U}\sum_{\langle ij\rangle}(X_i^{\uparrow\uparrow}X_j^{\downarrow\downarrow}+X_i^{\downarrow\downarrow}X_j^{\uparrow\uparrow})+\frac{t_1t_2}{U}\sum_{\langle ij\rangle}(X_i^{\uparrow\downarrow}X_j^{\downarrow\uparrow}+hc)-\frac{H}{2}\sum_{i}(X_i^{\uparrow\uparrow}-X_i^{\downarrow\downarrow}). \tag{3}$$

Since the Hubbard operators $X^{\alpha\beta}$ generate an $SU(2)$ algebra, and their commutation relations are isomorphic to those of the pseudospin operator L ($2L^z=X^{\uparrow\uparrow}-X^{\downarrow\downarrow}$ and $L^{+}=X^{\uparrow\downarrow}$), the effective Hamiltonian above can be written in the form

$$H_{\mathrm{eff}}=J_{\parallel}\sum_{\langle ij\rangle}(2L_i^zL_j^z-\tfrac{1}{2})+J_{\perp}\sum_{\langle ij\rangle}(L_i^{+}L_j^{-}+hc)-H\sum_{i}L_i^z, \tag{4}$$

with $J_{\parallel}=(t_1^2+t_2^2)/2U$ and $J_{\perp}=t_1t_2/U$. Thus, to lowest order, the GM is strictly equivalent to an anisotropic antiferromagnet with external field. Using analogies of this kind one may advantageously translate the substantial existing knowledge about spin systems to mixed-valence systems.

The transformed Hamiltonian is valid for all t_1, t_2, and in earlier work[7] the case $t_1 \ll t_2$ was described. It is also easy

to show that taking $t_1=t_2$ (Hubbard model) gives a spin analog equivalent to Anderson superexchange,[8] H_{An}. Here we examine in greater detail the FK-like case $t_1\to 0$. Expanding the resulting effective Hamiltonian to fourth order gives

$$H_{Is}=\frac{t_2^2}{U}\sum_{nn} L_i^z L_j^z+\frac{t_2^4}{U^3}\sum_{nnn} L_i^z L_j^z-H\sum_i L_i^z+\text{const} \quad (5)$$

so that any exact results from the Ising model can be easily transferred to the FK model in the strong interaction limit. In particular, one expects the appearance of a spatially ordered phase in the GM in two dimensions, similar to results described earlier[4] about the appearance of a chessboard structure of f fermions in $D\geq 2$ in the symmetric case ($H=0$). We show below, however, that even with $H\neq 0$, there is a region where the chessboard structure is stabile. Higher-order corrections as in Eq. (5) are important for their implications regarding additional spatially ordered phases for $H\neq 0$.

Comparing the Anderson Hamiltonian H_{An} with H_{Is} above, we see that the difference between the Hubbard and FK models in the strong interaction limit is no more than that between a classical Ising system and a quantum antiferromagnet. Thus, exactly at half-filling the FK model can be considered to be a classical analog of the Hubbard model. Below we show that, in spite the fact that $J_\parallel \geq J_\perp$, the inclusion of a finite, small bandwidth for the f states changes the character of the phase transition from second to first order and stabilizes the quantum-liquid (QL) state with strong excitonic correlations.

All these effects can be derived analytically using a generalized mean field approximation (GMFA) for bipartite systems, i.e., those consisting of two sublattices A and B. Taking the most general decoupling scheme for Hubbard operators in Eq. (3) the Hamiltonian can be reduced to the two-site form,

$$H_{\text{eff}}^{MF}=(-J_\parallel z\tilde{n}_{2a}-H/2)X_1^{\uparrow\uparrow}+(-J_\parallel z\tilde{n}_{2f}-H/2)X_1^{\downarrow\downarrow}+(-J_\parallel z\tilde{n}_{1a}-H/2)X_2^{\uparrow\uparrow}+(-J_\parallel z\tilde{n}_{1f}-H/2)X_2^{\downarrow\downarrow}+J_\perp z\Delta_2(X_1^{\uparrow\downarrow}+X_1^{\downarrow\uparrow})$$
$$+J_\perp z\Delta_1(X_2^{\uparrow\downarrow}+X_2^{\downarrow\uparrow})+J_\parallel z(\tilde{n}_{1f}\tilde{n}_{2a}+\tilde{n}_{1a}\tilde{n}_{2f})-2J_\perp z\Delta_1\Delta_2, \quad (6)$$

where z is the coordination number of the lattice, and we have introduced the order parameters $\Delta_{1,2}=\langle X_{1,2}^{\sigma-\sigma}\rangle$ for the excitonic correlations (orbital mixing) in xy plane and $\eta=\langle X_1^{-\sigma-\sigma}-X_2^{-\sigma-\sigma}\rangle$ for the spatial orbital ordering in z plane. The number of particles n_1 and n_2 on the A and B sites is then $n_1=\tilde{n}_{1f}+\tilde{n}_{1a}$ and $n_2=\tilde{n}_{2f}+\tilde{n}_{2a}$ and the total number of particles on the two sublattices, exactly at half-filling, is $n_1+n_2=2$.

After diagonalization of Eq. (6) one can find eigenstates $E_{1,2}^{\pm}$ and the partition function Z depending on Δ, η, and $m=2\tilde{n}_f-1$. The analysis of self-consistent equations for these gives the dependence of the valence $\tilde{n}_f$ on the position of the f level H,

$$h=\frac{H}{2J_\parallel z}=mg+\sqrt{m^2+(g^2-1)\eta^2(m)}. \quad (7)$$

Analysis of Eq. (7) reveals many phases, which are shown in Fig. 1. In a strong magnetic field we have ferromagnetic ordering or integer valence (IV) states $\tilde{n}_f=0$ or 1. On decreasing the magnitude of h, the system undergoes a transition into an excitonic insulator at $h^*=1+1/g$. In this region $\tilde{n}_f$ changes linearly with h, $\tilde{n}_f=h/h^*$. This phase most closely resembles a uniform QL with strong hole-particle correlations, and with $(2m_0+1)/2<\tilde{n}_f<1$, where $m_0=\sqrt{[(g-1)/(g+1)]}$. For h between $\pm\sqrt{(g^2-1)}\,\tilde{n}_f$ is multivalued until some critical field $\pm h_0$ where the system undergoes a first-order transition from a mixed state with $\eta\neq 0$, $\Delta\neq 0$, in which valence-density waves (VDW) coexist with the QL, into a pure spatially ordered phase with VDW. When the mass of the f fermions goes to infinity we obtain at $T=0$ two consecutive jumps from IV states into VDWs with $\tilde{n}_f=\tilde{n}_s=1/2$, as shown in Fig. 1. It is also possible to obtain such a transition in systems with short-range electron-phonon interactions.[10] The transition, however, becomes continuous at any finite temperature. Thus, the stabilized excitonic phase is ruled out in the ground state whenever we exclude a finite bandwidth for f states, and there is no possibility to obtain a first-order transition in the FK model at finite temperatures. From Eq. (7) one can easily find the compressibility $\chi=-d\tilde{n}_f/dp$, which is small in IV configurations and in spatially ordered phases ($\tilde{n}_f=1/2$), but in the QL phase becomes constant $\chi=1/h^*$. The value increases with pressure, and reaches a maximum near the transition into the mixed state. Such behavior has been seen in experiments in SmS under pressure.[5,10]

The inclusion of local hybridization in the GM $V(c_\uparrow^+c_\downarrow+c_\downarrow^+c_\uparrow)$ would be the same as considering the GM in presence of a transverse magnetic field $V(L^++L^-)$. This factor is of an excitonic type and increases the tendency toward a first-order transition from a spatially ordered phase into QL state with strong excitonic correlations.

If we consider the Ising-type interaction ($t_1\to 0$) to all orders in t/U, which includes the antiferromagnetic long-range interactions with all neighbors (analogous to a classical gas with Coulomb repulsion,[11] then an infinite number of incommensurate modulated phases is found between the ferromagnetic and the VDW "antiferromagnetic" ordered phases in the one-dimensional case. This means that the FK model at $U\to\infty$ can be converted into an Ising model with long-range antiferromagnetic interactions. The crystallization of f particles into a periodic structure and dielectric splitting of the f band has been found in the 1D case.[12] The similarity between the ground-state energy and the partition functions of the FK model and the classical lattice gas has also been found recently for the 1D case.[13]

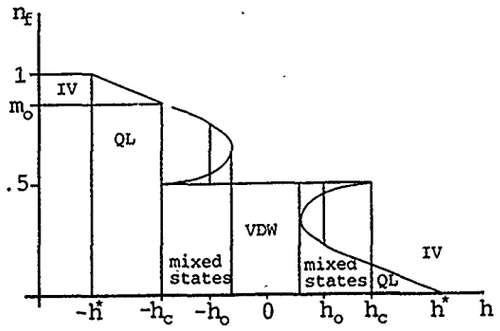

FIG. 1. The occupation number $\tilde{n}_f$ as a function of h in a generalized Hubbard model at $0<1/g<1$.

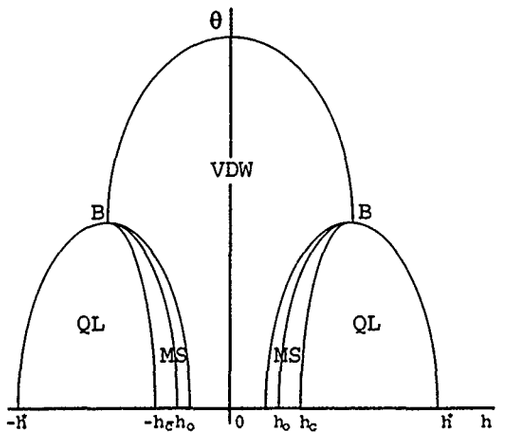

FIG. 2. The predicted h-T phase diagram for the generalized model for $D\geq 3$.

The thermodynamic behavior of our system can be analyzed easily. From analysis of these equations one can easily find the thermodynamic characteristics, and investigate the phase diagram at finite temperatures. The schematic phase diagram of critical temperatures versus magnetic field (or pressure) of the GM in the strong interaction limit is shown in Fig. 2. In some cases[14] the transition from the VDW to the QL state can be realized through an intermediate mixed state (MS), where the first-order transition line is split into two lines terminating in tetracritical point B. One first order phase transition from the QL into the VDW state is also possible by increasing the temperature at constant field (pressure) (see Fig. 2). Physically, this result is connected with the fact that excitonic effects, which are absent at high temperatures, become important at low temperatures. The phase boundary between the QL and VDW states indicates an increase of entropy for the spatially ordered phase with temperature. The bicritical point T_{bc} and spinodals, which are characteristic of the first-order transition, are also seen in Fig. 2. We expect that in the 3D case only a finite number of commensurate crystalline ordered phases exists at finite temperatures and can survive near the equilibrium line in the VDW region. At high pressures, near the IV phase the transition from QL into normal state is smooth, and its dependence on the magnetic field is logarithmic $T_c=-J_\perp/\ln(h-h^*)$. This result means that the excitonic effect by itself cannot give rise to a first-order transition and is possible only near the boundary of a spatially ordered phase. The high-temperature compressibility in the normal paramagnetic phase behaves as predicted in mean field theory, $\chi=d\tilde{n}_f/dP=C/(T-T_c^*)$, where T_c^* and C are the Curie–Weiss temperature and the Curie constant. Thus, all anomalies in the behavior of n_f and χ in mixed-valence systems can be interpreted in analogy with the temperature dependence of the magnetic moment and susceptibility of a Heisenberg–Ising system under variation of external field.

Using analogies between the FK model at $U\rightarrow\infty$ and the antiferromagnetic Ising or classical lattice-gas model, we can predict spatial ordering (VDW). In addition the long-range interactions for the Ising model (see Ref. 11) give rise to numerous other modulated long-range-ordered phases and, similarly, using an analogy with the classical lattice-gas model, one can predict an infinite number of phase transitions with charge-density wave states under change of pressure in the FK model. Thus, the thermodynamic behavior as well as the value of all critical exponents for FK model can be obtained using analogies with exactly solvable one- and two-dimensional Ising or lattice gas models. Even a small bandwidth causes a the appearance of a valence fluctuation term (or spin-flop terms in the effective Heisenberg Hamiltonian), and drastically changes the properties of the system. In spite of the fact that the exact solution of the 2D Heisenberg–Ising model is not known, it is possible to reach some conclusions about the ground-state properties and correlation function behavior even in this case.[15] For example, at low temperatures the bounds obtained in Ref. 16 rule out the possibility of excitonic condensation in 2D lattices, but allow power-law-like decay for excitonic correlations in the GM, which can be of the Kosterlitz–Thouless type, whenever t_1 or t_2 is different from zero.

A method is presented for calculating the f-f ion interaction in systems where a d-electron species also hybridizes with the same Fermi sea. For the physical systems of interest, typically the f species is a light rare earth (e.g., Ce or Pr) or a light actinide (U) involving a partially filled f shell and the d species is a transition-metal ion; and there may be experimental evidence of competition between magnetic ordering of the f and d electron systems (e.g., when f is U and d is Mn). The method treats first the strong hybridization between the d and the conduction electrons to obtain a new ground state with delocalized d electrons. Then it calculates the f-f ion interaction by perturbation theory. The mechanisms by which the d electrons modify the f-f ion interaction are identified.

In recent years there has been considerable interest in the behavior of partially delocalized light-rare-earth and actinide systems where cooperative hybridization between a lattice of somewhat delocalized f-electron ions and the non-f-band electrons gives rise to orbitally driven magnetic ordering phenomenology characterized by extremely high anisotropy in the equilibrium, excitation, and critical behavior, and often by anomalously strong damping of the excitations.[1] The theory of this magnetic ordering and associated behavior is by now well developed[1] when a lattice of only a single f-electron species, such as cerium or uranium, is present. Interest in generalizing this understanding to the situation where there is a d-electron species also present is strongly motivated by the competition between magnetic d and f electrons that occurs in compounds[2,3] of the $ThCr_2S_2$-type structure of the type UMn_2X_2 and RMn_2X_2 [where R is a rare earth (Ce, Pr, Nd) and X is Si,Ge]. If the Mn is replaced by another transition metal, there is no magnetic moment on the transition metal. For the light-rare-earth/Mn compounds[2] there is magnetic ordering of Mn moments, with ordering temperatures above 300 K, that either is ferromagnetic or is antiferromagnetic with Mn planes that are ferromagnetic in alternating directions; and the rare-earth sublattices show no ordering. Quite different magnetic ordering behavior occurs for the corresponding heavy-rare-earth compounds where the more localized f electrons presumably have negligible hybridization, and where typically there is evidence of magnetic ordering on the rare-earth site. For the UMn_2X_2 compounds[3] the magnetic moment of the uranium sublattice is strongly coupled with that of the Mn sublattices.

In this article we present a method for calculating the f-f ion interaction in a system where both magnetic f electrons and d electrons on a lattice (or different sublattices) hybridize with a common band sea. The method treats first the strong hybridization of the d electrons with the band sea to construct a new ground state and then proceeds to treat the f hybridization by perturbation theory. Although we explicitly assume that the d species has no moment, the method can be generalized to the case where it does by introducing spin-polarized bands.

We start by writing the Anderson lattice Hamiltonian for a system of d and f electrons hybridizing with a common conduction band as

$$H=H_c+H_f+H_d, \tag{1}$$

where $H_c = \Sigma_{\mathbf{k}\sigma}\epsilon_{\mathbf{k}}c^{\dagger}_{\mathbf{k}\sigma}c_{\mathbf{k}\sigma}$ is the conduction-band Hamiltonian and $c^{\dagger}_{\mathbf{k}\sigma}$ is a creation operator for a conduction electron with wave vector $\mathbf{k}$ located in the first Brillouin zone and spin σ. Here

$$H_\alpha=\sum_{ia m}\epsilon_\alpha l^{\dagger}_{ia m}l_{ia m}+\frac{1}{2}\sum_{\substack{ia mm'\\ m\neq m'}}U_\alpha l^{\dagger}_{ia m}l_{ia m}l^{\dagger}_{ia m'}l_{ia m'}$$

$$+\frac{1}{\sqrt{N_s}}\sum_{\substack{ia m\\ \mathbf{k}\sigma}}(V^{(\alpha)}_{\mathbf{k}\sigma m}e^{-i\mathbf{k}\cdot\mathbf{R}_{ia}}c^{\dagger}_{\mathbf{k}\sigma}l_{ia m}+\text{c.c.}), \tag{2}$$

where $\alpha=\{f,d\}$, $l^{\dagger}_{ifm}=f^{\dagger}_{im}$ is a creation operator for a localized f electron located in the ith unit cell with total angular momentum j_α and projection of the latter along the quantization axis m, $l^{\dagger}_{idm}=d^{\dagger}_{i\sigma}$ is a creation operator for a localized d electron located at the origin of the ith unit cell with spin σ, and we have neglected the orbital degeneracy for the d electron system. Here N_s is the number of unit cells in the crystal and the d hybridization matrix element for simplicity is taken to be a constant, V_d.

For a general f-d electron system, both species can interact strongly with each other by modifying the Fermi band sea. Here, we consider the case where the f species is in the Ruderman–Kittel–Kasuya–Yoshida (RKKY) interaction dominated regime with local magnetic moments in contrast to the heavy fermion regime with quenched moments due to the formation of conduction–f-electron singlets. For such a system, the most significant renormalization of the Fermi band sea is due to the hybridization with the d electrons. Thus, we propose a method where we first approximately diagonalize the terms in the Hamiltonian involving the con-

[a]Present address: Los Alamos National Laboratory, Los Alamos, NM 87545.

duction electrons and the d electrons to obtain renormalized bands and then, afterward, treat the hybridization of the f species as a perturbation. The d hybridization effect introduces the well-known mixed valence nature of the renormalized bands and determines the enhancement in the density of states (DOS). An enhanced DOS plus various residual interactions between the d electrons not considered here could lead to a spontaneous magnetic moment for the d electrons. We consider the case where this does not happen; however, we believe that by introducing spin polarized bands, a generalization of this method can be achieved.

The d hybridization effect, however, is different than for simple metals since electron correlation effects between the narrow d bands electrons are significant and the intraatomic Coulomb interaction must be explicitly taken into account. To take those correlations effects into account, we have assumed that $U_d \to \infty$ and introduced a slave boson formalism[4-6] to diagonalize $H_c + H_d$ in a mean field approximation. The resulting Hamiltonian H_{c-d}^{MF} is one of hybridizing bands and can be diagonalized by a canonical transformation to yield renormalized bands[5,6] given by

$$H_{c-d}^{\mathrm{MF}} = \sum_{\mathbf{k}n\sigma} \epsilon_{\mathbf{k}n} a_{\mathbf{k}n\sigma}^{\dagger} a_{\mathbf{k}n\sigma} + N_s \Lambda (r^2 - 1), \tag{3}$$

where $n = 1,2$ is a band index, $\epsilon_{\mathbf{k}n} = \frac{1}{2}[\epsilon_{\mathbf{k}} + \tilde{\epsilon}_d + (-1)^n E_{\mathbf{k}}]$ are the hybridized band energies, $E_{\mathbf{k}} = [(\epsilon_{\mathbf{k}} - \tilde{\epsilon}_d)^2 + 4\tilde{V}_d^2]^{1/2}$, $\tilde{\epsilon}_d = \epsilon_d + \Lambda$ is the renormalized d energy level, and Λ is the corresponding energy shift. Here $\tilde{V}_d = V_d r$ is the renormalized d hybridization matrix element and r is the hybridization renormalization factor. Both Λ and r are expectation values of slave boson fields over the coherent equilibrium states and are determined by minimizing the mean field free energy[5,6] with respect to them. The hybridized band creation operators are given by[5,6]

$$a_{\mathbf{k}n\sigma}^{\dagger} = \gamma_{n,1}(k) \hat{d}_{\mathbf{k}\sigma}^{\dagger} + \gamma_{n,2}(k) c_{\mathbf{k}\sigma}^{\dagger}, \tag{4}$$

where $\gamma_{n,m}$ is an orthogonal matrix, $\hat{d}_{\mathbf{k}\sigma}^{\dagger} = \sum_i e^{i\mathbf{k}\cdot\mathbf{R}_i} \hat{d}_{i\sigma}^{\dagger}/N_s^{1/2}$, and $\hat{d}_{i\sigma}^{\dagger}$ is the slave fermion creation operator representing the $|d_{\sigma}^{(1)}\rangle_{\mathbf{R}_i}$ configuration. The limit of $U_d = 0$ can be formally obtained from the above equations by setting $r = 1$ and $\Lambda = 0$. The slave boson average r also gives the average electron occupation of a d site n_d by $n_d = 1 - r^2$, i.e., r^2 is a measure of the degree of delocalization or itineracy of the d electrons.[5,6] In other words, in the infinite U_d limit a conduction electron can jump to a d site only if it is empty and this results in a factor $V_d^2 r^2 = V_d^2(1 - n_d)$ in the transition probability.

Now, by replacing $H_c + H_d$ by H_{c-d}^{MF} in Eq. (1), and expressing the f hybridization term in terms of the renormalized band operators, we obtain an effective Hamiltonian in which the f electrons hybridize with two renormalized bands that already contain the effects of the d electron hybridization and is given by

$$H = H_{c-d}^{\mathrm{MF}} + \sum_{i,m} \epsilon_f f_{im}^{\dagger} f_{im} + \frac{1}{2} \sum_{\substack{imm' \\ m \neq m'}} U_f f_{im}^{\dagger} f_{im} f_{im'}^{\dagger} f_{im'}$$

$$+ \frac{1}{\sqrt{N_s}} \sum_{imk n\sigma} (\tilde{V}_{\mathbf{k}n\sigma m}^{(f)} e^{-i\mathbf{k}\cdot\mathbf{R}_i} f a_{\mathbf{k}n\sigma}^{\dagger} f_{im} + \mathrm{c.c.}), \tag{5}$$

where $\tilde{V}_{\mathbf{k}n\sigma m}^{(f)} = V_{\mathbf{k}\sigma m}^{(f)} \gamma_{n,2}(k)$ is a renormalized f hybridization matrix element. The renormalized f hybridization matrix element takes into account the mixed valence nature of the renormalized bands, i.e., an electron in a state $|\mathbf{k}n\sigma\rangle$ and energy $\epsilon_{\mathbf{k}n}$ has a probability $\gamma_{n,2}(k)^2$ of being in a conduction-band state and hopping into the localized f state. The calculation of an effective magnetic Hamiltonian for the f ions starting from Eq. (5) is accomplished by a combination of a Schrieffer–Wolff (SW) transformation and perturbation theory.[6] Two distinct physical processes contribute to the two-ion interaction: (1) an induced interaction mediated by the interchange of a particle-hole excitation in the conduction band; (2) a kinetic superexchange contribution due to an effective hopping or banding interaction between the localized electrons that results after applying the SW transformation to the Anderson Hamiltonian. The resulting ionic interaction between two localized f^1 electrons located at sites i and j is given by

$$h_{ij} = -\sum_{m,m'} E_{m'm;mm'}(\mathbf{R}_i - \mathbf{R}_j) f_{im'}^{\dagger} f_{im} f_{jm}^{\dagger} f_{jm'}. \tag{6}$$

For a matrix element of the form

$$\tilde{V}_{\mathbf{k}\sigma m}^{(f)} = \sqrt{4\pi} V_f \gamma_{n,2}(k) Y_{3,m-\sigma}(\hat{k}) \times \langle 3,1/2,m-\sigma,\sigma|3,1/2.j,m\rangle,$$

where $Y_{l,m}(\hat{k})$ is a spherical harmonic, $\langle 3,1/2,m-\sigma,\sigma|3,1/2,j,m\rangle$ is a Clebsch–Gordon coefficient for a spin-orbit coupled f state, and a quantization axis along $\mathbf{R}_i - \mathbf{R}_j$, it can be shown that the asymptotic behavior of the range function is given by[1,6] $E_{m'm;mm'} = g(m,m')E(R)$. The factor

$$g(m,m') = \delta_{|m|,1/2}\delta_{|m'|,1/2}$$

remains unchanged from the case where there are no d electrons and implies a highly anisotropic interaction that favors having two ions point their charge along the bonding axis ($m = \pm 1/2$) thereby developing a small covalent bonding energy and causing the ionic orbital moments to align perpendicular to the bonding axis.[1] The radial factor $E(R)$ is a complicated function of the renormalized f hybridization and renormalized bands.[6]

To explore the physics that comes out of this approach, we have done a model calculation for a system of f ions with $j = 5/2$ and d electrons with $s = 1/2$. The conduction band was assumed to be parabolic with a bandwidth $W = 5$ eV. We took ϵ_d and ϵ_f to be 0.3 and 1 eV below the conduction Fermi surface, respectively. Before hybridization, the d band holds 1 electron per site and the conduction band 0.6 electrons per site, and therefore after hybridization the lower hybridized band holds 1.6 electrons per site. The various parameters were chosen as follows: $V_d = 1$ eV, $V_f = 0.1414$ eV, $U_f = 3.0$

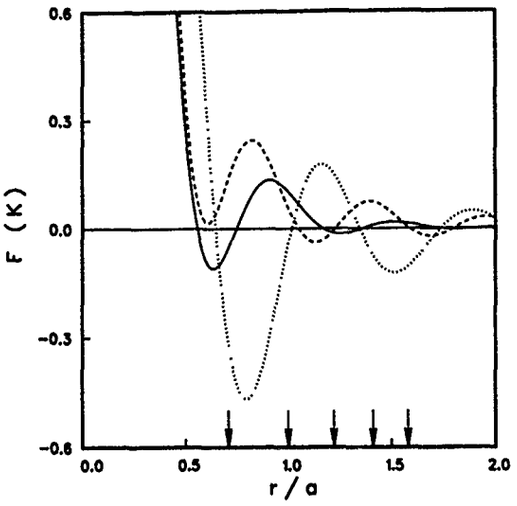

FIG. 1. The range function (intersite coupling strength) as a function of the ratio of the distance between the two f sites to the unit-cell fcc lattice constant a. Here the solid, dashed, and dotted curves correspond to $E_{V,U}$, E_V, and E_0, respectively. The arrows indicate the nearest-neighbor distances for a fcc lattice.

eV, and U_d infinite. In Fig. 1 we show the calculated f-f ion interaction range function under different circumstances: (1) by taking into account the hybridization and correlations between the d electrons as outlined here, $E_{V,U}$ (solid curve); (2) by treating the hybridization of the d electrons but neglecting their correlations, i.e., $U_d=0$, E_V (dashed curve); and (3) by neglecting both the hybridization and correlations between the d electrons, E_0 (dotted curve). We note that both $E_{V,U}$ and E_V oscillate more rapidly with distance than E_0 due to renormalizations in the partial densities of states with a net effect of electrons spilling from the d band into the conduction band.[7] The difference between $E_{V,U}$ and E_V is due to the correlations between the d electrons which are significant for the case considered here. A detailed analysis of these results is presented elsewhere.[6]

In conclusion, we have presented a method to compute the f-f ion interaction in systems where both d and magnetic f electrons hybridize with a conduction band. Our calculations elucidate some of the mechanisms by which two different transition shell species can interfere with each other through cooperative hybridization with a common Fermi band sea. We found that correlations between the d electrons in addition to hybridization must be taken into account in the calculation of the f-f interaction.

The temperature dependence of the antiferromagnetic order in superconducting UPt_3 has been measured using x-ray resonance magnetic scattering. The magnetic Bragg intensity at $Q=(1/2,0,2)$ grows linearly from $T_N=5$ K to $T\cong 0.6$ K ($T_{C+}=0.53$ K), where it becomes suppressed with temperature to a reduction of $\sim 6\%$ at $T=180$ mK. These results demonstrate a coupling of the superconducting and antiferromagnetic order parameters and are consistent with a suppression in the magnitude of the ordered moments below T_c when compared with previously obtained neutron-scattering data.

UPt_3 has emerged as a model system in which to study unconventional superconductivity.[1] The unconventional nature can be seen, for example, in the anisotropic response of bulk measurements in the superconducting phase, such as the ultrasound attenuation,[2] magnetic penetration depth,[3] flux lattice,[4] and tunneling,[5] which shows indirect evidence that the superconducting gap is anisotropic and that the Cooper pairs carry orbital angular momentum, e.g., *d*-wave pairing. It has been suggested that the rich phase diagram of UPt_3 for example, the splitting of the superconducting transition observed by specific heat,[6] arises from a breaking of the orbital degeneracy by a coupling of the superconducting order parameter to another symmetry-breaking field in the system.[7] Scattering studies, which are a direct microscopic probe, have pointed to several possible symmetry-breaking fields. Neutron-scattering[8,9] measurements have shown a coupling of superconductivity to the weak antiferromagnetic order in UPt_3, while electron-scattering[10] studies have suggested the possibility of a coupling between superconductivity and an incommensurate structural modulation of the lattice. While these different results are tantalizing they point to the need for more microscopic measurements. Therefore, we have used x-ray magnetic diffraction to study the interplay of magnetism and superconductivity in UPt_3. X-ray scattering is the only microscopic probe, along with neutron scattering, that is sensitive to the very small ordered moment found in this heavy fermion system. We show that there is a large suppression of the antiferromagnetic scattering intensity below the superconducting transition temperature T_{C+}, demonstrating a direct coupling between the superconducting and antiferromagnetic order parameters in UPt_3. Applying the polarization selection rules unique to x-ray resonance scattering and comparing our results to the previous neutron-scattering measurements of Aeppli *et al.*,[8] we show that the suppression of the magnetic scattering in the superconducting phase is consistent with a suppression in the magnitude of the ordered moment below T_C.

Our x-ray scattering measurements have been performed at Beamline X14A at the National Synchrotron Light Source at Brookhaven National Laboratory.[11] Monochromatic x rays (3.728 keV) are horizontally focused at the sample by a sagittally bent, double-crystal Si(111) monochromator collecting up to 5 mrad, and vertically focused by an x-ray mirror to a spot size of approximately 1 mm^2. The mirror serves the additional function of low-pass filter, helping to suppress the higher-order components passed by the monochromator (e.g., $\lambda/4$ at $E=14.912$ keV). A neon or argon gas proportional counter is used as a detector with an energy resolution of approximately 750 eV which allows us to separate the remaining higher-order contamination from λ, and gives us a direct measure of the instrumental resolution function.

The UPt_3 sample is mounted in vacuum on the mixing chamber of an Oxford Instruments dilution refrigerator. The temperature of the sample is monitored with a Ge diode sensor mounted on the mixing chamber next to the sample. The refrigerator is fitted into a cryostat with three concentric cylindrical Be windows (two thermal shields, one at 4 K and a second at 77 K, and a vacuum shroud at 300 K). The cryostat is mounted on a two-circle diffractometer with a horizontal scattering plane, i.e., the plane of the synchrotron orbit. With this geometry we can access a larger volume in reciprocal space than the more conventional vertical scattering plane, while keeping the vertical axis of the cryostat within $\pm 10°$ of vertical. This is necessary in order to keep the ^{3}He dilute/rich interface inside the mixing chamber. Because of the larger beam divergence in the horizontal plane (the 5 mrad acceptance of the monochromator) the momentum resolution is defined by v slits just before the monochromator and scattering slits before the detector to be $\Delta q\cong 8\times 10^{-3}$ Å^{-1} (see Fig. 2). An additional advantage to the horizontal scattering plane is that for the magnetic reflection at $\mathbf{Q}=(1/2,0,2)$ there is significant suppression of the diffuse and higher-order ($\lambda/4$) scattering at $\mathbf{Q}=(2,0,8)$ that would otherwise saturate the detector. This suppression is due to the polarization factor, which for a Bragg angle of $\theta\cong 44.6°$ [$\mathbf{Q}=(1/2,0,2)$ with $E=3.728$ keV] is $\cos^2(2\theta)\cong 2\times 10^{-4}$.

The UPt_3 sample that we use is cut from the same boule

[a)]Also at University of Konstanz, Konstanz 7750, Germany.

 0021-8979/94/76(10)/6133/4/$6.00 © 1994 American Institute of Physics

that was used in muon spin relaxation measurements.[3] The boule was grown by the float-zone refining method and annealed at 1230 °C for 40 h in vacuum and slowly cooled to room temperature. The specific heat shows the now well-known splitting of the superconducting transition with $T_{C+} \cong 0.530$ K and $T_{C-} \cong 0.427$ K. The superconducting coherence length is about 120 Å as determined with muon spin relaxation by Broholm *et al.* in a sample cut from the same boule.[3] Our sample is a 5-mm-diam×1-mm-thick disk with a shiny, polished surface whose normal is within 1° of c^*. UPt_3 has the hexagonal closed-pack Ni_3Sn structure with the $P6_3/mmc$ space group. In this article Bragg reflections are expressed using Miller indices with reciprocal lattice vectors $a^* = b^* = 4\pi/a\sqrt{3} = 1.264$ Å^{-1} and $c^* = 2\pi/c = 1.285$ Å^{-1}. The antiferromagnetic transition at $T_N \cong 5$ K corresponds to a doubling of the unit cell along $[h,0,0]([0,k,0])$ with the moments aligned along $[h,0,0]$ $([0,k,0])$.[12] Thus, the magnetic Bragg peaks occur at half-order positions, e.g., $Q=(h+1/2,0,l)$ for integer values of h and l. The sample is fixed on the mixing chamber with the $(h,0,l)$ plane normal to the horizontal scattering plane such that the (1/2,0,2) magnetic Bragg reflection is specular $[\theta = 1/2(2\theta)_{Bragg}]$. This configuration optimizes our sensitivity to a rotation of the ordered moments in the basal plane, given the polarization selection rules associated with resonant magnetic scattering (see below).[13]

In order to measure the very small ordered moment in UPt_3 of $(0.02 \pm 0.005)\mu_B$ we use the recently developed technique of x-ray resonance magnetic scattering.[14,15] In previous work it was demonstrated that the weak antiferromagnetic ordering could be measured in the heavy fermion superconductor URu_2Si_2 $(0.04\mu_B)$[16] by tuning the incident x-ray energy to the peak of the so-called "white line" feature at the uranium M_{IV} absorption edge at $E=3.728$ keV. The lower curve in Fig. 1 shows the integrated scattering intensity versus energy in UPt_3 of the magnetic Bragg reflection at $Q=(1/2,0,2)$ corrected for both background and absorption (upper curve) at $T=0.25$ K. This resonance corresponds to a dipole transition from the $3d_{3/2}$ core state to an unoccupied $5f_{5/2}$ orbital. The quantum-mechanical contact between the $5f_{5/2}$ states and the s,p, and d bands is what gives rise to the interesting low-temperature properties in this system, including the weak antiferromagnetism that we are probing. The measurements described in this article are carried out at the peak of the profile where the magnetic signal is a maximum. Since the penetration depth is a minimum at the same energy ($\sim 1/2$ μm), and since the crystal quality could have an effect on both the superconducting and antiferromagnetic coherence lengths, we determine whether the crystal quality of the bulk is the same as near the surface by measuring the sample mosaic. This is shown in the inset in Fig. 1 where we plot mosaic scans (intensity versus sample angle θ) at $Q=(0,0,2)$ for $E=7.59$ keV with a penetration depth of ~ 1 μm and for $E=16.0$ keV with a penetration depth of ~ 10 μm. Similar scans are also seen for $E=3.728$ keV at the peak of the white line. These scans were taken with higher angular resolution than the magnetic scans, i.e., $\Delta\theta = 0.2$ mrad. The mosaic widths differ by less than 5% leading us to believe that the crystal quality of the bulk and

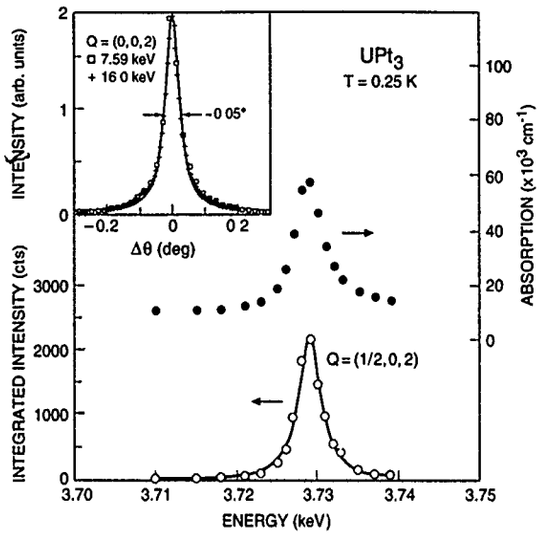

FIG. 1. X-ray magnetic scattering resonance profile at the M_{IV} edge in UPt_3 ($\mu \cong 0.04$ μ_B). The lower curve shows the magnetic scattering intensity at $Q=(1/2,0,2)$ as a function incident energy for $T=0.25$ K. The solid line is a Lorentzian fit to the data which has been corrected for background and absorption. The absorption profile is shown in the upper curve. Inset: The mosaic widths for incident x-ray energies 7.59 keV (○) and 16.00 keV (+) are shown to be nearly the same ($\Delta\theta_{FWHM} \sim 0.05°$) demonstrating that the crystal quality near the surface (<1 μm) is similar to the bulk (10 μm).

surface region are the same. It is interesting to note that an as-grown (unannealed) sample cut from the same boule has a considerably broader mosaic width of 0.33° and a superconducting transition which is suppressed to $T=0.4$ K with no evidence of a splitting in the specific heat.

Figure 2 shows a longitudinal (θ-2θ) scan through the magnetic Bragg reflection at $Q=(1/2,0,2)$ for $T=0.25$ K.

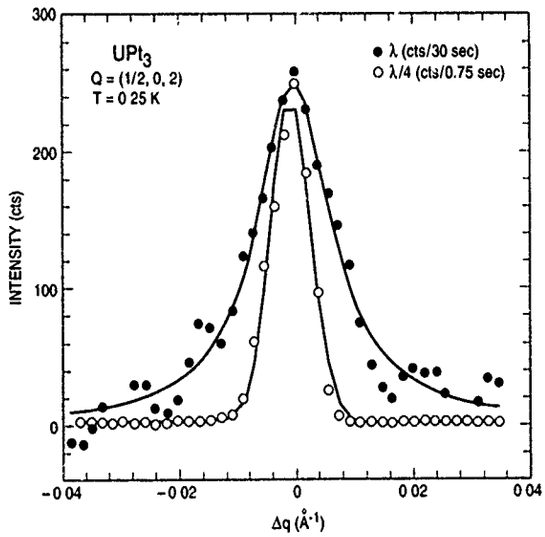

FIG. 2. Longitudinal scans (θ-2θ) through the magnetic (1/2,0,2) and charge (2,0,8) (collected at λ/4) Bragg reflections at $T=0.25$ K. The width of the (2,0,8) charge peak is a direct measure of the resolution function of our spectrometer. From a fit of a Lorentzian to the data we determine the magnetic correlation length to be $\xi \cong 185$ Å.

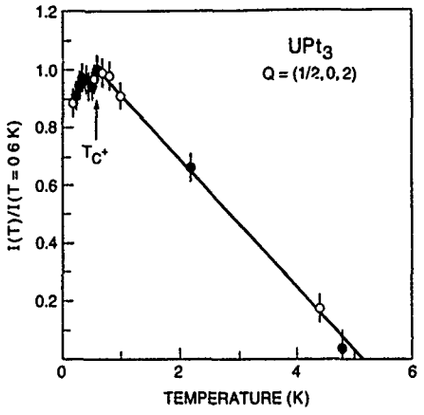

FIG. 3. Integrated scattering intensity of the magnetic reflection at $Q=(1/2,0,2)$ as a function of temperature corrected for background and normalized to fluorescence. The solid circles reflect temperatures for which intensities were measured repeated times for both cooling and warming. The arrow indicates the position of the upper superconducting transition at $T_{C+}=0.53$ K.

The peak intensity of the scan is a remarkable 10 counts/s. A temperature-independent ($0.2\ \text{K}<T<10\ \text{K}$) diffuse background, due primarily to unresolved fluorescence, of about 30 counts/s has been subtracted from the scan. The line shape of the longitudinal scan (solid line) is a Lorentzian convoluted with the nearly triangular resolution function. The resolution function, which we recall is determined by slits, is measured simultaneously by collecting the higher-order scattering ($\lambda/4$) at $Q=(2,0,8)$ shown by the open circles in Fig. 2. A fit to the data gives a full width at half maximum of $\xi^{-1}=0.013\ \text{Å}^{-1}$, corresponding to a magnetic correlation length of approximately 185 Å. This is not much larger than the superconducting coherence length as determined by muon spin rotation (see Ref. 3). There is no measurable change in the magnetic correlation length above T_{C+} at $T=2.3$ K. This lack of long-range order with a similar correlation length has been observed with neutron scattering.[8] This is additional evidence that the near-surface magnetization as measured by x-ray resonance magnetic scattering is similar to that of the bulk as measured by neutrons.

The principle result of our experiment is shown in Fig. 3. Here we plot the background corrected integrated intensity of the magnetic Bragg peak at $Q=(1/2,0,2)$ as a function of temperature, normalized to the value at $T=0.6$ K, near T_{C+}. The solid lines are least-squares linear fits to the data above and below T_{C+}, respectively, and cross at $T\cong 0.61$ K. The data have been normalized to the fluorescence to correct for scattering volume effects due to variations in x-ray beam position on the sample. The remaining systematic errors are shown by the error bars which are estimated from repeated scans at several temperatures (solid circles) taken for both warming and cooling. The scattering intensity shows a relatively abrupt onset at $T_N=5$ K and grows as (T_N-T) to $T=0.6$ K. While this linearity is consistent with mean field behavior, it extends over an unusually large temperature range to approximately $T_N/10$. Similar behavior is observed in the heavy fermion superconductor URu_2Si_2, where the magnetic scattering intensity increases linearly until it saturates near $T_N/10$ ($T_N=17$ K) with a small ordered moment ($\mu\cong 0.04\mu_B$).[15,17] The reason for this unusual behavior is not well understood. Below $T=0.6$ K there is a kink and a subsequent suppression with temperature to a reduction of approximately 6% at $T=180$ mK, the base temperature of this measurement. The dip in the order parameter just above T_C at $T=0.45$ K is about twice the size of the estimated error bars and, as such, will require further study.

The reduction of the magnetic Bragg intensity at $Q=(1/2,0,2)$ below T_{C+} can arise from one of the following possibilities: (i) a rotation of the ordered moment, or (ii) a suppression in the magnitude of the ordered moment. First we examine case (i). Our sensitivity to the orientation of the ordered moment arises from the resonant magnetic scattering polarization selection rules. With the incident x-ray energy tuned to the peak of the uranium M_{IV} edge (see Fig. 1) the polarization dependence of the resonance magnetic scattering cross section is given by $|-(\boldsymbol{\epsilon}_f^*\times\boldsymbol{\epsilon}_i)\cdot\mathbf{z}|^2$, where $\boldsymbol{\epsilon}_i$ and $\boldsymbol{\epsilon}_f$ are the polarization of the electric field of the incident and scattered photons, respectively, and $\mathbf{z}$ is a unit vector along the direction of the ordered moment $\boldsymbol{\mu}$.[13] For the geometry of our experiment $(\boldsymbol{\epsilon}_f^*\times\boldsymbol{\epsilon}_i)=-\mathbf{k}_i/|\mathbf{k}_i|$, where $\mathbf{k}_i$ is the wave vector of the incident photon, and we recall that $\boldsymbol{\mu}$ lies in the hexagonal basal plane. Because of our choice of scattering geometry we are particularly sensitive to a rotation of the moments, i.e., $\mathbf{k}_i\cdot\mathbf{z}$ is nearly linear in the orientation of $\boldsymbol{\mu}$. A 6% suppression would imply a spin rotation of only 2°, assuming that the rotation is purely in plane, which is justified because the in-plane magnetic susceptibility is larger than along $\mathbf{c}$.[18] We recall that the size of the suppression observed with magnetic neutron scattering was ~5%, which is very similar in magnitude to our results.[8] However, because the geometry and polarization selection rules for that measurement were different $[|\mathbf{Q}\times(\boldsymbol{\mu}\times\mathbf{Q})|^2$, where $\mathbf{Q}=(1,1/2,0)$ is the total neutron momentum transfer], a larger rotation would be required to produce the same suppression. Thus, we conclude that, within the error bars of our experiment, the reduction of the magnetic scattering intensity below T_{C+} is most likely due to a reduction in the magnitude of the ordered moment and not a rotation. This conclusion is reinforced when we consider that the observation of a reduction in the magnetic intensity due to rotation would require dominant chirality in the basal plane, which is not known to exist in the absence of a magnetic field. It would be more likely that an equal distribution of domains with clockwise and counterclockwise rotations should exist, which would average out and produce no net change in the scattering intensity.

In conclusion, we have measured the antiferromagnetic Bragg reflection at $\mathbf{Q}=(1/2,0,2)$ to $T=180$ mK using x-ray resonance magnetic scattering. The kink in the scattering intensity, which occurs very near the upper superconducting transition at $T_{C+}=0.53$ K, is evidence that superconductivity influences antiferromagnetism in UPt_3. The 6% reduction in scattering intensity that we observe is very similar in magnitude to what was previously observed with neutron scattering, but with quite different scattering geometry and polarization selection rules. This leads us to conclude that the reduction arises from a suppression of the ordered moment

rather than a rotation. Such a reduction points to a direct coupling of the two order parameters, which in turn points to the anisotropic nature of the superconductivity. While we cannot explicitly determine the nature of this anisotropy with this measurement, it is consistent with the general picture in which the formation of an anisotropic superconducting gap (e.g., which vanishes along lines on the Fermi surface) competes with the highly anisotropic antiferromagnetic state.[19] In this scenario antiferromagnetism could provide the symmetry breaking field that gives rise to the rich superconducting phase diagram in UPt_3.

Non-Fermi liquid ground states in strongly correlated *f*-electron materials (invited) (abstract)

M. B. Maple
Department of Physics and Institute for Pure and Applied Physical Sciences, University of California, San Diego, La Jolla, California 92093-0319

Strongly correlated electron materials, especially the high transition temperature (T_c) cuprate superconductors and heavy fermion rare earth and actinide compounds, have been the focus of intense investigation in recent years. The unusual normal state properties of the high T_c cuprates have been ascribed by some researchers to a non-Fermi liquid (NFL) metallic state, while the anomalous properties of certain heavy fermion U-based superconductors such as UBe_{13} have been attributed to NFL behavior due to a two-channel quadrupolar Kondo effect.[1] Although NFL behavior has not been established in any of the U-based heavy fermion superconductors, evidence for its occurrence in an *f*-electron material has been found in the U alloy system $Y_{1-x}U_xPd_3$.[2] Subsequently, NFL behavior was observed in a number of other *f*-electron alloy systems, including $Sc_{1-x}U_xPd_3$, $UCu_{3.5}Pd_{1.5}$, $Th_{0.1}U_{0.9}Be_{13}$, $Th_{1-x}U_xRu_2Si_2$ ($x \leq 0.07$), $Th_{1-x}U_xPd_2Al_3$, $La_{0.9}Ce_{0.1}Cu_2Si_2$, and $CeCu_{5.9}Au_{0.1}$. Evidence for NFL behavior in $Y_{1-x}U_xPd_3$ and related systems is reviewed and discussed within the context of possible microscopic mechanisms. Some systematics of the NFL low temperature behavior observed in several *f*-electron materials include a linear temperature dependence of the electrical resistivity $\rho \sim 1 - aT$ with the coefficient a either >0 or <0, a logarithmically diverging specific heat $C/T \sim -\ln T$, and $T^{1/2}$ asymptotic behavior of the magnetic susceptibility $\chi \sim 1 - T^{1/2}$.

Magneto-oscillatory phenomena in highly correlated metals (invited) (abstract)

S. R. Julian, G. J. McMullan, C. Pfleiderer, F. S. Tautz, and G. G. Lonzarich
Cavendish Laboratory, Cambridge CB3 0HE, United Kingdom

A central question in the physics of interacting electron systems is whether conditions exist under which the conventional Landau description fails to describe the low energy excitations of the "normal" metallic state. Measurements of the temperature and magnetic field dependences of the magnetization and resistivity—in particular of the de Haas–van Alphen and Shubnikov effects which provide sensitive probes of microscopic processes in metals—are currently being used to examine this question. Advances in material preparation and detection techniques have made it possible to conduct exhaustive studies in selected examples of systems of highly correlated *d* and *f* electrons. Most of our results will be shown to be consistent with the broad predictions of the Landau model. In some extreme circumstances, however, near low temperature transitions as a function of hydrostatic pressure or applied magnetic field, evidence has been collected which appears difficult to reconcile with the standard model of the metallic state.

New rare-earth (R), iron-rich ternary intermetallic compounds of the form $R_3(Fe,M)_{29}$ with the monoclinic $Nd_3(Fe,Ti)_{29}$ structure (space group $P2_1/c$, #14, Z=2) have recently been shown to form with R=Ce, Nd, Pr, Sm, and Gd, and M=Ti, V, Cr, and Mn. This novel structure is derived from the alternate stacking of Th_2Zn_{17} and $ThMn_{12}$-type segments and contains two R sites and fifteen Fe(M) sites. Reported Curie temperatures of the 3:29 compounds range from 296 K (R=Ce, M=Cr) to 524 K (R=Sm, M=V). The 3:29 compounds all show improved magnetic properties after interstitial modification with H or N; in particular, room-temperature coercivity has been reported in $Sm_3(Fe,Ti)_{29}N_5$, making this compound a candidate for possible permanent-magnet applications. In this article we will review the work carried out to date on the 3:29 compounds.

The past ten years have witnessed a renewed interest in the structural and magnetic properties of rare-earth (R), iron-rich intermetallic compounds. These intermetallics often show potential for application as permanent-magnet materials, as in the case of $Nd_2Fe_{14}B$, and much effort has been devoted to the search for intermetallic systems whose magnetic properties might surpass those of $Nd_2Fe_{14}B$, which is limited in application by its comparatively low Curie temperature.[1] Two families of intermetallics, the rhombohedral $R_2(Fe,M)_{17}$ and tetragonal $R(Fe,M)_{12}$ compounds, have received special attention since they are both able to absorb N and C as interstitial atoms, with remarkable improvements in their magnetic properties resulting. In fact, $Sm_2Fe_{17}N_{3-\delta}$ and $Nd(Fe,Ti)_{12}N_{1-\delta}$ both have uniaxial anisotropy and Curie temperatures over 700 K.

As early as 1990, Jang and Stadelmaier[2] demonstrated that the tetragonal $NdFe_{11}Ti$ phase is unstable at temperatures below about 1000 °C, decomposing into $Nd_2(Fe,Ti)_{17}$, Fe_2Ti, and α-Fe(Ti), a fact missed by many workers. In 1992, whilst studying the conditions of formation of $NdFe_{11}Ti$, with a view to preparing single-phase material for subsequent nitrogenation and ultimately $NdFe_{11}TiN_{1-\delta}$ based permanent magnets, Collocott *et al.*[3] reported the formation of a new high-temperature phase in the Fe-rich corner of the Nd-Fe-Ti ternary phase diagram (see also Margarian *et al.*[4]). The new structure was given as $Nd_2(Fe,Ti)_{19}$ by Collocott *et al.*[3] and its x-ray diffraction (XRD) pattern was indexed on the basis of a (2a,4c) superstructure of the hexagonal $TbCu_7$ structure. The $Nd_2(Fe,Ti)_{19}$ compound had a rather low Curie temperature of 411 K but absorption of nitrogen gave a roughly 50% increase in Curie temperature. However, the easy direction of magnetization is in the basal plane (referred to the underlying hexagonal $TbCu_7$ cell) for both the parent and nitride compounds, precluding its use as a permanent magnet.

There are a number of reports of Sm-Fe-Ti and Nd-Fe-Ti phases at around the same composition as the $Nd_2(Fe,Ti)_{19}$ compound of Collocott *et al.*[3] For example, Saito *et al.*[5] and Ohashi *et al.*[6] both observed a transformation from a tetragonal $ThMn_{12}$ structure to a disordered hexagonal $TbCu_7$ structure in rapidly quenched $SmFe_{11}Ti$ as the quenching rate increased. Similarly, Katter *et al.*[7] observed a transformation from the rhombohedral Th_2Zn_{17} structure to the $TbCu_7$ structure in Sm-Fe alloys around the 1:9 composition, and Neiva *et al.*[8] reported the formation of a 1:7 phase with composition $Sm(Fe,Ti)_9$. Jang and Stadelmaier[2] reported a Ti-stabilized $NdFe_7$ phase in as-cast alloys. At the same conference at which Collocott *et al.* reported the formation of the $Nd_2(Fe,Ti)_{19}$ phase,[3] Hirosawa *et al.*[9] reported the formation of a $Nd(Fe,Ti)_9$ phase with the $TbCu_7$ structure during a study of the formation of the $ThMn_{12}$-type $NdFe_{11}Ti$ phase. A common feature of many of these reports is the transformation from the 2:17 or 1:12 structures to the disordered 1:7

 0021-8979/94/76(10)/6138/6/$6.00 © 1994 American Institute of Physics

structure by rapid solidification with increasing quenching rate.

At the 38th Annual MMM Conference in Minneapolis in November 1993, Cadogan *et al.*[10] reported that the new $Nd_2(Fe,Ti)_{19}$ structure is monoclinic with a cell derived from that of $TbCu_7$. At the same conference, Li *et al.*[11] reported the observation of a $Pr_2(Fe,Ti)_{19}$ phase in a study of the $(Pr_{1-x}Ti_x)Fe_5$ compounds. During discussions at the MMM Conference we learned that the General Motors group (Fuerst *et al.*) had also observed the formation of a new structure in samples of the form $NdFe_{9.5-x}M_x$ ($x=0.5$ for M=Ti, 1.5 for M=Cr and $x>3.5$ for M=Mn) with virtually identical XRD patterns to that of our $Nd_2(Fe,Ti)_{19}$ sample.[3,10] Fuerst *et al.*[12] were the first to suggest that the new phase belongs to the $P2_1/c$ space group, which was later confirmed by x-ray[13] and neutron[14] powder diffraction work. The structural determinations[13,14] also showed that the stoichiometry previously referred to as $Nd_2(Fe,Ti)_{19}$ is in fact $Nd_3(Fe,Ti)_{29}$. The $R_3(Fe,Ti)_{29}$ phase is now known to form with R=Sm,[15] Pr,[11] Ce,[16] and Gd,[17] in addition to R=Nd.

In this article we shall review the structural and magnetic properties of the new $R_3(Fe,M)_{29}$ phases.

In the original paper by Collocott *et al.*[3] the new Nd-Fe-Ti phase was denoted $Nd_2(Fe,Ti)_{19}$ and found to form with high-temperature annealing (1100 °C). This structure only forms for a Ti content in the range 3.8–5.1 at. % and was indexed as a (2a,4c) superlattice of the hexagonal $TbCu_7$ structure. Earlier work by Ivanova, Shcherbakova, and co-workers[18,19] also showed evidence of a new structure in the $R_2(Fe_{0.91}V_{0.09})_{17}$ (R=Y, Nd, Sm, and Gd) compounds and these workers described the crystal cell as being a (5a,5c) superlattice of the hexagonal $CaCu_5$ structure for R=Y and a distorted orthorhombic variant of the hexagonal $CaCu_5$ structure for R=Nd, Sm, and Gd. The similarities between the XRD patterns of the $Sm_2(Fe_{0.91}V_{0.09})_{17}$ sample of Shcherbakova *et al.*[19] and the $Nd_2(Fe,Ti)_{19}$ sample of Collocott *et al.*[3] strongly suggest that these samples in fact have the same crystal structure.

The structure of $Nd_2(Fe,Ti)_{19}$ was reported as monoclinic by Cadogan *et al.*[10] and Fuerst *et al.*,[12] the latter group suggesting the $P2_1/c$ space group and also that the crystal cell contained six $NdFe_{9.5-x}M_x$ units, on the basis of density measurements.

The final structural refinement was obtained from x-ray powder diffraction work by Li *et al.*[13] who confirmed the monoclinic $P2_1/c$ space group and showed that the correct stoichiometry of the new phase is $Nd_3(Fe,Ti)_{29}$ with two formula units per cell. The 3:29 stoichiometry represents a difference of 1.7% from the original 2:19 stoichiometry. At the same time, Yelon and co-workers[14] refined the 3:29 structure by neutron powder diffraction, and there is excellent agreement between these two structural refinements. In Fig. 1 we show the powder XRD patterns (Cu$K\alpha$ radiation) of $Nd_3(Fe,Ti)_{29}$, together with those of $Nd_2(Fe,Ti)_{17}$ and $Nd(Fe,Ti)_{12}$ for comparison, and in Fig. 2 we show the crystal structure of $Nd_3(Fe,Ti)_{29}$ (courtesy of Hu and Yelon[14]).

The structure of $Nd_3(Fe,Ti)_{29}$ is intermediate between the well-known rhombohedral Th_2Zn_{17} and tetragonal $ThMn_{12}$ structures. The common feature of all these structures is that

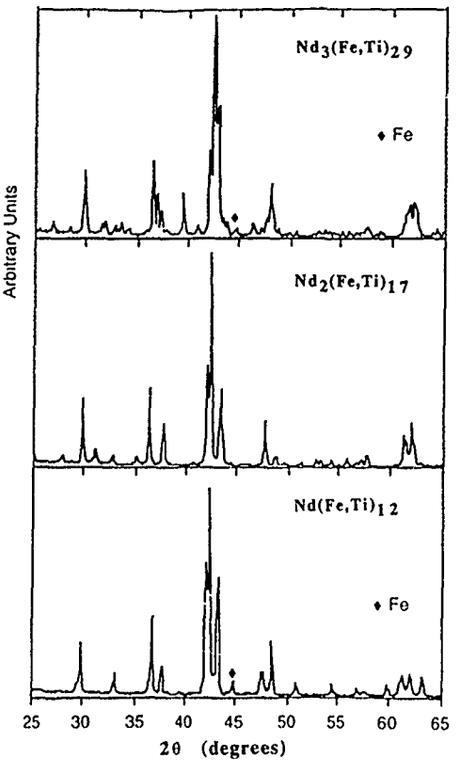

FIG. 1. X-ray powder diffraction patterns (Cu$K\alpha$) of monoclinic $Nd_3(Fe,Ti)_{29}$, rhombohedral $Nd_2(Fe,Ti)_{17}$ and tetragonal $Nd(Fe,Ti)_{12}$.

they are formed by the replacement of R atoms by T-T "dumb-bells" in the hexagonal RT_5 structure. This process may be described by the equation

$$R_{1-x}(2T)_xT_5 \rightarrow RT_y$$

with the 2:17 structure corresponding to a $\frac{1}{3}$ replacement and the 1:12 structure corresponding to a $\frac{1}{2}$ replacement. The new 3:29 structure corresponds to a $\frac{2}{5}$ replacement and is formed by the alternate stacking of 2:17 and 1:12 segments, in the

ratio 1:1. Such structural relationships were considered by Stadelmaier in 1984,[20] who indeed predicted the occurrence of a number of novel structures including the 3:29 structure. Stadelmaier showed that such new structures must have one edge length equal to $a_0\sqrt{3}$ where a_0 is the relevant lattice parameter of the 1:5 cell. Both structural refinements of $Nd_3(Fe,Ti)_{29}$ (Refs. 13,14) have $b\sim a_0\sqrt{3}$, in agreement with Stadelmaier's criterion. In Table I we give the lattice parameters and indexation cells of the various $R_3(Fe,M)_{29}$ compounds studied to date.

The monoclinic $R_3(Fe,M)_{29}$ structure contains two R sites (2a and 4e) and fifteen Fe(M) sites (2d and fourteen 4e sites), and in Table II we give the atomic positions of these sites, deduced by Li *et al.*[13] from x-ray powder diffraction. The relationships between the lattice parameters of the 3:29 and 1:5 structures are

$$a=\sqrt{(2a_0)^2+(c_0)^2}$$

$$b=\sqrt{3}a_0$$

$$c=\sqrt{(a_0)^2+(2c_0)^2}$$

$$\beta=\arctan\left(\frac{2a_0}{c_0}\right)+\arctan\left(\frac{a_0}{2c_0}\right),$$

and in Fig. 3 we show the relationship between the 3:29 and 1:7 crystal cells.[10] In Fig. 4 we show a schematic representation of the dumb-bell substitution sequence, projected onto the (110) plane of the $CaCu_5$ structure, for the 2:17, 3:29, and 1:12 structures.[13]

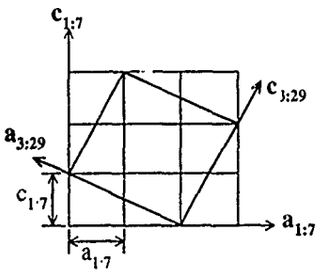

FIG. 3. Crystallographic relationship in the a-c plane between the monoclinic unit cell of $Nd_3(Fe,Ti)_{29}$ and the hexagonal $TbCu_7$ cell (Ref. 10).

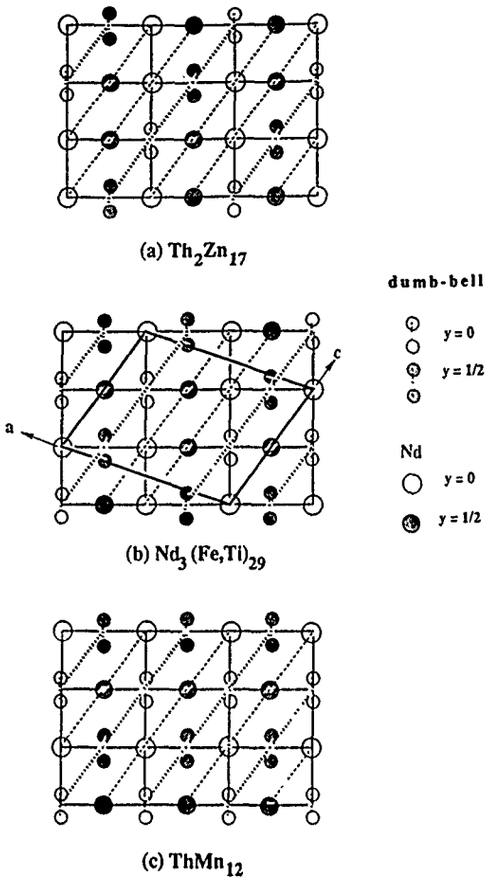

FIG. 4. Schematic representation of the geometrical relationship and the dumb-bell substitution sequence, in a projection onto the (110) plane of the hexagonal $CaCu_5$ structure for the 3:29, 2:17, and 1:12 structures (Ref. 13).

The rhombohedral 2:17 structure forms with light R atoms by a regular dumb-bell replacement in the 1:5 structure, and we therefore suggest that the new monoclinic 3:29 structure will also form only for light R (including Gd). It is quite likely that a different structure derived from the stacking of *hexagonal* 2:17 and tetragonal 1:12 segments will exist for 3:29 compounds with heavy R atoms. It is also likely that other intermediate phases based on the stacking of the rhombohedral 2:17 and tetragonal 1:12 segments will exist, besides 3:29. For example, a 2:1 stacking ($\frac{3}{8}$ dumb-bell replacement) would correspond to a 5:46 phase, whereas a 1:2 stacking ($\frac{3}{7}$ dumb-bell replacement) would correspond to a 4:41 phase.

Hu and Yelon[14] drew attention in their paper to the fact that the crystal structure of 3:29 shows a distinct stacking along the *b* direction which is reminiscent of the $Nd_2Fe_{14}B$ structure, in that there is an alternating stacking of R-containing and R-free layers. Furthermore, they pointed out that the distinction between the dumb-bell and non-dumb-bell Fe sites is not as clear-cut as in the 2:17 and 1:12 structures, since the 3:29 structure exhibits a number of rather short Fe-Fe bonds (<2.45 Å). Taking advantage of the fact that Ti has a negative neutron scattering length, Hu and Yelon demonstrated that the Ti atoms in $Nd_3(Fe,Ti)_{29}$ occupy sites with a low Nd coordination. In a subsequent paper, Hu and Yelon[21] presented a comprehensive summary of the bond lengths in $Nd_3(Fe,Ti)_{29}$ and showed that the distribution in bond length is virtually continuous over the range 2.36–3.01 Å, in contrast to the $Nd_2(Fe,Ti)_{17}$ and $Nd(Fe,Ti)_{12}$ compounds. In their paper, Hu and Yelon also reported the formation of $Nd_3(Fe,V)_{29}$ and $Nd_3(Fe,Al)_{29}$, but no structural details were presented.

The $R_3(Fe,M)_{29}$ compounds are ferromagnetic with Curie temperatures in the range 296 K [R=Ce, M=Cr (Ref. 30)] to 524 K [R=Gd, M=V (Ref. 19)]. XRD experiments on magnetically aligned powder samples of $Nd_3(Fe,Ti)_{29}$ (Ref. 22) and $Sm_3(Fe,Ti)_{29}$ (Ref. 15) indicate that the easy direction of magnetization is in the *a*-*b* basal plane (hexagonal description), along [201], whereas the powder neutron diffraction results of Hu and Yelon[14,21] were interpreted in

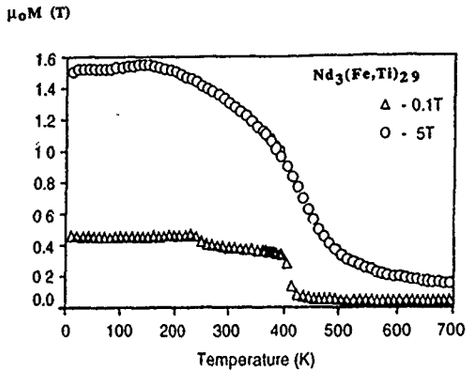

FIG. 5. Magnetization curves for $Nd_3(Fe,Ti)_{29}$ in applied fields of 0.1 and 5 T (Ref. 10).

terms of the magnetically easy direction being the crystal a-axis at 295 K. The saturation magnetization of $Nd_3(Fe,Ti)_{29}$ is 58 μ_B/f.u. at 4 K and 47 μ_B/f.u. at 295 K, and its anisotropy field B_a=7.7 T at 295 K and 9.8 T at 12 K.[10,22] In Table III we summarize the intrinsic magnetic properties of the various $R_3(Fe,M)_{29}$ compounds.

The temperature dependence of the magnetization of $Nd_3(Fe,Ti)_{29}$ presented by Cadogan *et al.*[10] (Fig. 5) shows clear evidence of a magnetization reorientation around 220 K (B_{appl}=0.1 T), and recent low-temperature neutron work by Hu and Yelon[21] confirms a shift in the easy direction of magnetization away from the crystal a axis (at 295 K) to the a-b plane (at 12.5 K). Our analysis of ^{57}Fe average hyperfine fields, deduced from Mössbauer measurements, also supports the occurrence of a spin reorientation at low temperatures.[23] Other evidence of magnetization reorientations in the form of FOMPs (first-order magnetization processes) has been reported by Fuerst *et al.*[12] who observed a FOMP in the magnetization of $NdFe_{9.0}Ti_{0.5}$ measured on fixed powders at 5 K; the observed FOMP field is 2.0 T. Yang *et al.*[15] also observed a FOMP in $Sm_3(Fe,Ti)_{29}$ by singular-point detection measurements; their FOMP fields are 2.2 T at 77 K and 3.0 T at 4 K. The exact nature of the magnetization reorientations in $Nd_3(Fe,Ti)_{29}$ are as yet unclear.

Finally, Fuerst *et al.*[12] reported that their $NdFe_{6.0}Mn_{3.5}$ sample had a coercive field of 3.8 kOe at 5 K, whereas their $NdFe_{9.0}Ti_{0.5}$ and $NdFe_{8.0}Cr_{1.5}$ samples had coercivities less than 1.2 kOe.

Shcherbakova *et al.*[19] demonstrated that their $R_2(Fe_{0.91}V_{0.09})_{17}$ (R=Y, Nd, Sm, and Gd) phases all absorb nitrogen with substantial increases in Curie temperature ensuing (see Table IV). Significantly, they also found an easy [001] direction of magnetization (hexagonal description) in $Sm_2(Fe_{0.91}V_{0.09})_{17}N_{2.5}$ and measured anisotropy fields B_a of 23.9 T at 4 K and 17.3 T at 260 K. The formation of a carbide $Y_2(Fe_{0.91}V_{0.09})_{17}C_{1.0}$, which had a modest 30 K increase in Curie temperature over the parent phase, was also reported by these authors.

Collocott *et al.*[3] showed that $Nd_3(Fe,Ti)_{29}$ absorbs nitrogen, with a 5.4% increase in volume and a 45% increase in Curie temperature resulting. However, their XRD patterns on magnetically aligned powder samples showed that both the parent and nitride compounds had a-b planar anisotropy.

Yang *et al.*[24] reported the formation of $Sm_3(Fe,Ti)_{29}N_5$ with a 7.1% volume increase relative to the parent phase. The Curie temperature of the nitride was 750 K compared to 486 K for the parent phase and, importantly, $Sm_3(Fe,Ti)_{29}N_5$ shows c-axis anisotropy. The anisotropy field of $Sm_3(Fe,Ti)_{29}N_5$ is 18.1 T at 4 K, and Yang *et al.*[24] were able to develop a coercivity of $\mu_0 H_{c_i}$ = 1.3 T at 4 K. Subsequent work by Hu *et al.*[25] on ball-milled $Sm_3(Fe,Ti)_{29}N_5$ produced a maximum energy product $(BH)_{max}$ of 105 kJ m^{-3} after ball milling for 4.5 h.

Ryan *et al.*[26] have studied the absorption of hydrogen and nitrogen by $Nd_3(Fe,Ti)_{29}$ using thermopiezic analysis, thermogravimetric analysis (TGA), and ^{57}Fe Mössbauer spectroscopy, and found that the addition of hydrogen leads to a significant increase in Curie temperature but very little change in Fe moment, whereas the addition of nitrogen increases both parameters. Attempts to form a $Nd_3(Fe,Ti)_{29}$ carbide were unsuccessful due to disproportionation of the material, although a "magnetic event" was observed by TGA at 660 K which was tentatively assigned to a $Nd_3(Fe,Ti)_{29}C_x$ phase.

As mentioned earlier, the 3:29 structure is formed by the 1:1 alternate stacking of 2:17 and 1:12 segments and Li[27] has identified the interstitial sites available to N or C atoms in the 3:29 structure by considering the interstitial sites in the 1:12 and 2:17 structures. There are two 4e interstitial sites with the special atomic positions $(\frac{1}{5}\frac{1}{2}\frac{2}{5})$ and $(\frac{1}{2}\frac{1}{4}\frac{1}{4})$, giving a maximum N content of $Nd_3(Fe,Ti)_{29}N_4$ according to the relation

TABLE IV. Intrinsic magnetic properties and volume expansions of the $R_3(Fe,M)_{29}N_x$ compounds [×=12 K measurement and * refers to $Nd_3(Fe,Ti)_{29}H_x$].

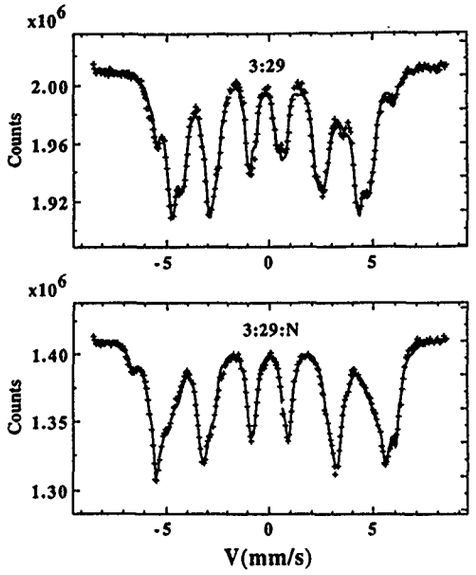

FIG. 6. ^{57}Fe Mössbauer spectra of $Nd_3(Fe,Ti)_{29}$ and $Nd_3(Fe,Ti)_{29}N_{4.5}$ obtained at 12 K with a ^{57}CoRh source (Ref. 26).

$$R_2M_{17}N_3+RM_{12}N_1 \rightarrow R_3M_{29}N_4.$$

Ryan and Cadogan[26] calculated the sizes of the holes in the 3:29 structure and found that all holes capable of accommodating interstitial H, N, or C are 4*e* sites. The two largest holes have radii of 0.64 and 0.59 Å and are thus able to accommodate N or C, giving $R_3M_{29}X_4$ as the maximum interstitial X content. The next largest hole has a radius of 0.45 Å, which is too small for N or C but can accommodate H, giving a maximum H content of $R_3M_{29}H_6$, as observed.[26]

In Table IV we summarize the work on interstitially modified 3:29 compounds. The interstitial contents are approximate values, and we note that the results on the $Sm_3(Fe,Ti)_{29}$ nitride by Yang *et al.*[24] and Hu *et al.*[25] give a nitrogen content of N_5. Ryan *et al.*[26] calculated a nitrogen content of $N_{4.5}$ in $Nd_3(Fe,Ti)_{29}N_x$ but caution that such results with $N_{>4}$ may be due to partial decomposition of the samples.

The room-temperature ^{57}Fe Mössbauer spectra of $Nd_3(Fe,Ti)_{29}$ and its nitride were presented by Cadogan *et al.*,[28] along with spectra of $Nd_2(Fe,Ti)_{17}$ and $Nd(Fe,Ti)_{12}$ for comparison. The $Nd_3(Fe,Ti)_{29}$ phase has an average ^{57}Fe hyperfine field $\langle B_{hf}\rangle$ of 20.8 T at 295 K which corresponds to an average Fe moment of 1.33 μ_B, assuming a conversion factor of 15.6 T/μ_B.[29] The corresponding $\langle B_{hf}\rangle$ values of $Nd_2(Fe,Ti)_{17}$ and $Nd(Fe,Ti)_{12}$ are 15.4 and 24.8 T, respectively. The $\langle B_{hf}\rangle$ of $Nd_3(Fe,Ti)_{29}N_4$ is 29.6 T at 295 K, the 42% increase in field being attributed to the N-induced increase in Curie temperature of about 200 K. Subsequent low-temperature (12 K) ^{57}Fe Mössbauer studies by Ryan *et al.*[26] gave $\langle B_{hf}\rangle$ values of 29.0 and 33.4 T for $Nd_3(Fe,Ti)_{29}$ and $Nd_3(Fe,Ti)_{29}N_{4.5}$, respectively. The $\langle B_{hf}\rangle$ values of $Nd_3(Fe,Ti)_{29}H_{6.1}$ are 30.2 and 26.4 T at 12 and 295 K, respectively.[26] Given the large number of Fe sites in the $Nd_3(Fe,Ti)_{29}$ structure (15 sites) and the effects of site occupation by Ti in $Nd_3(Fe,Ti)_{29}$, one can only deduce the average hyperfine parameters from the Mössbauer spectra, with any certainty. In Fig. 6 we show the ^{57}Fe Mössbauer spectra of $Nd_3(Fe,Ti)_{29}$ and $Nd_3(Fe,Ti)_{29}N_{4.5}$ obtained at 12 K with a ^{57}CoRh source.

Interestingly, a comparison of $\langle B_{hf}\rangle$ of $Nd_3(Fe,Ti)_{29}$ at 12 and 295 K (Ref. 26) with saturation magnetization results[22] suggests that the low-temperature magnetic structure of $Nd_3(Fe,Ti)_{29}$ is noncollinear (Cadogan *et al.*[23]).

Structural and magnetic properties of $R_3(Fe,T)_{29}$ compounds

C. D. Fuerst, F. E. Pinkerton, and J. F. Herbst
Physics Department, General Motors NAO Research and Development Center, 30500 Mound Road, Warren, Michigan 48090-9055

We report the formation of several members of the recently discovered class of $R_3(Fe,T)_{29}$ compounds and some of their intrinsic properties. Focusing on materials with T=Ti and Cr, we have prepared $R_3(Fe,Ti)_{29}$ (R=Ce, Pr, Nd, Sm) and $R_3(Fe,Cr)_{29}$ (R=Ce, Nd, Sm) compounds which all feature the novel monoclinic crystal structure first established for $Nd_3(Fe,Ti)_{29}$. In each of the Ti- and Cr-containing groups the Ce member has the smallest magnetization, Curie temperature, and unit cell, suggesting that the Ce ion is tetravalent, or nearly so, in this family of materials. We observed no evidence of $R_3(Fe,Ti)_{29}$ phase formation for R=Y, Gd, Dy, and Er. Our magnetization measurements indicate that only $Nd_3(Fe,Ti)_{29}$ and $Nd_3(Fe,Cr)_{29}$ exhibit spin reorientations, at temperatures of 235 and 145 K, respectively.

I. INTRODUCTION

A new class of rare earth-iron (R-Fe) compounds stabilized by a third element (T) has recently been discovered to form. The class was recognized initially as having the $R_2(Fe,T)_{19}$ stoichiometry, with $Nd_2(Fe,Ti)_{19}$ (Refs. 1–3), and $Nd_2(Fe,Cr)_{19}$, $Nd_2(Fe,Mn)_{19}$ (Ref. 3) as representatives; alloys of nominal composition $R_2(Fe_{0.91}V_{0.09})_{17}$ are also likely members.[4] Its prototypical lattice symmetry was identified as monoclinic and was found to correspond to the $P2_1/c$ space group (No. 14 of Ref. 5).[3] Structural investigations of the Nd-Fe-Ti phase by neutron[6] as well as x-ray[7] powder diffraction have since established that the precise stoichiometry is $R_3(Fe,T)_{29}$. Here we report the preparation and characterization of several other members of this fascinating class of compounds, including two Ce-based representatives: $R_3(Fe,Ti)_{29}$ (R=Ce, Pr, Nd, Sm) and $R_3(Fe,Cr)_{29}$ (R=Ce, Nd, Sm).

II. SAMPLE PREPARATION AND PHASE FORMATION

Ingots for this inquiry were prepared by induction melting high-purity elemental constituents in boron nitride crucibles. Our starting compositions contained 2%–10% excess rare earth relative to the $R_3(Fe,T)_{29}$ stoichiometry. The ingots were heat treated in vacuum for periods between five days and three weeks at various temperatures T_A to maximize the amount of $R_3(Fe,T)_{29}$ component. For the T=Ti (Cr) materials an anneal temperature T_A=1100 °C (1000 °C) was most appropriate, with the exception of $Ce_3(Fe,Ti)_{29}$ and $Ce_3(Fe,Cr)_{29}$, both of which required a much lower T_A of 900 °C. Phase occurrences were monitored by x-ray diffraction and electron beam microprobe analyses. The latter indicated (i) a rare earth concentration of 9.4±0.1 at. % for the principal phase, in excellent agreement with the $R_3(Fe,T)_{29}$ stoichiometry, and (ii) the values of x given in Table I for the specific $R_3Fe_{29-x}T_x$ compositions.

The heat-treated (R=Ce, Pr, Nd; T=Ti) materials were essentially single-phase $R_3(Fe,Ti)_{29}$. To illustrate this point with a representative example, Fig. 1 compares the Cu-K_α x-ray powder diffraction pattern of $Pr_3Fe_{27.5}Ti_{1.5}$ with a pattern calculated for that compound using the sites and nuclear position parameters obtained by Hu and Yelon[6] for $Nd_3(Fe,Ti)_{29}$. In the other samples contaminant phases detected by the electron microprobe analyses included $R(Fe,T)_{12}$, $R_2(Fe,T)_{17}$, $R(Fe,T)_2$, and α-Fe admixed with the element T. Figure 2 compares the observed Cu-K_α x-ray spectra of the annealed Ce-Fe-Ti and Ce-Fe-Cr ingots. The former [Fig. 2(a)] is essentially single-phase $Ce_3Fe_{27.4}Ti_{1.6}$, while the analytical results indicate that the latter [Fig. 2(b)] contains, in addition to the principal $Ce_3Fe_{24.9}Cr_{4.1}$ phase, minor amounts of $CeFe_{9.9}Cr_{2.1}$, $Fe_{0.8}Cr_{0.2}$, and $CeFe_{1.9}Cr_{0.1}$.

In our opinion the $R_3(Fe,T)_{29}$ phases are "high temperature" materials in the sense that they are not thermodynamically stable at room temperature. Put another way, they crystallize only at temperatures above some minimum value. To test this conjecture we heat treated an as-cast $Sm_{3.3}Fe_{27.5}Ti_{1.5}$ ingot for five days at 900 °C [well below T_A=1100 °C found to yield material chiefly composed of monoclinic

TABLE I. Crystallographic and magnetic properties of $R_3Fe_{29-x}T_x$ compounds. The monoclinic lattice parameters are a, b, c, and β; the unit cell volume is $V=abc\sin\beta$; ρ is the density derived from the lattice constants; T_C is the Curie temperature; and $4\pi M_s$ is the saturation magnetization.

$Sm_3(Fe,Ti)_{29}$]. The x-ray pattern of the $T_A = 900$ °C sample closely resembles a pattern calculated for $SmFe_7$ having the rhombohedral $ThFe_4Co_4$-type defect structure,[8,9] which, judging from the similarity of their x-ray signatures, is related to the rhombohedral Th_2Zn_{17}-type structure characterizing Sm_2Fe_{17}.

Using compositions and anneal schedules similar to those employed for the materials of Table I we attempted to form $R_3(Fe,Ti)_{29}$ compounds with R=Y, Gd, Dy, and Er. All these samples, however, consisted primarily of material having the hexagonal Th_2Ni_{19}-type structure.[10,11] We surmise that monoclinic $R_3(Fe,Ti)_{29}$ does not form for Y and the heavy rare earths, for which a hexagonal Th_2Ni_{19} type [or hexagonal Th_2Ni_{17} type for slightly lower (Fe+Ti):R ratios] is the stable low temperature phase. Apparently monoclinic $R_3(Fe,Ti)_{29}$ can be formed only when the equilibrium room temperature phase has a rhombohedral structure of the $ThFe_4Co_4$ or Th_2Zn_{17} variety.

It is doubtful that $R_3(Co,Ti)_{29}$ compounds occur, at least for the light rare earths. A Nd-Co-Ti ingot annealed at 1000 °C principally contained Th_2Zn_{17}-type material.

III. RESULTS AND DISCUSSION

Crystallographic and magnetic information on the $R_3(Fe,T)_{29}$ compounds investigated here is summarized in Table I. The lattice parameters a, b, c, and β (corresponding to the second monoclinic setting, $\beta \neq 90°$) were inferred from the x-ray diagrams. The lanthanide contraction is evident from the decrease of a, b, and c as the atomic number of the rare earth constituent increases from Pr to Sm. The largest decline with R atomic number is shown by b, analogous to the larger decline of c in the tetragonal $R_2Fe_{14}B$ series (cf. Ref. 12). The common behavior likely reflects the fact that the R ions in $R_3(Fe,T)_{29}$ [$R_2Fe_{14}B$] reside in planes normal to the b direction[6,7] [c direction]. Through the $R_2Fe_{14}B$ series the basal plane cell constant a is confined to a narrow range by the particularly stable trigonal prisms of the $Nd_2Fe_{14}B$-type structure,[12] and we speculate that local atomic coordination effects restrict, in a similar way, the variation of a and c with R in the $R_3(Fe,T)_{29}$ series.

We determined Curie temperatures (T_C) by differential scanning calorimetry, and magnetization measurements were performed from 5 to 295 K with a vibrating sample magnetometer using a maximum applied field of 9 T. Values of T_C and the saturation magnetization ($4\pi M_s$) at 5 and 295 K are included in Table I.[13] For both the T=Ti and T=Cr groups T_C and $4\pi M_s$(5 K) are lowest for the Ce member, as is the (room temperature) unit cell volume V. Together these facts strongly suggest that the Ce ion is essentially tetravalent (i.e., has no $4f$-derived magnetic moment) in the $R_3(Fe,T)_{29}$ class of compounds.

If we assume that the Ce moment is zero, the $4\pi M_s$(5 K) values for $Ce_3Fe_{27.4}Ti_{1.6}$ and $Ce_3Fe_{24.9}Cr_{4.1}$ imply average Fe moments of ~1.7 and ~1.4 μ_B for the Ti and Cr materials, respectively. These average Fe moments together with the $4\pi M_s$(5 K) results for the other compounds indicate that the R moments are near their free ion values. Magnetization versus temperature measurements in a small applied field, 1 kOe, revealed spin reorientations of the easy magnetization

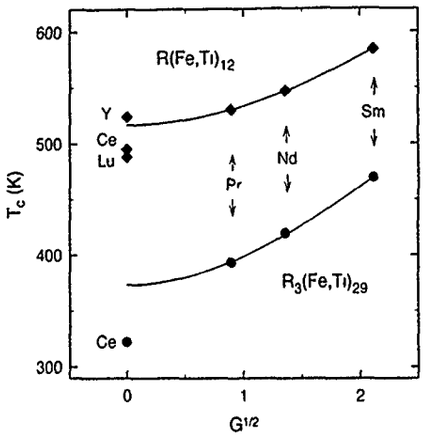

FIG. 3. Curie temperatures T_C of $R_3(Fe,Ti)_{29}$ (●) and $R(Fe,Ti)_{12}$ (♦) compounds vs $G^{1/2}$. The curves are specified by Eqs. (1)–(3) for the R=Pr, Nd, and Sm compounds of each series with the parameters given in the text.

direction at $T_s \cong 235$ K in $Nd_3Fe_{27.4}Ti_{1.6}$ and $T_s \cong 145$ K in $Nd_3Fe_{24.6}Cr_{4.4}$, but in none of the other compounds in Table I. Our $T_s(Nd_3Fe_{27.4}Ti_{1.6})$ agrees well with the measurements of Cadogan *et al.*[14] The slightly larger low-temperature magnetization of $Pr_3Fe_{27.5}Ti_{1.5}$ as compared with that of $Nd_3Fe_{27.4}Ti_{1.6}$ may reflect a noncollinear moment arrangement in the latter below T_s.

As is often the case for rare earth-transition metal series, T_C is an increasing function of the effective rare earth spin, gauged by $G^{1/2}$ where $G \equiv (g-1)^2 J(J+1)$ is the de Gennes factor for an R ion having gyromagnetic ratio g and total angular momentum quantum number J. This is shown for the T=Ti compounds by the filled circles of Fig. 3, which displays T_C vs. $G^{1/2}$. Ascribing the magnetism to Fe-Fe and R-Fe exchange interactions and neglecting R-R exchange, we can write $T_C(G)$ in the nearest-neighbor, mean-field approximation of the two-sublattice Heisenberg model, which is used widely in analyzing systematic T_C behavior in rare earth-transition metal compound series, as

$$T_C(G) = \tfrac{1}{2} T_C(0)(1+\sqrt{1+\gamma G}), \tag{1}$$

where

$$3k_B T_C(0) = Z_{FF} S_F(S_F+1) j_{FF} \tag{2}$$

and

$$\gamma = 4\left(\frac{Z_{FR}Z_{RF}}{Z_{FF}^2}\right)\frac{1}{S_F(S_F+1)}\left(\frac{j_{RF}}{j_{FF}}\right)^2. \tag{3}$$

Here Z_{AB} is the number of B neighbors of atom A (A,B≡R or Fe), S_F the Fe spin, and j_{AB} the exchange interaction energy of the A and B *spins*. A negative j_{RF} implies ferromagnetic coupling of light R and Fe *moments* and antiferromagnetic coupling of heavy R and Fe *moments*. From the work of Hu and Yelon[6] we estimate $Z_{FF}=10$, $Z_{FR}=2$, and $Z_{RF}=18$, and we take $S_F=1$ since the average Fe moment is $\sim 2\ \mu_B$ and the corresponding g factor can be expected to be near 2. A least-squares fit of Eqs. (1)–(3) to the Curie temperatures of the (R=Pr, Nd, Sm; T=Ti) compounds, in which the R ion is presumably trivalent, yields $j_{FF} \cong 2.4$ meV and $j_{RF} \cong -1.5$ meV. The fit generates the lower curve in Fig. 3 and provides excellent accommodation of the experimental results; the departure of $T_C(Ce_3Fe_{27.4}Ti_{1.6}) \cong 322$ K from the trend underscores the likelihood that Ce is tetravalent. For comparison purposes Fig. 3 also displays T_C values (diamonds) for the cognate $R(Fe,Ti)_{12}$ compounds.[15,16] A corresponding fit to them (the same estimates for Z_{AB} and S_F can be used)[15] yields $j_{FF} \cong 3.3$ meV and $j_{RF} \cong -1.4$ meV and is shown by the upper curve in Fig. 3. The stronger Fe-Fe exchange is responsible for the fact that the $R(Fe,Ti)_{12}$ Curie temperatures are 120–170 K higher than those of their $R_3(Fe,Ti)_{29}$ counterparts.

Magnetic and crystal structure of the novel compound $Nd_3Fe_{29-x}Ti_x$

Z. Hu and W. B. Yelon
University of Missouri Research Reactor, Columbia, Missouri 65211

The structure of the compound previously reported as $Nd_2Fe_{19-x}Ti_x$ has been solved by powder neutron diffraction, which reveals a monoclinic cell and a stoichiometry of $Nd_3Fe_{29-x}Ti_x$ ($x=1.24$) and two formula units per unit cell. This low symmetry, and the large number of crystallographically unique sites (17), lead to a wide range of Fe—Fe bond lengths (from 2.36 to 3.01 Å) in a nearly continuous band. The phase forms through the replacement of two-fifths of the rare earths in the RFe_5 phase by Fe-Fe dumbbells. The magnetic moments at room temperature lie along the monoclinic a axis with an average iron moment of 1.05 μ_B, while the magnetic moments at 12.5 K lie in the a-b plane with an average iron moment of about 1.36 μ_B.

I. INTRODUCTION

Binary rare-earth (R)-Iron (Fe) compounds are unsuitable for permanent magnet application due to their low Curie points. $Nd_2Fe_{14}B$, nitrides and carbides of R_2Fe_{17} and $RFe_{12-x}T_x$, where T is a transition element,[1–3] and pseudobinary compounds such as $R_2Fe_{17-x}T_x$, where T is Si, Al, or Ga, have significantly enhanced Curie points compared to the parent binary phases.[4–6] Studies of these materials have recently led to the discovery of a new pseudobinary phase, first identified as $R_2Fe_{17-x}T_x$ with a structure different from the well known Th_2Zn_{17} and Th_2Ni_{17} types,[7,8] then identified as $R_2Fe_{19-x}T_x$[9–11] and which has now been shown to have stoichiometry $R_3Fe_{29-x}T_x$.[12,13] This compound was originally formed with T=Ti at about 6% Fe/Ti replacement and has also been shown to form at higher replacement levels with Cr and Mn.[9] In attempting to form doubly-substituted $RFe_{12-x}T_x$, this phase was also formed with a V+Al replacement.[14] The monoclinic cell of this new phase is related to the $CaCu_5$ structure, and an approximate x-ray structure determination, based on the idealized positions of the $CaCu_5$ structure, was recently reported.[12] At the same time, powder neutron diffraction was used for an exact solution in which the magnetic moments at room temperature were also reported.[13] In this article the neutron diffraction results are extended to low temperature, further structural details are reported, and the results for $R_3Fe_{29-x}T_x$ are compared to those of Ti substituted Nd_2Fe_{17} and $NdFe_{12}$. These three different phases can be considered as modifications of the $CaCu_5$ structure with differing degrees of Fe-Fe dumbbell replacement of some of the rare earths.

II. RESULTS

The room-temperature and 12.5-K results of the neutron diffraction analysis of $Nd_3Fe_{27.76}Ti_{1.24}$ are given in Table I. The structure adapted from Ref. 13 is shown in Fig. 1. The layered structure is apparent from the figure in which only the shortest bonds (<2.4 Å) are shown. Although not constrained by symmetry, all of the Fe/Ti and Nd atoms in the first layer lie within 0.06 Å of the $y=0$ plane. In the second layer, which contains only Fe/Ti atoms, most are found very close to $y=\frac{1}{4}$. The atoms that deviate from this are clearly visible in the figure and are displaced due to the presence of Nd atoms nearly directly above or below them. The arrangement of the Fe/Ti atoms in this layer forms a nearly perfect hexagonal grid. As previously discussed, both the stacking of layers with and without rare earth, and the hexagonal arrangement, are also seen in $R_2Fe_{14}B$.[15] Other projections of the $R_3(Fe/Ti)_{29}$ structure show planes of atoms, although none so clearly as seen in this direction. This is a reflection of the relatively close-packed nature of the structure.

Table I also gives the coordinates used in the x-ray study.[12] Relatively few of these were refined, but the generally good agreement between these two sets of coordinates is an indication of the small deviation of this structure from the parent structure from which it is derived. It is easy to see that the R_2Fe_{17} structure is derived from the RT_5 structure ($CaCu_5$) by replacement of one-third of the rare earths by Fe-Fe pairs. It has been pointed out that the RFe_{12} structure can be formed from the same parent by replacement of one-half of the rare earths by the Fe-Fe dumbbells. The new compound, $R_3(Fe/T)_{29}$, is produced in the same fashion by replacement of two-fifths of the rare earths. This appears to be entirely regular and leads to the stoichiometric compound observed here. In Nd_2Fe_{17}, the dumbbell is clearly visible and the Fe—Fe bond length is unusually small—2.36 Å. In RFe_{12}, the dumbbells are less apparent, but it is important to note that this compound contains at least one T atom per unit cell and is thus expanded with respect to the idealized, but nonexistent pure Fe phase.

Because of the low symmetry and the large number of Fe sites, there are many more distinct bonding pathways in this compound than in either the R_2Fe_{17}- or RFe_{12}-type structures. The minimum bond length is 2.36 Å, as is seen in Nd_2Fe_{17}, but it is less separated from the other bonds, which form a continuous band up to at least 3 Å. The longest bonds are associated with the 14 coordinated Fe atoms shown in Table I, but similar 14-fold coordination is also seen in the R_2Fe_{17} and RFe_{12} structures. The Fe atoms have from one to three Nd neighbors, but the Ti atoms are found only at the three sites with a single Nd neighbor. Neutron diffraction data for $Nd_2Fe_{16.07}Ti_{0.93}$ and $NdFe_{10.9}Ti_{1.1}$ were also collected and analyzed, and the same Ti environment was observed in these compounds.

The range of bond lengths around each site and the average bond lengths are given in Table II for $Nd_3Fe_{27.76}Ti_{1.24}$, $Nd_2Fe_{16.07}Ti_{0.93}$, and $NdFe_{10.9}Ti_{1.1}$. This table excludes

Fe—Fe bonds over 2.8 Å that are assumed to contribute little or no magnetic energy. As already discussed, the Nd_2Fe_{17} parent has a short 2.36-Å bond. In the Ti-substituted compound, however, this bond has expanded to 2.47 Å due to the strong preference for the dumbbell Fe site by the larger Ti atom. The high symmetry of the RFe_{12} phase produces two groups of bonds, long and short, with a gap between. The other two compounds have a broader distribution. Table III gives the overall average bond lengths for these three samples (and Nd_2Fe_{17}) as well as their Curie points. For $Nd_3Fe_{27.76}Ti_{1.24}$, two values are given, including bond lengths to 2.8 and 2.99 Å. The dependence of the Curie point on bond length in other NdFe compounds[16] has previously been noted and a similar relationship is observed here if one does not include the very long Fe—Fe bonds, which obviously contribute little to the magnetic exchange energy.

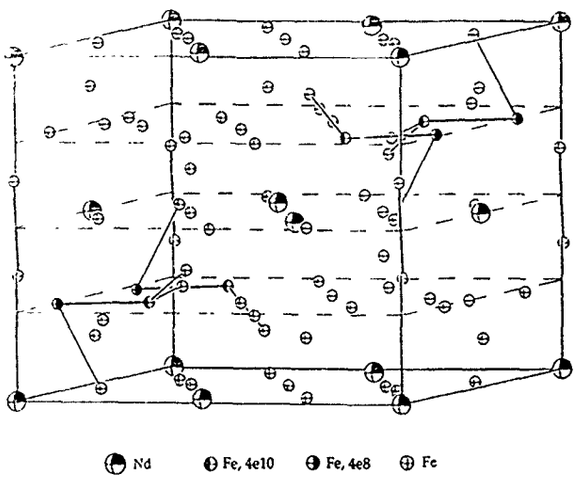

FIG. 1. Monoclinic unit cell of $Nd_3Fe_{29-x}Ti_x$ with the *B* axis up. The layers with $y=1/4$, 1/2, and 3/4 are drawn as well as the Fe—Fe bonds under 2.4 Å.

TABLE III. The overall average bond length (OABL) and Curie temperature.

Compound	OABL	T_c (K)	Comments
$Nd_2Fe_{16.03}Ti_{0.97}$	2.5811	383	
$NdFe_{10.9}Ti_{1.1}$	2.5814	530	
Nd_2Fe_{17}	2.5801	330	
$Nd_3Fe_{27.76}Ti_{1.24}$	2.5801	361	no bond>2.8 Å
	2.5929		no bond>2.99 Å

The magnetic moments are also given in Table I. For $Nd_3Fe_{27.76}Ti_{1.24}$ at room temperature, the Fe moment refinements were unstable on a few sites, oscillating about relatively small values. These were constrained to their average, while the others were allowed to refine freely. The overall average site moments of $Nd_3Fe_{27.76}Ti_{1.24}$, $Nd_2Fe_{16.07}Ti_{0.93}$, and $NdFe_{10.9}Ti_{1.1}$ at room temperature are 1.05, 1.95, and 2.36 μ_B, respectively. The moments of $Nd_3Fe_{27.76}Ti_{1.24}$ are found to lie along the a axis. The moments of $Nd_2Fe_{16.07}Ti_{0.93}$ are found to lie perfectly in the basal plane, while the moments of $NdFe_{10.9}Ti_{1.1}$ are found to lie perfectly along the c axis.[17] The Fe and Nd atoms couple ferromagnetically in all three compounds, suggesting that the reported enhancement in the Curie point through interstitial substitution could lead to highly desirable properties due to their high Nd:Fe ratio. For $Nd_3Fe_{27.76}Ti_{1.24}$ at 12.5 K, the easy direction is found to be changed from the a axis at room temperature to the a-b plane at 12.5 K. It was found that the component ratio, μ_x/μ_y, on all sites is close to 0.6 when every component was refined independently. Then a constraint was made to keep all site moments in the same direction and with a component ratio of 0.6. The amplitudes of the site moments at 12.5 K given in the last column of Table I, as expected, are larger than that at room temperature. The overall average iron site moment of $Nd_3Fe_{27.76}Ti_{1.24}$ at 12.5 K is $1.36\mu_B$. This low value may be due to the fact that nearly all sites have at least some very short (<2.45 Å), presumably antiferromagnetic, bonds. It is particularly interesting to note that one Fe site, $4e10$, has three short bonds and refines with the smallest moment at both temperatures. A second site, $4e8$, has two such bonds and has the second smallest moment at room temperature, which remains small at 12.5 K. In contrast, Fe4 and Fe5 have the largest 12.5-K moments, average bond lengths over 2.6 Å, and no short bonds.

III. CONCLUSIONS

The new pseudobinary rare earth-iron phase, $Nd_3Fe_{27.76}Ti_{1.24}$, was studied by neutron diffraction and compared with Ti-substituted Nd_2Fe_{17} and $NdFe_{12}$ compounds. The structures of all those three compounds are related to the structure of RT_5, with differing degrees of Fe-Fe dumbbell replacement of the rare earth. The Ti atoms were found to occupy those sites with a single Nd neighbor in all three compounds. A dependence of the Curie points on bond length similar to other NdFe compounds was observed. The Nd sublattice couples ferromagnetically to the Fe sublattice in all three compounds with different easy directions, that is, a axis for $Nd_3Fe_{27.76}Ti_{1.24}$, basal plane for $Nd_2Fe_{16.03}Ti_{0.97}$, and c axis for $NdFe_{10.9}Ti_{1.1}$, respectively. An easy direction change, from the a axis to a-b plane, for $Nd_3Fe_{27.76}Ti_{1.24}$ was observed when the temperature was lowered from 295 to 12.5 K.

ACKNOWLEDGMENTS

The authors would like to thank Dr. J. M. Cadogan and his collaborators for providing the sample $Nd_3Fe_{27.76}Ti_{1.24}$ used in this study, for the early report of the x-ray study, and for helpful discussions. We would also like to thank Dr. C. Fuerst and the General Motors group for providing samples $Nd_2Fe_{16.03}Ti_{0.97}$ and $NdFe_{10.9}Ti_{1.1}$ and a preprint of their work. Useful discussions with Dr. F. K. Ross are also greatly appreciated.

The effects of light atom intercalation on the magnetic properties of the monoclinic compound $Nd_3(Fe,Ti)_{29}$ have been studied by Mössbauer spectroscopy and thermogravimetric analysis. Maximum contents of 4 nitrogen atoms and 6 hydrogen atoms per formula unit have been achieved, consistent with structural calculations. The associated lattice expansion ranges from 2% in the hydride to 6.5% in the nitride. Attempts to introduce carbon were unsuccessful as the material decomposed rapidly during the reaction. Both hydrogen and nitrogen additions lead to substantial increases in the magnetic ordering temperature, but only the nitrogen leads to an increase in the iron moment.

I. INTRODUCTION

The search for high-performance magnetic materials, which was revived by the discovery of the $R_2Fe_{14}B$ system, has been expanded greatly by the observation that significant improvements can be obtained through the intercalation of alloys by a variety of light atoms. Often this intercalation process can be used to transform otherwise useless materials into highly promising permanent magnet candidates. The most striking examples of this are the R_2Fe_{17} alloys, which have ordering temperatures only slightly above room temperature, but the addition of either carbon or nitrogen by gas-phase reaction leads to a greatly enhanced T_c and, in the case of the Sm alloy, substantial uniaxial anisotropy.[1]

In 1992, Collocott *et al.* reported the existence of a new, iron-rich, phase in the Nd-Fe-Ti phase diagram.[2] Subsequent x-ray[3] and neutron[4] diffraction measurements showed that the alloy structure belonged to the monoclinic $P2_1/c$ space group, and that the correct stoichiometry was $Nd_3(Fe,Ti)_{29}$. The composition lies between the tetragonal $Nd(Fe,Ti)_{12}$ and rhombohedral $Nd_2(Fe,Ti)_{17}$ phases, and the 3-29 structure can be viewed as an alternating stack of these 1-12 and 2-17 units.[3] The magnetic ordering temperatures of the 3-29 compounds are in the range 411–486 K.[5] Previous work has shown that this phase absorbs nitrogen readily, exhibiting large increases in both T_c and magnetization.[6]

In this paper we report a more extensive study of the effects of H, C, and N interstitial modification on the magnetic properties of $Nd_3(Fe,Ti)_{29}$.

II. EXPERIMENTAL METHODS

$Nd_3(Fe,Ti)_{29}$ samples were prepared by arc melting appropriate amounts of 99.9% purity Nd, Ti, and Fe under Ti-gettered argon. Single-phased alloys were obtained by annealing at 1373 K for 72 h under argon in sealed quartz tubes, followed by water quenching. Structural measurements were made using Cu-K_α radiation on an automated Nicolet–Stoe diffractometer. Ordering temperatures were determined on a Perkin–Elmer TGA-7 by recording the apparent mass as a function of temperature in a small field gradient. ^{57}Fe Mössbauer spectra were obtained on a conventional constant acceleration spectrometer using a 25-mCi ^{57}CoRh source. Low-temperature spectra were obtained using a vibration-isolated closed-cycle He fridge. Calibration and isomer shifts are referred to α-Fe at room temperature. The $Nd_3(Fe,Ti)_{29}$ unit cell contains 6 Nd atoms on two sites, and 58 Fe atoms distributed among 15 distinct sites, one being a $2d$ and the remaining 14 being $4e$ sites. It is clear from the spectra in Figs. 1 and 2 that few of the subspectra arising from the 15 Fe sites are resolved, especially at room temperature. We have therefore fitted the spectra using the minimum number of subspectra needed to reproduce the most obvious features of the spectra. The number used varied from 3 in the case of the as-annealed material at room temperature, to 6 in the cases of the nitride and hydride at 12 K.

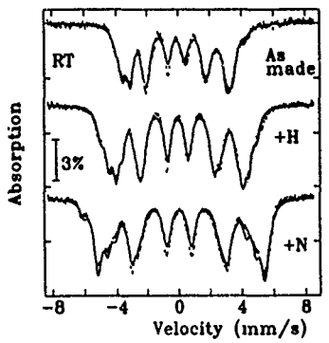

FIG. 1. Room-temperature Mossbauer spectra of $Nd_3(Fe,Ti)_{29}$ as-annealed, and with hydrogen and nitrogen added

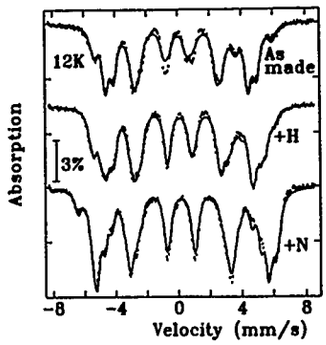

FIG. 2. Mössbauer spectra of $Nd_3(Fe,Ti)_{29}$ as-annealed, and with hydrogen and nitrogen added measured at 12 K.

The intercalation reactions were carried out at various temperatures in a thermopiezic analyzer (TPA) using hydrogen, nitrogen, and acetylene as sources of H, N, and C, respectively.

III. RESULTS AND DISCUSSION

Substantial amounts of hydrogen are absorbed readily by $Nd_3(Fe,Ti)_{29}$. Heating to 300 °C at 40 °C/min in ~1.6 bar of H_2 leads to a hydrogen uptake of over 6 H/formula unit (f.u.), with no evidence of decomposition. While the hydride appears stable at room temperature (no evolution of the material was apparent on the ~1-day timescale needed to record a Mössbauer spectrum), it decomposed rapidly on heating, making an accurate determination of T_c problematic. The value of 548 K given in Table I represents a lower limit, the value obtained on re-cooling was typically 100 K lower, reflecting a significant loss of hydrogen. The room temperature Mössbauer spectrum (Fig. 1) exhibits a substantially increased average hyperfine field; however, the measurement at 12 K (Fig. 2) shows this to be almost entirely due to the higher ordering temperature. The measured lattice expansion is ~2%, giving an effective volume change per hydrogen atom of ~2.0 Å^3, close to values typical of intermetallic hydrides.[7]

Nitrogen also reacts easily with this alloy. Annealing for 70 h in 1.6 bar of N_2 at 400 °C takes the reaction close to completion and yields nitrogen contents of ~4.5 N/f.u. Higher apparent concentrations (~5.8 N/f.u.) can be achieved by annealing at higher temperatures (e.g., 500 °C); however, the observed ordering temperature does not increase, and there is evidence of α-Fe precipitation. The 6.5%

TABLE I. Summary of magnetic and structural changes resulting from the addition of H, C, or N to $Nd_3(Fe,Ti)_{29}$.

Sample	T_c (K)	$\langle B_{hf} \rangle$ (T) 12 K	$\langle B_{hf} \rangle$ (T) RT	$\Delta V/V$ (%)

$Nd_3(FeTi)_{29}H_{6.1}$	>548	30.2	26.4	2.2±0.5
$Nd_3(FeTi)_{29}C_y$	~660	...	...	...
$Nd_3(FeTi)_{29}N_{4.5}$	723	33.4	31.0	6.5±0.7

TABLE II. The four largest voids in the $Nd_3(Fe,Ti)_{29}$ alloy system, derived from an analysis of the crystal structure. The $4e_3$ is assumed to be unoccupied as it is too small for nitrogen, and only coordinated by Fe atoms.

Site	Location x	y	z	Radius (Å)	Coordination	Occupied by
$4e_1$	0.49	0.75	0.23	0.64	2-Nd 4-Fe	HCN
$4e_2$	0.20	0.50	0.40	0.59	2-Nd 4-Fe	HCN
$4e_3$	0.10	0.51	0.95	0.45	4-Fe	empty(?)
$4e_4$	0.44	0.23	0.92	0.42	1-Nd 3-Fe	H

volume expansion corresponds to a volume change of ~7 Å^3/N atom, as found in the R_2Fe_{17} nitrides.[1] The Mössbauer spectra show a substantial increase in the hyperfine field both at room temperature and 12 K. Values listed in Table I are in close agreement with those reported earlier.[5] As in the 2-17 and 1-12 alloys, nitriding leads to an increase both in T_c and in the average Fe moment.

The carbide does not form easily. Conditions appropriate for 1-12 or 2-17 alloys tend to lead to a disproportionation reaction, with the principal magnetic phases being Fe_3C (possibly containing some of the Ti) and α-Fe. Even short duration (~30 min) anneals at temperatures between 350 and 500 °C led to partially decomposed samples. It therefore appears that in this phase, the competition from the disproportionation reaction is too strong, and the carbide tends not to form in significant amounts. A magnetic event at ~660 K is tentatively associated with a $Nd_3(Fe,Ti)_{29}C_y$ phase; however, the actual carbon content is unknown. Given the mixture of magnetic phases present, no attempt was made to extract Mössbauer parameters.

An analysis of the 3-29 structure yields only a very limited number of holes large enough to accommodate interstitial atoms (see Table II), and all of them are 4*e* sites (the 2*a* and 2*d* sites are occupied by Nd and Fe, respectively, and both the 2*b* and 2*c* sites lie inside other atoms). The two largest voids have radii of 0.64 and 0.59 Å, and could hold either carbon or nitrogen atoms. Full occupancy of these sites by nitrogen would yield a composition of $Nd_3(Fe,Ti)_{29}N_4$. This composition is also consistent with the 3-29 structure being derived from alternate stacking of 1-12 and 2-17 units, which can hold 1 and 3 nitrogen atoms, respectively. Our measured nitrogen content of 4.5 N/f.u. probably results from a partial decomposition of the material, with the excess nitrogen in the form of neodymium nitride. The next hole is only 0.45 Å in radius, far too small to accept either nitrogen or carbon. While this site is large enough to take a hydrogen atom,[7] the coordination solely by Fe atoms may make the environment energetically unattractive. The next largest site with one Nd neighbor has a radius of 0.42 Å and is more likely to be the hydrogen location. Occupation of the three largest rare-earth coordinated holes by hydrogen gives the composition $Nd_3(Fe,Ti)_{29}H_6$, as observed.

In conclusion, adding hydrogen leads to a significant increase in T_c, but essentially no change in the iron moment, whereas nitrogen leads to an increase in both parameters. These results are similar to those found in the 1-12 and 2-17 rare-earth iron alloys. Attempts to make the carbide were unsuccessful due to a rapid disproportionation of the mate-

rial. An examination of the crystal structure shows that the hydrogen and nitrogen concentrations achieved are the maximum values allowed.

High-temperature phase relations in the Fe-rich corner of the Nd-Fe-Ti ternary alloy system have been investigated and an equilibrium phase diagram has been constructed at 1100 °C. Arc-melted and annealed alloys of systematically varying compositions were characterized utilizing scanning electron microscopy, an energy dispersive x-ray microanalysis system (EDS), x-ray diffraction, and optical metallography. Three major phases have been identified, the well known $Nd(Fe,Ti)_{12}$ "1:12" ($ThMn_{12}$-type structure) and $Nd_2(Fe,Ti)_{17}$ "2:17" (Th_2Zn_{17}-type structure) compounds, and a phase with approximate composition $Nd_2(Fe,Ti)_{19}$ "2:19." The crystal structure of the latter phase has very recently been solved, and the "ideal" composition shown to be $Nd_3(Fe,Ti)_{29}$ "3:29." Quantitative EDS data has been used to identify the compositional limits for the three major phases. Annealing the "1:12" and "3:29" ternary phases at 900 °C results in a slow decomposition into $Nd_2(Fe,Ti)_{17}$, Fe_2Ti, and α-Fe(Ti).

I. INTRODUCTION

Intensive research during the past 25 years has seen the emergence of many rare-earth iron transition metal intermetallic compounds with technologically interesting magnetic properties. $Nd_2Fe_{14}B$ has many of the properties of an ideal permanent magnet, such as a high-remanence, large uniaxial magnetocrystalline anisotropy and low cost, yet its low Curie temperature (310 °C) restricts its applications to temperatures below 150 °C.

Nd-Fe-Ti alloys with the tetragonal $ThMn_{12}$-type structure, and especially their nitrides, have magnetic properties comparable to those of $Nd_2Fe_{14}B$ and are therefore possible candidates for permanent magnets. In attempting to prepare single-phase samples of $Nd(Fe,Ti)_{12}$, Collocott *et al.*[1] found a second ternary compound, with nominal composition $Nd_2(Fe,Ti)_{19}$. The structure of the "2:19" phase has been solved from powder x-ray diffraction[2] and neutron diffraction[3] data, and the ideal composition shown to be $Nd_3(Fe,Ti)_{29}$. To further understand the formation and interrelationships of phases in the Fe-rich section of the Nd-Fe-Ti ternary alloy system, we have carried out a systematic investigation of a range of alloy compositions and constructed an equilibrium-phase diagram at a temperature of 1100 °C.

II. EXPERIMENTAL PROCEDURE

Alloys weighing 2 g were prepared from Nd, Fe, and Ti of ≥99.9% purity by argon-arc melting on a water-cooled copper hearth. The samples were then wrapped in tantalum foil, encapsulated in sealed quartz tubes under an atmosphere of argon gas, and annealed for 3 days at 1100 °C, followed by a water quench. Selected samples were also given a second annealing treatment at 900 °C for periods of 7 and 21 days. Samples were characterized by powder x-ray diffraction using Cu $K\alpha$ radiation, optical metallography, and scanning electron microscopy (SEM) using a JEOL 35CF equipped with a Robinson backscatter electron detector and a LINK energy dispersive x-ray microanalysis system (EDS).

III. RESULTS AND DISCUSSION

Microstructural investigation of the alloys was carried out utilizing backscatter electron (BSE) imaging and x-ray microanalysis. Generally, backscattered electrons provide excellent contrast between phases of different mean atomic number in a polished section of sample. In our samples, where there are two or more phases with similar compositions, BSE imaging alone does not provide sufficient contrast and etching with a 2% solution of nitric acid in alcohol (Nital) was necessary to generate topological contrast.

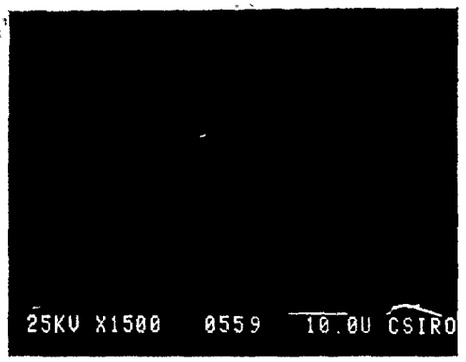

FIG. 2. Backscattered electron image of an etched $Nd_6Fe_{88}Ti_6$ alloy (major phase—1:12, depression—3:29 and dark region—Fe).

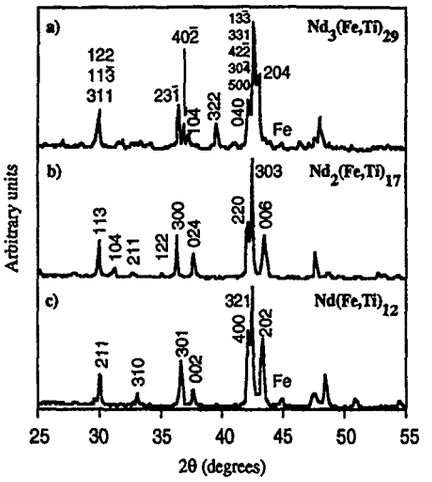

FIG. 3. X-ray diffraction spectra for the Fe-rich Nd-Fe-Ti phases: (a) $Nd_3(Fe,Ti)_{29}$, (b) $Nd_2(Fe,Ti)_{17}$, and (c) $Nd(Fe,Ti)_{12}$ (CuK_α radiation).

Detailed examination of alloys in the Fe-rich corner of the Nd-Fe-Ti ternary alloy system at 1100 °C revealed the existence of two ternary phases, $Nd(Fe,Ti)_{12}$, $Nd_3(Fe,Ti)_{29}$ [previously reported as $Nd_2(Fe,Ti)_{19}$], and the pseudobinary $Nd_2(Fe,Ti)_{17}$ phase, and allowed us to construct the ternary phase diagram shown in Fig. 1. Figure 2 shows a backscattered electron image of a $Nd_6Fe_{88}Ti_6$ composition (in the 1:12+3:29+Fe phase field) annealed at 1100 °C and etched with Nital. The 3:29 phase (depression) could not be observed prior to etching. The compositional limits for all the major phases were determined by quantitative x-ray microanalysis, although this was complicated by the strong overlap which exists between the Nd L and Fe K series lines. The Nd compositions were normalized by reference to a single phase sample of Nd_2Fe_{17} prepared with minimal weight loss (<0.1%) during arc melting and annealing. It was observed that the Nd content remained constant (to ±0.2%) within each of the three major phases, with only the Fe:Ti ratio changing. The compositional limits for the three major phases are presented in Table I.

Jang and Stadelmaier reported[4] the existence of two ternary phases in Nd-Fe-Ti alloys: the "1:12," and a $TbCu_7$-type (1:7) phase with a higher Nd content (≈12 at. %) than in the substituted binary $Nd_2(Fe,Ti)_{17}$, whereas the "3:29" reported here has a Nd content of 9.4 at. %, significantly lower than in the 2:17. Neiva *et al.*[5] have reported the formation of a $Sm(Fe,Ti)_9$ phase with a hexagonal $TbCu_7$-type structure at 1000 °C.

X-ray diffraction spectra of the major phases are shown in Fig. 3. The "1:12" [Fig. 3(c)] has the tetragonal $ThMn_{12}$-type structure, which is relatively common in R-Fe-T systems (R=a rare-earth and T=a transition element), but does not exist as a binary RFe_{12} phase except for the case of $SmFe_{12}$ thin films prepared by sputtering.[6,7] $Nd_2(Fe,Ti)_{17}$ [Fig. 3(b)] has the rhombohedral Th_2Zn_{17}-type structure and exists with up to 3.8 at. % of the Fe substituted by Ti.

$Nd_3(Fe,Ti)_{29}$ [Fig. 3(a)] has a complex structure that was originally indexed on a $2\times a$ and $4\times c$ superlattice of hexagonal $TbCu_7$.[1] The x-ray diffraction data has subsequently been reindexed on the basis of a monoclinic lattice[2,8] and very recently the structure was solved independently from powder x-ray diffraction[2] and neutron diffraction[3] data. The crystal structure is monoclinic ($P2_1/c$) with lattice parameters $a=1.064$ nm, $b=0.859$ nm, $c=0.975$ nm, and $\beta=96.928°$, and the "ideal" composition is $Nd_3(Fe,Ti)_{29}$. Figure 4 illustrates the crystallographic relationship in the a-c plane between the monoclinic unit cell of $Nd_3(Fe,Ti)_{29}$ and the hexagonal $TbCu_7$ lattice. Crystallographic data for the three major phases can be found in Table II. The "3:29" phase is not restricted to the Nd-Fe-Ti system, but also exists in R-Fe-Ti (R=Sm,[9,10] Ce,[9] Pr,[11] and Gd[12]) and in Nd-Fe-T (T=Cr, and Mn[8]).

Investigations into the thermal stability of $Nd(Fe,Ti)_{12}$ and $Nd_3(Fe,Ti)_{29}$ have shown that they are only stable at elevated temperatures. Annealing the compounds at a temperature of 900 °C results in a slow decomposition to

TABLE I. Compositional ranges of the three major phases.

Phase	Composition (at. %)		
	Nd	Fe	Ti
$Nd_2(Fe,Ti)_{17}$	11.0	balance	0–3.8
$Nd_3(Fe,Ti)_{29}$	9.4	balance	4.0–5.1
$Nd(Fe,Ti)_{12}$	7.9	balance	6.5–8.1

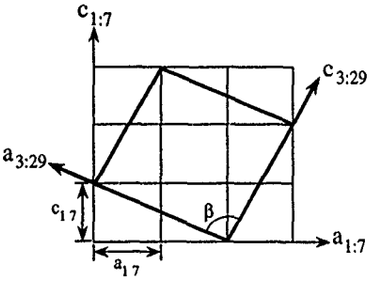

FIG. 4. Crystallographic relationship in the a-c plane between the unit cell of monoclinic $Nd_3(Fe,Ti)_{29}$ and the $3\times a$ and $3\times c$ superlattice of $TbCu_7$.

TABLE II. Crystallographic data for the three major phases.

Phase	Structure	Crystal type	Lattice parameters			
			a (nm)	b (nm)	c (nm)	β (°)
2:17	rhombohedral	Th_2Zn_{17}	0.860	···	1.251	···
3:29	monoclinic	$Nd_3(Fe,Ti)_{29}$	1.064	0.859	0.975	96.92
1:12	tetragonal	$ThMn_{12}$	0.859	···	0.479	···

$Nd_2(Fe,Ti)_{17}$, Fe_2Ti, and α-Fe(Ti), and this observation is in agreement with the findings of Jang and Stadelmaier,[4] that $Nd(Fe,Ti)_{12}$ is unstable at low temperatures. Itsukaichi *et al.*[13] also showed that mechanically alloyed Nd-Fe-Ti powder with the 1:12 composition does not crystallize in the $ThMn_{12}$ structure after a heat treatment at 800 °C.

IV. CONCLUSION

We have constructed an equilibrium-phase diagram for the Fe-rich corner of the Nd-Fe-Ti alloy system at 1100 °C, and determined the composition ranges for the major phases: tetragonal $Nd(Fe,Ti)_{12}$, monoclinic $Nd_3(Fe,Ti)_{29}$, and rhombohedral $Nd_2(Fe,Ti)_{17}$. $Nd(Fe,Ti)_{12}$ and $Nd_3(Fe,Ti)_{29}$ become thermodynamically unstable on cooling below some temperature between 900 and 1000 °C. $Nd(Fe,Ti)_{12}$, and especially its nitride $Nd(Fe,Ti)_{12}N_x$, are being examined as candidates for new permanent magnets, and this low-temperature instability will have profound implications on material processing.

Magnetic properties of $Sm_2Fe_{14-x}Co_xSi_2$-based quasiternary compounds

F.-M. Yang
Institute of Physics, Chinese Academy of Sciences, P.O. Box 603, Beijing 10080, China

W. Gong and G. C. Hadjipanayis
Department of Physics and Astronomy, University of Delaware, Newark, Delaware 19716-2570

The structural and magnetic properties of the off-stoichiometric R_2Fe_{17}-type $Sm_2Fe_{14-x}Co_xSi_2$ compounds with $0 \leqslant x \leqslant 7$ have been investigated by x-ray diffraction, thermomagnetic analysis, and magnetic measurements. Substitution of Co for Fe leads to an increase in Curie temperature, $\Delta T_c = 303$ K for samples with x from 0 to 7. The saturation magnetization M_s increased with increasing Co content at first and then decreased. A maximum saturation magnetization $M_s = 124$ emu/g was obtained at x about 4. The anisotropy changes from planar $x < 4$ to uniaxial $x \geqslant 4$ with $H_a = 23$ kOe for $x = 7$. Introduction of N leads to an increase in lattice constants causing a further enhancement in the Curie temperature and anisotropy field. The best properties were obtained for the $Sm_2Fe_{10}Co_4Si_2N_{2.3}$ compound with $T_c = 742$ K, H_a (300 K) = 175 kOe.

I. INTRODUCTION

Research in the field of permanent magnets intensified after the discovery of the R-Fe-B compounds[1,2] whose superior magnetic properties led to the high performance Nd-Fe-B type permanent magnets[3] which are being used in a wide variety of applications, most notably in the computer industry. However, the low Curie temperature and large temperature coefficients of B_r and H_c limit the temperature range of applications of Nd-Fe-B magnets. Recently the $R(FeT)_{12}$ compounds (T=Al, Cr, Mo, Si, Ti, V, and W) with the $ThMn_{12}$-type structure have been investigated extensively.[4,5] Recently, it has been found that 2:17-type rare-earth iron carbides and nitrides[4] show excellent intrinsic magnetic properties for permanent magnet applications.[6] A new type of ternary compounds with nominal composition $R_2Fe_{14-x}Co_xSi_2$ which crystallize in the off-stoichiometric 2:17-type structure has been studied[7,8] with R=Y or a heavy rare-earth element.

In this work, a detailed study of the structural and magnetic properties of the $Sm_2Fe_{14-x}Co_xSi_2$ nitrides was performed and some of the results are presented and discussed.

II. EXPERIMENT

$Sm_2Fe_{14-x}Co_xSi_2$ compounds with $x = 0-7$ were prepared by arc-melting the constituent elements which had at least 99.9% purity. The ingots were melted several times to ensure homogeneity. The as-cast ingots, without any annealing, were then pulverized to an average particle size of 20–30 μm and the powder samples obtained were heated in purified N_2 under a pressure of about 1.7 atm at 520 °C for 4–16 h to form the $Sm_2Fe_{14-x}Co_xSi_2N_y$ nitrides. The value of y was determined to be $2 < y < 3$ by weighing the samples before and after nitrogenation.

X-ray diffraction was employed to determine the structure and the lattice parameters. The x-ray diffraction patterns of the magnetically aligned powder samples obtained at room temperature were used to determine the easy magnetization direction (EMD) of the compounds. Thermomagnetic curves were measured by means of a vibrating sample magnetometer (VSM) with an applied field of 500 Oe, and the Curie temperature T_c was derived from M^2 vs T plots. The magnetization curves were measured by means of a superconducting quantum interference device magnetometer with applied fields up to 65 kOe at temperatures between 4.2 K and room temperature. The saturation magnetization M_s was derived by means of M vs $1/H^2$ plots, using the high field part of the magnetization curves.

The anisotropy fields H_a were derived from the extrapolated intersection of the two magnetization curves, measured with the field parallel and perpendicular to the alignment direction.

III. RESULTS AND DISCUSSION

A. $Sm_2Fe_{14-x}Co_xSi_2$ compounds

X-ray diffraction and thermomagnetic analysis show that all the investigated as-cast $Sm_2Fe_{14-x}Co_xSi_2$ alloys are of

7	8.404	12.293	751.28	112	23	c axis

single phase. The x-ray diffraction patterns have been indexed on the basis of the Th_2Zn_{17}-type structure. Figure 1, curve (a) shows an example for the $Sm_2Fe_{14}Si_2$ compound. Substitution of Co for Fe does not lead to any change in the crystal structure even for $x=14$. The lattice constants a and c exhibit a small decrease with increasing Co concentration. Experimental data in Table I show the lattice constants a and c as functions of Co concentration. The average decrease upon Co substitution is only 0.1% per Co atom. The average lattice constants are $a=8.252$ Å and $c=12.356$ Å, which are 1.3% and 1.5% smaller than those of the Sm_2Fe_{17} compound, respectively.

Figure 2, curve (A) shows the Curie temperature T_c as a function of Co concentration. It can be seen that T_c increases nearly linearly with Co content, from 514 K for $x=0$ to 817 K for $x=7$. The average increase upon Co substitution was determined to be 55 K per Co atom. It is worth noting that the Curie temperature of the $Sm_2Fe_{14}Si_2$ is about 100 K higher than that of the Sm_2Fe_{17} compound.

The saturation magnetization at room temperature as a function of Co content is summarized in Table I. It can be seen that the saturation magnetization M_s increases with increasing Co content, at first going through a maximum of 124 emu/g at $x\sim3$ and then it decreases with increasing Co content. The increase of the saturation magnetization at room temperature for smaller Co contents results from the enhancement in Curie temperature.

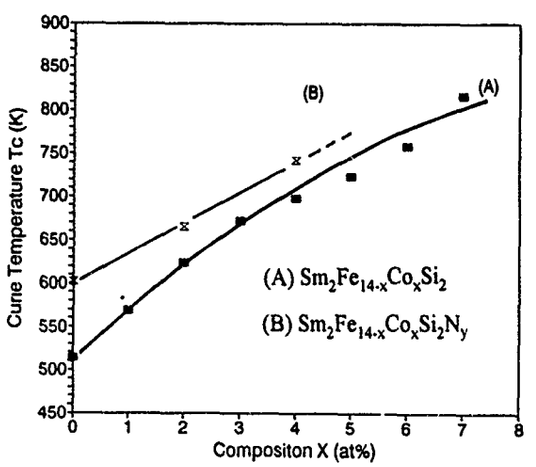

FIG. 2. Curie temperature T_c as a function of x in $Sm_2Fe_{14-x}Co_xSi_2$ compounds and their nitrides. (A) is $Sm_2Fe_{14-x}Co_xSi_2$ samples and (B) is $Sm_2Fe_{14-x}Co_xSi_2N_y$ when $x=0$, $y=2.6$, and $x=4$, $y=2.3$.

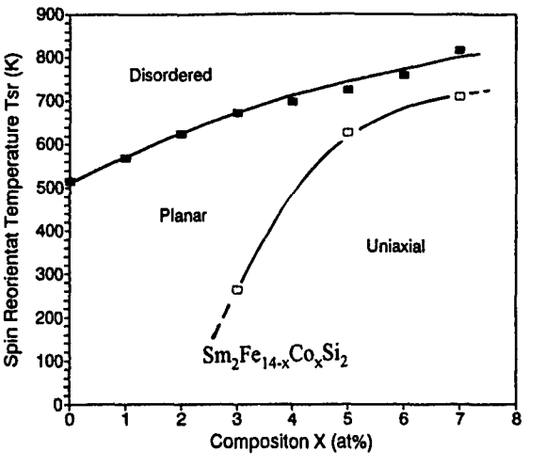

FIG. 3. A spin phase diagram for $Sm_2Fe_{14-x}Co_xSi_2$ compounds.

$Sm_2Fe_{14}Si_2$ exhibits a planar anisotropy. With increasing Co content, the magnetocrystalline anisotropy changes from planar to uniaxial at an x value between 3 and 4 (Table I).

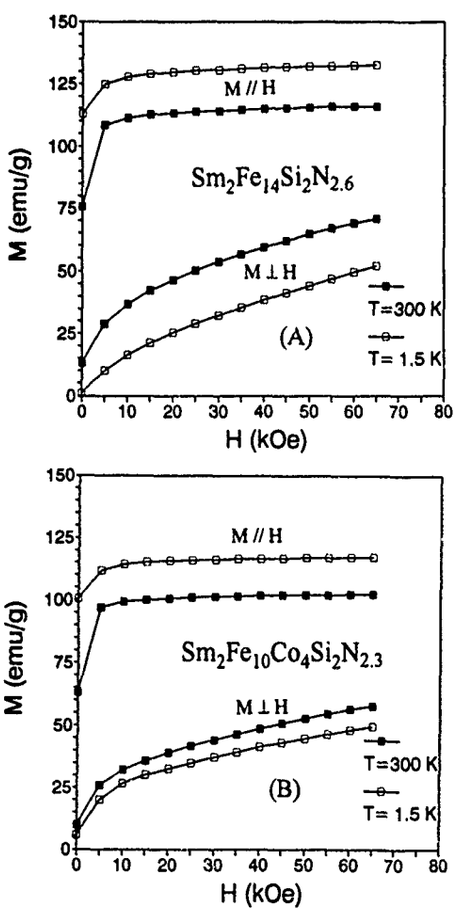

FIG. 4. Magnetization curves of the aligned powder samples, measured parallel (∥) and perpendicular (⊥) to the external magnetic fields.

TABLE II. The lattice parameters a, c, unit cell volume expansion, $\Delta V/V$, Curie temperature T_c, saturation magnetization M_s, anisotropy field and easy magnetization direction for $Sm_2Fe_{14-x}Co_xSi_2N_y$, and the parent compounds.

Compound	a (Å)	c (Å)	$\Delta V/V$ (%)	T_c (K)	M_s (emu/g) 1.5 K	M_s (emu/g) 300 K	H_a (kOe) 1.5 K	H_a (kOe) 300 K	EDM
$Sm_2Fe_{14}Si_2$	8.484	12.340		514	134	118			plane
$Sm_2Fe_{14}Si_2N_{2.6}$	8.633	12.478	4.2	602	133	117	227	157	c axis
$Sm_2Fe_{10}Co_4Si_2$	8.459	12.379		698	136	124		8	c axis
$Sm_2Fe_{10}Co_2Si_2N_{2.3}$	8.633	12.460	5.0	742	128	113	276	175	c axis

Figures 1(b) and 1(c) shows the x-ray diffraction patterns on the magnetically aligned powder samples of the $x=3$ and 4 compounds, respectively. For compounds with $x\leqslant 3$, a substantial increase in the $(h,k,0)$ reflection intensities and disappearance of $(0,0,l)$ lines show that the samples have easy plane magnetocrystalline anisotropy, in contrast with the compounds with $x\geqslant 4$; in the latter only the $(0,0,l)$ reflection intensity substantially increased, which shows a uniaxial magnetocrystalline anisotropy at room temperature. It can be seen that for the compounds with $x\leqslant 3$, H_a is very small due to the planar anisotropy, whereas for the compounds with $x\geqslant 4$, H_a increases with increasing Co content, changing from $H_a=8$ kOe for $x=4$ to $H_a=23$ kOe for $x=7$.

A spin phase diagram is shown in Fig. 3. It is clear that the spin reorientation temperature T_{sr} increases monotonously with increasing Co content. This suggests that substitution of Co for Fe leads to an increase in the contribution to the uniaxial anisotropy resulting from the Sm and Co sublattices.

B. $Sm_2Fe_{14-x}Co_xSi_2$ nitrides

$Sm_2Fe_{14-x}Co_xSi_2$ nitrides with $x=0$ and 4 have been prepared with the values of y determined to be $2<y<3$. The nitrides maintain the Th_2Zn_{17}-type structure, but with remarkable unit-cell volume expansions compared with the hosts. The x-ray diffraction patterns of $Sm_2Fe_{10}Co_4Si_2N_y$ (a), compared with that of the parent compound (B). The unit-cell volume expansion is 4.2% for $x=0$ ($y=2.6$) and 5% for $x=4$ ($y=2.3$). The introduction of nitrogen leads to an increase in Curie temperature from 514 to 602 K for $x=0$ and from 698 to 742 K for $x=4$, respectively. The increase in T_c may be partly associated with the unit cell volume expansion. The values of T_c for $Sm_2Fe_{14-x}Co_xSi_2N_y$ compounds are also shown in Fig. 2 [curve (B)]. Introduction of nitrogen also changed the anisotropy in $Sm_2Fe_{14}Si_2$ from planar to uniaxial at room temperature with an anisotropy field $H_a=157$ kOe and led to an increase in the room-temperature anisotropy field of $Sm_2Fe_{10}Co_4Si_2$ from 8 kOe for the parent compound to 175 kOe for the nitride. A very large anisotropy field was observed at low temperature, $T=1.5$ K, $H_a=227$ kOe for $Sm_2Fe_{14}Si_2N_{2.6}$ and $H_a=276$ kOe for $Sm_2Fe_{10}Co_4Si_2N_{2.3}$, respectively. The detailed experimental data are summarized in Table II and Fig. 4[(A) and (B)].

IV. CONCLUSIONS

The off-stoichiometric R_2Fe_{17}-type $Sm_2Fe_{14-x}Co_xSi_2$ compounds with $x=0$ to 7 crystallize in the Th_2Zn_{17}-type structure. Substitution of Co for Fe leads to an increase in Curie temperature T_c from 514 K for $x=0$ to 817 K for $x=7$. The room-temperature saturation magnetization increases from 118 emu/g for $x=0$ to 124 emu/g for $x=4$ and then it decreases slightly with increasing Co content. Co substitution enhances the uniaxial anisotropy and the spin reorientation temperature T_{sr}. The anisotropy changes from planar in $Sm_2Fe_{14-x}Co_xSi_2$ to uniaxial for $x\geqslant 4$. The anisotropy field is 23 kOe for $x=7$.

Introduction of N leads to an increase in lattice constant and unit cell volume, causing a further enhancement in Curie temperature. Furthermore, introduction of N results in a further increase in the contribution to uniaxial anisotropy from the Sm sublattice. It has been found that for the $Sm_2Fe_{10}Co_4Si_2N_{2.3}$ compound, $T_c=742$ K, M_s (300 K) $=113$ emu/g and H_a (300 K)$=175$ kOe.

Mössbauer study of permanent-magnet materials: $Sm_2Fe_{17-x}Al_x$ compounds

I. A. Al-Omari, S. S. Jaswal, A. S. Fernando, and D. J. Sellmyer
Behlen Laboratory of Physics and Center for Materials Research and Analysis, University of Nebraska, Lincoln, Nebraska 68588-0111

The Fe^{57} Mössbauer spectra of $Sm_2Fe_{17-x}Al_x$, where $x=0$, 1.0, 2.0, 3.0, and 4.0, have been measured at room temperature and analyzed. The ternary compounds $Sm_2Fe_{17-x}Al_x$ have the rhombohedral Th_2Zn_{17} structure. Mössbauer measurements showed that all the compounds studied were ferromagnetic. The average hyperfine field was found to decrease with the increasing aluminum concentration, which is in qualitative agreement with magnetic measurements. The decrease in the average hyperfine field was from 224 kOe at $x=0$ to 174 kOe at $x=4$. By fitting the spectra we found that the hyperfine fields for the iron sites decrease in the order $6c$, $9d$, $18f$, and $18h$. The measured average isomer shift relative to α-iron was found to increase linearly with x. Analysis of the spectra showed that Al atoms occupy the $6c$, $18h$, and $18f$, but not $9d$, Fe sites and the fraction of occupancy of Al was found to depend on x.

I. INTRODUCTION

It has been discovered recently that the hard-magnet properties of Fe-rich intermetallic compounds improve considerably upon nitrogenation.[1-3] Efforts are underway to see if substitutional impurities can accomplish the same goal. Compounds of the type $R_2Fe_{17-x}M_x$, (R=Ho, Y, Sm, Ce, Pr, and Nd; M=Al, Ga, V, Co, and Ni) have been studied[3-6] and their magnetic ordering temperatures were found to increase by substituting other elements for iron. Weitzer *et al.*[7] found that the Curie temperature (T_c) changed from 265 K for Ce_2Fe_{17} to 385 K for $Ce_2Fe_{15}Al_2$, and from 335 K for Nd_2Fe_{17} to 440 K for $Nd_2Fe_{15}Al_2$ and to 520 K for $Nd_2Fe_{15}Ga_2$. Effects of Al substitution on the magnetic anisotropy and Curie temperature of $Sm_2Fe_{17-x}Al_x$ compounds have been studied by Wang and Dunlap.[8] They found that T_c for these compounds depends on the Al concentration (x) and it reaches a maximum of 471 K for $Sm_2Fe_{14}Al_3$, compared to 391 K for the parent compound Sm_2Fe_{17}. They found also that the anisotropy changed from planar for $x\leq 1$ to uniaxial for $x\geq 3$. These changes in T_c and the anisotropy are promising improvements to the permanent-magnet properties of the parent compounds. Low-temperature measurements for $Sm_2Fe_{17-x}Al_x$ by McNeely and Oesterreicher[9] showed that the magnetization of these compounds decreases by 83% as x increases from 0 to 9.5. The coercive force (H_c) increases by increasing x and it reaches a value of 15 kOe with $x=9.5$ at $T=4.2$ K. In this article we report on Mössbauer studies for $Sm_2Fe_{17-x}Al_x$ to understand the effect of Al on their magnetic properties and the site occupation of the different Fe sites. Also we use Mössbauer spectroscopy to look for small amounts of α-Fe in these compounds.

II. EXPERIMENTAL PROCEDURE

Bulk samples of $Sm_2Fe_{17-x}Al_x$ with $x=0$, 1, 2, 3, and 4 were prepared by arc melting the elemental constituents in a water-cooled copper boat in a flowing-argon gas atmosphere. All the starting elements used were at least of 99.99% purity. The alloys were melted several times to insure homogeneity. The samples were wrapped separately in tantalum foils and heat-treated below 3×10^{-6} Torr vacuum at 1000 °C for about 72 h, and subsequently quenched in water.

Room-temperature x-ray diffraction measurements on powder samples using Cu $K\alpha$ radiation showed only the rhombohedral Th_2Zn_{17} structure with a small amount of α-Fe. The magnetization of the compounds was measured at 5 and 300 K with a superconducting quantum interference device (SQUID) and alternating force gradient magnetometer (AFGM), respectively.

The samples for Mössbauer spectroscopy were prepared by sprinkling a thin layer of the powder of $Sm_2Fe_{17-x}Al_x$ on a piece of tape. The samples were studied by using a Ranger Mössbauer spectrometer, model MS1200. The velocity drive of this spectrometer operates in the constant acceleration mode. Co^{57} in Pd was used as the γ-ray source in this experiment. All the isomer shifts were measured relative to α-iron at room temperature and α-iron was also used for calibration.

III. RESULTS AND DISCUSSION

Figure 1 shows the room-temperature Mössbauer spectra and the fitting (the solid curves) for $Sm_2Fe_{17-x}Al_x$ with $x=0$, 1, 2, 3, and 4. The spectra show that all the samples are magnetically ordered for all values of x and all of them have different subspectra with different magnetic hyperfine fields. A standard program was used to fit the spectra, where each spectrum was fitted with a set of seven subspectra, which is similar to the previous models used by Ping *et al.*,[10] Long *et al.*,[11] and Yelon *et al.*[12] for 2:17 compounds. The weak features indicated by arrows in Fig. 1 are the first and sixth lines due to α-Fe in samples with $x=1$ and 2. From the relative intensity of the subspectrum the atomic percentage of α-Fe was estimated to be less than 2%. For the rhombohedral Th_2Zn_{17} structure there are four different iron sites, $6c$, $9d$, $18f$, and $18h$, with different environments. Previous Mössbauer measurements by Long *et al.*[11,13] for Nd_2Fe_{17} and

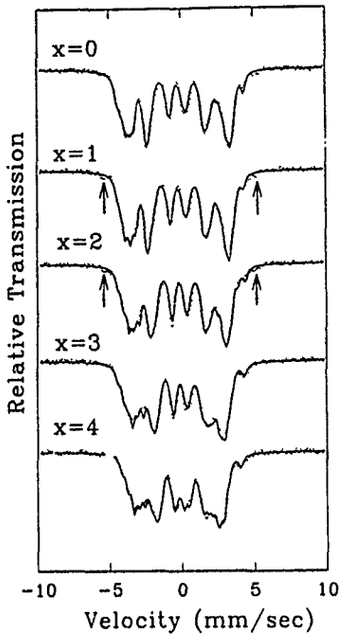

FIG. 1. Room-temperature Mössbauer spectra of $Sm_2Fe_{17-x}Al_x$ compounds. The solid curves represent the fitting. Arrows indicate the first and sixth lines due to α-Fe.

$Nd_2Fe_{17}N_{2.6}$, Mössbauer and neutron diffraction by Yelon *et al.*[12] for $Nd_2Fe_{17-x}Al_x$, and Mössbauer measurements by Hu *et al.*[10] for $R_2Fe_{17}N_{3-\delta}$ showed that the hyperfine fields decrease in the order $6c$, $9d$, $18f$, and $18h$. The $6c$ site has the largest hyperfine field since it has the largest number of iron nearest neighbors. In our fitting and analysis of the data we kept the same order. The seven subspectra used in fitting correspond to one spectrum for $6c$ and two subspectra for each of the other three sites with the relative intensity 2:1. The parent compound Sm_2Fe_{17} was studied for comparison with other compounds and other data. The average hyperfine field for different sites and for different Al concentrations was found to decrease with increasing concentration of the nonmagnetic element, Al, as seen in Fig. 2. This decrease is in qualitative agreement with the magnetization measurements by McNeely and Oesterreicher.[9] The average hyperfine field for the parent compound was 224 kOe which is in good agreement with other values of 221 kOe by Hu *et al.*[10]

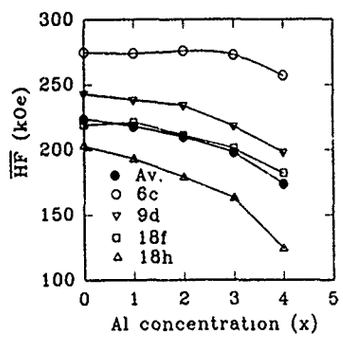

FIG. 2. Dependence of the average hyperfine field for the different Fe sites of $Sm_2Fe_{17-x}Al_x$ on the Al concentration x, at $T=295$ K.

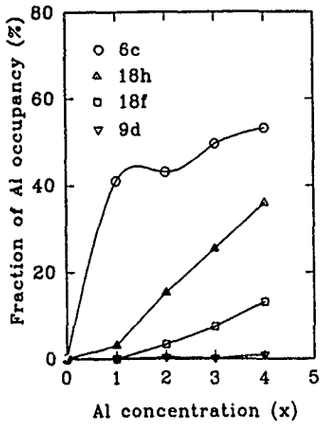

FIG. 3. Dependence of the percentage fraction of aluminum occupancy for different sites on the Al concentration x.

and 216 kOe by Long *et al.*[11] for related compounds. The Curie temperature for these compounds increases with x and reaches a maximum at $x=3$: T_c changes from 391 K for Sm_2Fe_{17} to 471 K for $Sm_2Fe_{14}Al_3$.[8] This increase of 20% in T_c in spite of the decrease in the average hyperfine field by 12% must be due to the increase in the interatomic exchange interactions upon volume expansion.

The intensity of each subspectrum is proportional to the Fe-site occupation. Using the fitted intensities we calculated the percentage of iron and aluminum at each site. Figure 3 shows the percentage fraction of Al occupancy of each site for the different sites and for different concentrations. From this figure we see that Al prefers to go to the different sites in the order $6c$, $18h$, and $18f$, but not $9d$, which has the smallest Wigner–Seitz cell volume. This is in agreement with previous observations on $Nd_2Fe_{17-x}Al_x$ by Yelon *et al.*[12]

The average isomer shift $\overline{(IS)}$ relative to α-iron was found to increase linearly by increasing the Al concentration as shown in Fig. 4, where the circles are the experimental $\overline{IS}$ and the solid line is the linear fit. The parameters for the linear fitting are given by the equation

$$\overline{IS}(\text{mm/s}) = -0.12 + 0.03x.$$

Figure 4 shows that $\overline{IS}$ is negative and the magnitude of $\overline{IS}$ decreases with increasing Al concentration. This decrease

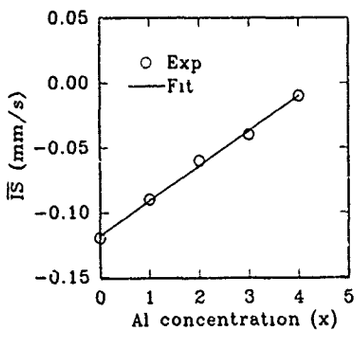

FIG. 4. Dependence of the average isomer shift $\overline{(IS)}$ relative to α-iron for $Sm_2Fe_{17-x}Al_x$ compounds on the Al concentration x.

means a decrease in the probability of finding the s electrons at the nucleus that can be attributed to the expansion of the cell volume. $\delta\overline{IS}/\delta \ln V$ for these compounds was 3.0 mm/s compared to 1.13 mm/s for α-Fe given by Shenon and Wagner[14] and 1.5–2.3 mm/s for R_2Fe_{17} and $R_2Fe_{17}N_{3-\delta}$ at 15 K given by Hu *et al.*[10] The present value is higher than the other values due to the smaller change in the cell volume compared to the others.

IV. CONCLUSIONS

Samples of $Sm_2Fe_{17-x}Al_x$ magnetic compounds have been fabricated and studied by Mössbauer spectroscopy. These compounds have rhombohedral Th_2Zn_{17} single phase with less than 2% α-Fe impurity. All the samples studied are ferromagnetic and the average hyperfine fields, and hence the magnetic moments, are found to decrease as x increases from 0 to 4. Therefore the increase in T_c with x up to $x=3$ must be due to the increase in interatomic exchange interactions between Fe atoms with volume expansion. Adding more Al lowers the exchange interaction due to the decrease in the number of Fe-Fe nearest neighbors, thereby lowering the T_c for $x>3$. Aluminum is found to occupy the three iron sites $6c$, $18h$, and $18f$ with varying degrees of occupancy, but not the $9d$ site. The change in isomer shift with increasing Al concentration corresponds to the decreasing s-electron density at the nucleus caused by the volume expansion.

Neutron diffraction and magnetic studies of $Nd_2Fe_{17-x-z}Al_xSi_z$

Z. Hu and W. B. Yelon
University of Missouri Research Reactor, Columbia, Missouri 65211

The Al and Si double-substituted 2:17 phase, $Nd_2Fe_{17-x-z}Al_xSi_z$, was prepared and analyzed using neutron powder diffraction and SQUID magnetization measurements. Rietveld analysis of the neutron diffraction data indicates that the lattice parameters are close to a linear combination of the corresponding single-substitution compounds. The unit cell could be expanded or contracted, depending on the Al/Si ratio. The aluminum and silicon fractional occupancy on the different crystallographic sites in the double-substitution compounds are related to those of single-substitution compounds. The SQUID measurements show that all samples in this study have Curie points higher than that of the unsubstituted compound. For a Si/Al ratio of 2:1, the Curie point, 492 K, was found at a total substituent content less than in the singly substituted Si compound with the same T_c.

I. INTRODUCTION

The substitution of aluminum for iron in Nd_2Fe_{17} raises the Curie temperature and leads to an expansion in the unit cell volume.[1] In this kind of compound, it is believed that the lattice expansion is sufficient to decrease antiferromagnetic exchange and enhance the ferromagnetic exchange.[2] When silicon is used as the substituent for iron in Nd_2Fe_{17}, the lattice contracts upon substitution, which would normally be expected to lower the Curie temperature. However, the Curie temperatures of the compounds are strongly increased.[3,4] The enhancement of magnetic properties with Si substitution is apparently related to the expansion of the lattice in the $9d$-$18h$ plane.[3] It may be expected that a combined substitution of Fe by Si and Al at the appropriate level could lead to further enhancement of the magnetic properties. In this paper, neutron diffraction and magnetic studies of the Al and Si double-substituted 2:17 phase, $Nd_2Fe_{17-x-y}Al_xSi_y$, are presented.

II. EXPERIMENT

Samples of $Nd_2Fe_{17-x-y}Al_xSi_y$ used in this study were prepared by rf induction melting of the constituent elements of purity 99.9–99.995% in a water-cooled copper boat under flowing argon at the Graduate Center for Materials Research, University of Missouri-Rolla. The ingots were annealed at 980 °C for one week. The ingots were then crushed and ground in an acetone bath for neutron diffraction studies or SQUID measurements. Neutron diffraction data were collected at the University of Missouri Research Reactor using the linear position-sensitive detector diffractometer at room temperature on approximately 2 g samples in 24 h. The neutron wavelength was 1.4783 Å. The data were measured from 5°–105° in 2θ. The Curie temperatures, T_c, were measured by SQUID using a Quantum Design MPMS System.

The neutron diffraction powder patterns were analyzed by the Rietveld method using the FULLPROF program[5] for multiphase refinement including magnetic structure refinement. α-Fe (5.62–8.57% in volume) was observed in all samples.

III. RESULTS AND DISCUSSIONS

The refinement results are given in Table I. Since each sample has some α-Fe (5–8% in volume) as the second phase, the stoichiometry of the compounds differs from the nominal composition. However, by using the site-effective scattering length and assuming the nominal Si/Al ratio, the stoichiometry of the compounds can be determined (see Appendix). The results are given in Table I. In a previous study,[2] the unit cell volume increased in the Al-only substituted compound, $Nd_2Fe_{17-x}Al_x$, at a rate of 9 Å^3/Al, while the unit cell volume decreased in the Si-only substituted compound, $Nd_2Fe_{17-y}Si_y$, at a rate of 3.4 Å^3/Si.[4] It is found that the unit cell volume, as well as the cell parameters, a and c, are close to a linear combination of that of the corresponding single-substitution compounds. The deviations are in the range of ±0.11%. The unit cell could, thus, be expanded or contracted, depending on the Al/Si ratio. All double-substitution compounds were found to have a higher c/a ratio than the pure Nd_2Fe_{17} phase. The site occupancies of the substituents in double-substitution compounds are not a simple addition of the Al occupancies and the Si occupancies of corresponding single-substitution compounds. Unfortunately, the substituent occupancies cannot be determined directly from the neutron refinements. However, they can be determined using a few reasonable assumptions. Previous studies show that no Al occupies the $9d$ site in the $Nd_2Fe_{17-x}Al_x$ compounds up to $x=8$, since the $9d$ is the smallest site,[1,2] and no Si occupies the $6c$ sites in $Nd_2Fe_{17-y}Si_y$ compounds up to at least $y=4.2$, since the $6c$ is the largest site.[4] In $Nd_2Fe_{17-x-y}Al_xSi_y$, it is assumed that (a) no Al atoms occupy the $9d$ sites, (b) no Si atoms occupy the $6c$ sites, and (c) the average bond length of the $18h$ sites depends only on the occupancies of Al and Si on this site. The dependence functions of the $18h$ site average bond length of single-substitution compounds are applied to double-substitution compounds. The results for the separate Al and Si site occupancies (see Appendix) are given in Table II. These appear reasonable in comparison to the singly substituted results, but an anomalous x-ray scattering study, combined with the neutron data, would be useful to uniquely fix the occupancies. Figure 1 shows the dependence of site occupancies upon the substituent contents for those samples

[a]ASBL=average site bond length.

with an approximate Al/Si ratio of one. In the singly substituted compounds, either the 9d or 6c sites remain full of Fe and, therefore, the remaining sites must, on average, have a higher than random substituent occupancy. In the present case, both sites are occupied and therefore there is a lower total occupancy of the remaining 18f and 18h sites. It is found that the 18f site takes up less substituent, while the 18h site fills at roughly the same rate as in the singly substituted compounds. Table I also gives the bond lengths and the average bond length of each site. It was found that the average bond length increases in 6c, 9d, and 18f sites in all samples in this study. On the 18h site, the average bond length increases in some samples and decreases in other samples, depending on the Al/Si ratio and the total substituent content.

The site magnetic moment of these compounds are also given in Table I. It was found that the Nd sublattice couples ferromagnetically to the Fe sublattice in all compounds. For those samples of low total substituent content, the magnetic moments lie in the basal plane. For those samples of high total substituent content, canted magnetic structures were observed. However, the refinement was not stable for the sample of highest content and the minimum was found by iteration of the $\mu(z)/\mu(x)$ ratio. An easy direction change was found in $Nd_2Fe_{17-y}Si_y$ only with $y>3$ (Ref. 4) but not found in $Nd_2Fe_{17-x}Al_x$ up to $x=9$.[2] It is possible that an easy axis system could be produced at a lower substituent content than is found in any singly substituted compound. The Curie temperatures, measured by SQUID, are also given in Table I. All compounds have a Curie point higher than that of the pure Nd_2Fe_{17} phase, which is 330 K. The Curie temperature was found to depend on both the total substituent content and the Al/Si ratio, and those compounds with a higher Si/Al ratio have higher Curie points, indicating that Si has a stronger effect on the ferromagnetic exchange than Al. In the $Nd_2Fe_{17-x}Al_x$, the maximum Curie temperature, about 460 K, is found for x of approximately three. In $Nd_2Fe_{17-y}Si_y$, the maximum Curie temperature, about 495 K, is at y of about 3.7. The maximum Curie point of the double-substitution compounds (with the limited Al and Si contents and their ratio in this study) was found to be 492 K, similar to that of Si-only substitution compounds. The total substituent content is significantly lower than in the singly substituted compound (2.7 compared to 3.7, about 27% less),

which is important because the lower substituent content means less reduction in the magnetization of the compound. It is possible that the higher Fe content on the $18f$ site plays a role in the observed enhancement in the magnetic properties. Note that the magnetic moment on this site is relatively large in most of the specimens.

ACKNOWLEDGMENTS

The authors would like to thank Dr. W. J. James, University of Missouri-Rolla, for help in preparing samples, the Division of Materials Research of the U.S. National Science Foundation for Grant No. DMR 9305782, and M. Seewoster for helping in preparing tables and figures.

APPENDIX

For a double-substitution 2:17 phase, $Nd_2Fe_{17-x-y}Al_xSi_y$, the effective scattering lengths of the four iron sites are

$$cb_{fe}=x_1b_{al}+y_1b_{si}+(0.167-x_1-y_1)b_{fe}, \quad \text{(A1)}$$

$$db_{fe}=x_2b_{al}+y_2b_{si}+(0.167-x_2-y_2)b_{fe}, \quad \text{(A2)}$$

$$fb_{fe}=x_3b_{al}+y_3b_{si}+(0.167-x_3-y_3)b_{fe}, \quad \text{(A3)}$$

$$hb_{fe}=x_4b_{al}+y_4b_{si}+(0.167-x_4-y_4)b_{fe}, \quad \text{(A4)}$$

where c, d, f, and h are refined Fe site occupancies. b_{al}, b_{si}, and b_{fe} are the scattering lengths of Al, Si, and Fe, respectively. x_i ($i=1$, 2, 3, and 4) are Al site occupancies and y_i ($i=1$, 2, 3, and 4) are Si site occupancies.

To solve for the eight unknowns, x_i and y_i, four more independent equations are needed:

(a) No Al or Si out of the 2:17 phase, then

$$\Sigma x_i/\Sigma y_i=(W_{al}/M_{al})/(W_{si}/M_{si}), \quad \text{(A5)}$$

where W_{al} and W_{si} are the starting weights of Al and Si, and M_{al} and M_{si} are the atomic weights of Al and Si, respectively.

(b) No Al atoms occupy the $9d$ sites,

$$x_2=0. \quad \text{(A6)}$$

(c) No Si atoms occupy the $6c$ sites,

$$y_1=0. \quad \text{(A7)}$$

(d) The average bond length of the $18h$ sites depends only on the occupancies of Al and Si on this site. The dependence functions of the $18h$ site average bond length of single-substitution compounds can be applied to double-substitution compounds. The site average bond length for the $18h$ sites depends only on the substituent occupancies.

$$ABL_h=f_h(x_4)+f'_h(y_4)-ABL_0, \quad \text{(A8)}$$

where ABL_h is the refined h site average bond length of $Nd_2Fe_{17-x-y}Al_xSi_y$, ABL_0 is the refined h-site average bond length of Nd_2Fe_{17}, $f_h(x)$ is the dependence function of the h site average bond length on Al occupancy in $Nd_2Fe_{17-x}Al_x$, which was extracted from the Al-only substituted compounds in a previous study.[2] $f'_h(y)$ is the dependence function of the h-site average bond length on Si occupancy in $Nd_2Fe_{17-y}Si_y$, which was extracted from the Si-only substituted compounds in a previous study.[4]

By solving the independent equations (A1)–(A8), x_i ($i=1$, 2, 3, and 4) and y_i ($i=1$, 2, 3, and 4) are determined.

The compound $SmCo_4B$ is a hard magnetic material; however, the saturation moment and the Curie temperature need to be increased for the compound to be a candidate for a permanent magnetic material. For this purpose, Fe substitution for the Co and Pr substitution for the Sm of $SmCo_4B$ have been attempted. In addition, the nitrogenation of $SmCo_2Fe_2$ is also attempted. The magnetic characteristics of $SmCo_2Fe_2B$ have been investigated in a pulsed high magnetic field up to 350 kOe. and the data are compared with those of other related compounds investigated in this work. The compound with more Fe content, $SmCo_{1.7}Fe_{2.3}B$, has been successfully made, and $T_C=794$ K and saturation moment $M_s=81.4$ emu/g at 300 K have been obtained. It is found that the Fe substitution does not decrease the uniaxial magnetic anisotropy. Heat treatments in nitrogen gas at 500 °C of $SmCo_2Fe_2B$ have brought about significant increases of magnetization; however, the increase of T_C is only about 20 K and the crystal volume is unchanged to within experimental uncertainty.

It has been known[1,2] that boron substitution for the Co of RCo_5 (R=rare earth) leads to a formation of compound systems with discrete B content expressed by the general formula $R_{n+1}Co_{3n+5}B_{2n}$ $(n=0,1,2,\ldots,)$. In our previous papers,[3,4] we focused on the Sm system of hard magnetic materials. The compound $SmCo_4B$ is especially interesting because it has a huge uniaxial magnetic anisotropy at $T=4.2$ K. However, both the saturation moment and the Curie temperature are about half of those of $SmCo_5$. It is also known[4] that Fe and Pr substitutions increase the magnetization as well as the Curie temperature of $SmCo_4B$. In order to improve the magnetic characteristics of $SmCo_4B$ for a hard magnetic material, three kinds of trials have been made in this work: the first is to re-examine the magnetic characteristics of $SmCo_{4-x}Fe_xB$ in a high magnetic field; the second is to make samples with greater Fe content than $x=2$ in $SmCo_{4-x}Fe_xB$ and also to create Pr substitution for the Sm; the last is to make nitrogen-absorbed samples of $SmCo_2Fe_2B$. Magnetic and crystallographic measurements have been performed and discussed for the samples mentioned above.

Samples in the present study were prepared by an arc furnace. The melting was repeated generally more than six times to homogenize the composition of the melts. Especially in the case of $SmCo_{1.7}Fe_{2.3}B$, ingots of Co, Fe, and B with desired ratio of mass were first melted ten times, and then the ingot thus prepared was melted together with a suitable mass of Sm at least six times. This method seems to be effective to obtain a single phase of the compound with a large content of Fe. Several days of heat treatment at about 1000 °C was generally made to homogenize the ingots obtained by the arc melting. By this method, we obtained a single phase of $SmCo_{1.7}Fe_{2.3}B$, which implies that there is hope that higher Fe contents are attainable, but not certainty. In the case of the $Sm_{0.7}Pr_{0.3}Co_2Fe_2B$ compound, the sample prepared included a small amount of the 2:17 phase and a very small amount of the 1:5 phase. If composition loss of the Sm and B occurs during the melting process, we will have the three phase samples mentioned above.[2] Excess nominal composition of Sm and B will be needed to obtain a single phase of $Sm_{0.7}Pr_{0.3}Co_2Fe_2B$. The crystal structures of $CaCu_5$ type for $SmCo_5$ and $CeCo_4B$ type for $SmCo_4B$, etc., are illustrated in Fig. 1. The lattice parameters of $SmCo_{1.7}Fe_{2.3}B$ have been determined by x-ray diffraction to be $a=5.138$ A and $c=6.948$ A, which are larger than $a=5.087$ A and $c=6.89$ A for $SmCo_4B$, respectively. About 3% volume expansion occurs by the Fe substitution.

Magnetization curves have been measured in a pulsed high magnetic field up to 35 T(=350 kOe) for field-oriented samples of $SmCo_5$, $SmCo_4B$, and $SmCo_2Fe_2B$. Particle size of powdered samples is generally less than 32 μm in diameter. The magnetization curves of $SmCo_5$ and $SmCo_4B$ are similar to our previous data.[3] The anomalous behavior of the magnetization curve with $H\|c$ at around $H=0$ for $SmCo_4B$ is considered to be caused by the experimental method: the magnetization in the process of decreasing external field is first measured in the region from $H=35$ T to $H=0$ and then the cylindrical field-oriented sample direction was reversed to measure the magnetization in the region from $H=0$ to

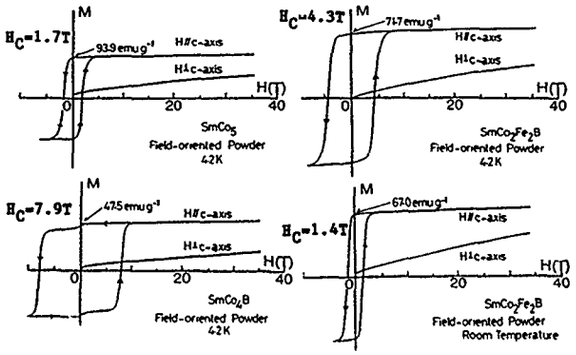

FIG. 2. Magnetization curves measured in pulsed magnetic field for field-oriented samples of $SmCo_5$ and $SmCo_{4-x}Fe_xB$ with $x=0$ and 2. C indicates the direction of field orientation.

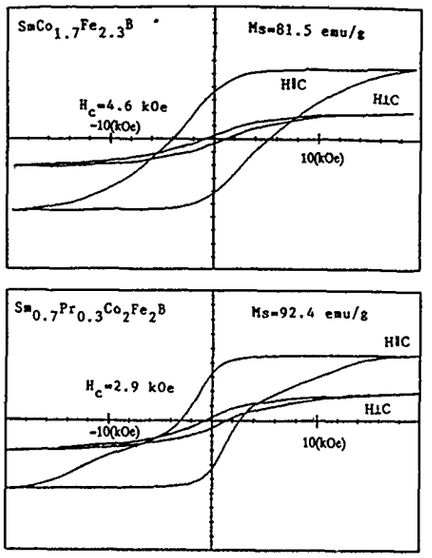

FIG. 3. Magnetization curves for field-oriented samples of $SmCo_{1.7}Fe_{2.3}B$ and $Sm_{0.7}Pr_{0.3}Co_2Fe_2B$. C indicates the direction of field orientation. The coercivity H_c is defined as an average of H_c in the processes of decreasing and increasing fields.

$H=-10$ T. The magnetization curve in the process of increasing field was measured by a similar method. The data for $SmCo_2Fe_2B$ at $T=4.2$ and 300 K are obtained for the first time in this work. Coercivity H_c, which depends on the various factors, is also shown for the respective samples in Fig. 2. As seen in Fig. 2, the magnetization curves with $H\perp c$ have a small amount of residual magnetization at $H=0$, which means a slight lack of alignment of the field-oriented samples. To avoid the error in the estimation of anisotropy field H_A due to the lack of alignment, the linear part of the initial magnetization curve with $H\perp c$ is moved in parallel so as to start from the origin, and then the anisotropy field is determined as the magnetic field at which the straight line corresponding to the linear part mentioned above reaches the spontaneous magnetization. The anisotropy field has been determined by this method for the respective sample in Fig. 2. The saturation magnetization values have been calibrated by making use of the data for the loose powder of each sample. Anisotropy constant K_1 has been calculated by the equation of $K_1=(1/2)M_sH_A$, where M_s is the spontaneous magnetization per unit volume.

The magnetization curves for the field-oriented samples of $SmCo_{1.7}Fe_{2.3}B$ and $Sm_{0.7}Pr_{0.3}Co_2Fe_2B$ have been measured in a magnetic field up to 20 kOe. The data are shown in Fig. 3. In this case, the particle size is larger than that of the samples in Fig. 2, but less than 32 μm. Since there is considerable lack of alignment and also the maximum field used is only 20 kOe in Fig. 3, it is hard to obtain a reliable value of anisotropy field. Rough values of H_A in both cases in Fig. 3 have been estimated to be about 120 kOe by a method similar to that used in Fig. 2. The magnetic data mentioned above are summarized in Table I together with Curie temperatures determined by a magnetic balance in this work. Some data in Table I are taken from references cited therein. We can see some important points in Table I. The magnetization of $SmCo_4B$ is considerably increased; however, the anisotropy constant remains almost unchanged by the Fe substitution. The magnetization of $YCo_{4-x}Fe_xB$ is known to increase with x.[9,10] It has also been clarified by Onodera *et al.*[10] that both Fe and Co moments increase with x. A similar mechanism, which occurs also in the Fe-Co alloy, must occur in $SmCo_{4-x}Fe_xB$. A fundamental concern is also in the magnetic state of the Sm sublattice; however, we do not discuss it here. According to Dung *et al.*,[9] the anisotropy constant K_1 at $T=4.2$ K of YCo_4B and $YCo_{2.5}Fe_{1.5}B$ take about -4×10^6 erg/cm^3 and -1×10^7 erg/cm^3, respectively. These values are negligibly small compared with those of $SmCo_4B$ and $SmCo_2Fe_2B$ at $T=4.2$ K, which means that the K_1 value in the Sm system mentioned above is supplied mainly by the Sm sublattice. The data of K_1 in Table I suggest that the Sm-sublattice anisotropy is enhanced by the Fe substitution. Therefore, to make $SmCo_4B$ a candidate for permanent magnet materials, we only need to increase the magnetization and the Curie temperature of $SmCo_4B$ by Fe substitution as much as possible. As seen in Table I, the Curie temperature of $SmCo_{1.7}Fe_{2.3}B$ is about 1.6 times higher than that of $SmCo_4B$. The Pr substitution is also effective to increase the magnetization. In the case of $YCo_{4-x}Fe_xB$, the maximum Fe content seems to be $x=1.5$,[9] which means the

TABLE I. Magnetic data of $SmCo_4B$ and related compounds. T_C, Curie temperature; M_s, saturation magnetization; H_A, anisotropy field in the unit of Tesla; K_1, anisotropy constant. Saturation induction equals $4\pi M_s\rho$ (Gauss), where specific mass ρ is 8.58 for $SmCo_5$ and 8.54 for other compounds.

$Sm_{0.7}Pr_{0.3}Co_2Fe_2B$	749	92.4(300 K)		

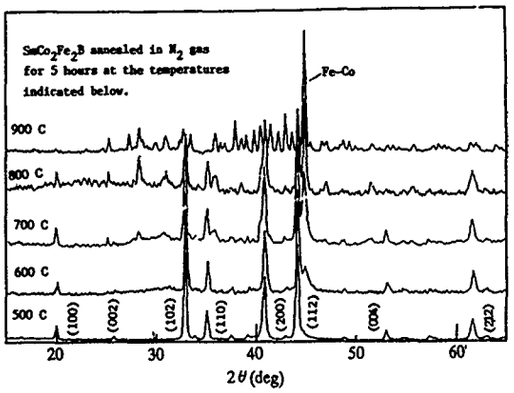

FIG. 4. X-ray diffraction patterns for $SmCo_2Fe_2B$ powder annealed in N_2 gas for 5 h at the indicated temperatures.

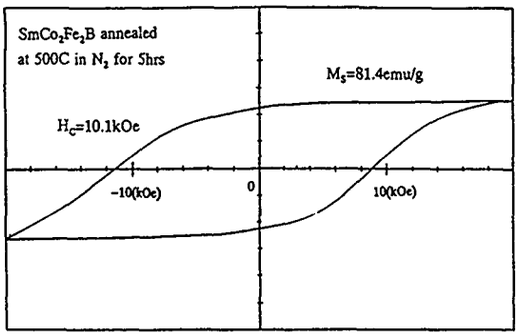

FIG. 6. Hysteresis loop of field-oriented $SmCo_2Fe_2B$ powder annealed at 500 °C in N_2 gas for 5 h. Definition of H_c is the same as those in Fig. 3.

maximum Fe content in $RCo_{4-x}Fe_xB$ seems to depend on the kind of rare earth R.

As mentioned in the preceding section, the three phases of $Sm_{0.7}Pr_{0.3}Co_2Fe_2B$ could be attributed to the composition shift during the melting process, so if appropriate initial nominal composition is found, it will be possible to obtain the single phase sample of $Sm_{0.7}Pr_{03}Co_2Fe_2B$.

To improve the magnetic characteristics of the materials mentioned in Sec. III, the nitrogenation will be another effective method. In this work, heat treatments of $SmCo_2Fe_2B$ powder in atmospheric N_2 gas have been carried out at various temperatures. X-ray diffraction patterns of the sample after the heat treatments are shown in Fig. 4. The heat treatments at temperatures above 600 °C seem to promote the precipitation of Fe-Co alloy. Therefore, nitrogenation of $SmCo_2Fe_2B$ was tried at 500 °C in N_2 gas for 5, 10, and 24 h. Magnetization curves measured for loose powders at 300 K are shown in Fig. 5. These data clearly show an effect of heat treatments in N_2 gas. The saturation magnetization increases more than 10%; however, x-ray diffraction patterns before and after the heat treatment do not bring about significant volume expansion. The Curie temperatures that are shown in the inset of Fig. 5 also do not show a clear difference, although an N_2 gas effect is seen in the magnetizations. It is not clear at present whether the sample absorbed nitrogen into the inner part of the crystal. A hysteresis loop of the heat treated N_2 gas for 5 h is shown in Fig. 6. The coercivity takes a very similar value to that of the sample without heat treatment in N_2 gas. The crystallographic site that the nitrogen atom may occupy is shown by the open square symbols, which is the site similar to the $9e$ site in Sm_2Fe_{17}[11] in Fig. 1. Since the four near neighboring sites around the square site are occupied by Co or Fe atoms in equal probability in the present case, the probability that all the four sites are occupied by Fe atoms will be $(\frac{1}{2})^4$. Therefore, if the nitrogen atom is supposed to occupy the square site with four Fe surroundings, the possible formula of nitride of $SmCo_2Fe_2B$ will be $SmCo_2Fe_2BN_{0.1875}$, which means that the quantity of nitrogen that may be absorbed by the sample is small, unlike the case of Sm_2Fe_{17}. This may be one of the reasons why nitrogen is not easily absorbed by $SmCo_2Fe_2B$.

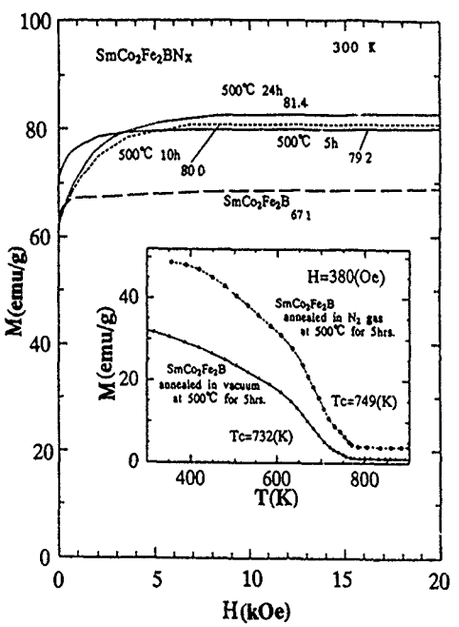

FIG. 5. Magnetization curves for $SmCo_2Fe_2B$ loose powders. 500 °C, 24 h indicates that the sample was annealed in N_2 gas at 500 °C for 24 h. The inset shows the temperature dependence of the magnetization of $SmCo_2Fe_2B$ annealed in two different conditions.

Dissipation in macroscopic quantum tunneling and coherence in magnetic particles (invited)

Anupam Garg
Department of Physics and Astronomy, Northwestern University, Evanston, Illinois 60208

For quantum phenomena involving a macrovariable such as the total moment of a ferromagnetic particle, or the Néel vector of an antiferromagnetic one, environmental couplings play a crucial role. The effect of such couplings, or dissipation, is studied, with emphasis on the nuclear spin environment. It is shown that magnetic macroscopic quantum tunneling (MQT) and coherence (MQC) both become harder to see. Quantitative calculations are presented for the tunneling rate in MQT, and the tunnel splitting and ac susceptibility for MQC. A recent claim to have seen MQC in a resonance experiment on ferritin is critically discussed and the absorption is found to be at least 1500 times larger than predicted by MQC.

I. INTRODUCTION

Even the best quantum mechanics texts[1] sometimes state that for billiard balls and cannon shells, the de Broglie wavelength is so absurdly small that any quantum mechanical effect such as two-slit diffraction would be washed out by the limited resolution of any measurement apparatus. This is usually taken as sufficient reason for the inadvisability of applying quantum mechanics to such objects. Yet, if one were to press the issue, and ask what the practical difficulties would be in experimentally verifying quantum effects in such cases, one would soon conclude that the small de Broglie wavelength was completely overshadowed by another phenomenon, namely, interaction with the environment. Different particle trajectories would be correlated with very different states of the rest of the universe, so that even if the trajectories ended with the particle in the same position, the environment would not, and the interference terms in the square of the total amplitude would vanish by virtue of the zero overlap between the states of the environment. To put it another way, the environment would "measure" the trajectory taken by the particle, and one would never obtain the case of indistinguishable alternatives.[2]

This view of the quantum mechanics of macroscopic objects has been developed considerably further by Leggett and his co-workers over the last decade.[3] Interaction with the environment, or dissipation, as it has come to be called, is *the* feature which distinguishes macroscopic objects from microscopic ones. It is usually present in myriads of ways, and one would have to go to impossible lengths to eliminate it for the vast majority of macroscopic systems. As Leggett has pointed out, the two phenomena likely to yield the most unambiguous evidence of quantum behaviour are macroscopic quantum tunneling (MQT), or the decay of a metastable state, and macroscopic quantum coherence (MQC), or the resonance between degenerate states (see Fig. 1). Most of the early work was done with a view of seeing MQT and MQC of the order parameter in Josephson junction based systems,[4–9] but in the last few years, small magnetic particles have emerged as potential candidates too.[10,11] The macrovariable is the total magnetic moment of the particle if it is ferromagnetic, or the Neél vector if it is antiferromagnetic, and the different states correspond to different directions of these vectors. Other magnetic systems such as domain walls have also been proposed.[12]

It is essential to realize at the outset that MQT and MQC are very different phenomena, especially when environmental couplings are considered. In general, both become harder to see, but the effect on MQC is more severe. The essential requirement for MQC is degeneracy. If the bottoms of the wells of the MQC potential in Fig. 1 are nondegenerate by much more than the tunnel splitting, the mixing between the states localized near the well bottoms will be negligible, and one will not see any MQC. The environment can be viewed as giving rise to a dynamically fluctuating potential for the system. If this potential is asymmetric for most of the time, or if the degeneracy persists for times much less than the tunneling time, MQC will be reduced. Another way of saying this is that phase coherence must be maintained for much longer durations in MQC than MQT (inverse of the tunnel splitting versus the small oscillation period in the metastable well), and is therefore more easily destroyed by an environment. In fact, for ohmic and subohmic dissipation, as defined in Ref. 7(b), the environment can suppress MQC completely, localizing the particle in the initial well![8]

The purpose of this paper is to discuss dissipation in magnetic particle systems. The dissipation mechanisms which have been studied to date include phonons,[13,14] nuclear spins,[15] and Stoner excitations and eddy currents in metallic magnets.[16] Except for nuclear spins and Stoner excitations, the other mechanisms are generally weak. We will focus only on nuclear spins, and refer the reader to the literature for the rest. The work, for the most part, elaborates on Refs. 15(a) and 15(b), which deal, respectively, with MQT and MQC. We will consider MQT in Sec. II. We rebut

 0021-8979/94/76(10)/6168/6/$6.00 © 1994 American Institute of Physics

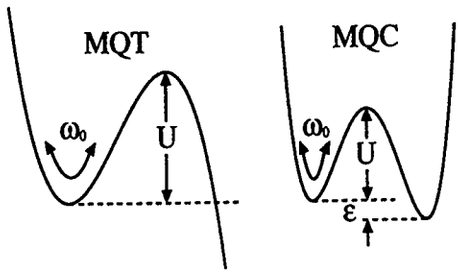

FIG. 1. Potentials for MQT and MQC. For MQC, the bias ϵ must be small.

Chudnovsky's recent statement that nuclear spins are unimportant,[17] and explicitly obtain the WKB exponent in the presence of dissipation. We find that unless the number of magnetic nuclei is less than a few percent of the atomic magnetic moments, the exponent is multiplied by a factor of order unity. If the exponent is as large as 20 or 30 in the absence of dissipation, this can substantially reduce the escape rate. We consider MQC in Sec. III, and show that even for systems where magnetic nuclei are rare, the suppression of MQC can be large. As a technical point, we note that unlike the case of MQT, for the MQC problem, nuclear spins cannot be reduced to an equivalent bath of harmonic oscillators. Because $\omega_n \ll \omega_e$, where ω_n and ω_e are the nuclear and electronic Larmor frequencies, the nuclei act almost as a c-number bias field, and sizeable resonance occurs only when the net nuclear spin polarization in a given particle is zero. Since the polarization decreases with increasing temperature T, we predict that MQC may be enhanced with increasing T in some range. We also suggest double resonance experiments—driving the nuclear polarization to zero by a strong rf pulse at ω_n should enhance the MQC signal while the nuclear polarization relaxes. We apply our results to Awschalom *et al.*'s claim to have seen MQC in antiferromagnetic ferritin particles.[18] When nuclear spin dissipation is included in a previous calculation of the expected power absorption,[19] the experimental signal is found to be too large by a factor exceeding 1500. Taken with previously discussed difficulties,[20] this renders the possibility of MQC occurring in ferritin rather implausible.

II. NUCLEAR SPINS AND MQT

Consider an isolated, nonmetallic, ~50 Å radius, single domain, ferromagnetic particle, at a temperature well below the anisotropy gap. Let us suppose that it has $N \sim 10^4$–10^5 atomic moments, each of spin s, and magnetogyric ratio γ. The total magnetic moment $\mathbf{M}$ then has essentially fixed magnitude $M_0 = Ns\hbar\gamma$, and its direction $\hat{\mathbf{M}}$ is the only dynamical variable left. In the presence of an external field $\mathbf{H}$, the Hamiltonian is given by

$$\mathscr{H}(\hat{M}) = E_{an}(\hat{M}) + \frac{1}{2v_0} N_{ij} M_i M_j - \mathbf{M}\cdot\mathbf{H}. \tag{2.1}$$

The three terms are due to crystal anisotropy, shape anisotropy, and the dipole coupling; v_0 is the particle volume, and N_{ij} is a shape dependent tensor with trace 4π. The first two terms will combine to create easy and hard directions for $\mathbf{M}$, which will in general not be along the crystal axes. This point must be kept in mind if one ever reaches the stage of doing single particle experiments, as it raises the issue of how the magnetic axes are to be found. We will denote the easy axis by $\hat{z}$, the hard axis by $\hat{y}$, and assume that $\mathbf{H} \| -\hat{z}$. [For results for small misalignments of $\mathbf{H}$, see Ref. 13(b).] The state $\mathbf{M} \| \hat{z}$ is then metastable with respect to $\mathbf{M} \| -\hat{z}$. As the field strength is increased, the barrier from $\mathbf{M} \| \hat{z}$ to $\mathbf{M} \| -\hat{z}$ will be lowered, and eventually vanish at some "coercive field" H_c. Since the tunneling rate is low for large barriers, we anticipate that we will need $H \approx H_c$ to see appreciable tunneling, and parametrize H as $H = (1-\epsilon)H_c$, where $\epsilon \ll 1$. Writing $\hat{\mathbf{M}}$ in terms of polar angles θ and ϕ, and subtracting a constant term, we arrive at the general Hamiltonian (model III in Ref. 10)

$$\mathscr{H}(\theta,\phi) = K_1\theta^2(\epsilon - \theta^2/4) + K_2\theta^2 \sin^2\phi. \tag{2.2}$$

Here, K_1 and K_2 are shape plus crystal anisotropy coefficients ($K_1 > K_2 > 0$). For hard magnets, we expect these to be close to the crystal anisotropy coefficients. In any case, we expect that per unit volume, $K_1 \sim K_2 \sim 10^6$–10^7 ergs/cm^3.

The quantum mechanical dynamics of $\mathbf{M}$ can be specified by giving the action and using path integrals to calculate any desired amplitude. For tunneling rates, it is better to use the "imaginary time" or Euclidean action, and this is given by

$$S_0[\hat{\mathbf{M}}] = \int [\mathscr{H}(\theta,\phi) - i\gamma M_0 \cos\theta\dot{\phi}(\tau)]d\tau. \tag{2.3}$$

The escape rate from an MQT potential such as in Fig. 1 can generally be written as $\Gamma_0 = c\omega_0 \exp(-S_0^{\rm cl}/\hbar)$, where ω_0 is the small oscillation frequency in the metastable well, c is a constant of order unity, and $S_0^{\rm cl}$ is the least or "classical" action for trajectories crossing the barrier. For our problem, ω_0 is the frequency for small amplitude precession of $\mathbf{M}$ around the stable direction $\theta = 0$—essentially the ferromagnetic resonance frequency—which from Eqs. (2.2) and (2.3) is $\omega_p = (2\gamma/M_0)(K_1K_2\epsilon)^{1/2}$. (Note that K_1, K_2, and M_0 are all proportional to the particle volume, so that ω_p is an intensive quantity.) As for the exponent $S_0^{\rm cl}/\hbar$, it can be obtained by standard WKB or instanton techniques,[10,13(b),(c),21] and it is useful to write it in three equivalent ways:

$$\frac{S_0^{\rm cl}}{\hbar} = \frac{8M_0}{3\hbar\gamma}\sqrt{\epsilon^3 r} = \frac{8Ns}{3}\sqrt{\epsilon^3 r} = \frac{16U}{3\hbar\omega_p}. \tag{2.4}$$

Here, $r = K_1/K_2$, $U = K_1\epsilon^2$ is the barrier height, and N is the total number of atomic moments in the particle. The second form follows from the first on recalling that $M_0 = Ns\hbar\gamma$, and the last form reveals a general feature for all smooth potentials, namely, that the WKB exponent is of order $U/\hbar\omega_p$. The second form shows explicitly that tunneling becomes harder as the number of moments increases, and makes the need for keeping ϵ small absolutely clear. Since $\omega_p \sim 10^{10}$ s^{-1}, one must have $S_0 < 30$, say, to have any hope of getting a reasonable value for Γ_0. Since $r > 1$, and $s > 1/2$, it follows that we must have $\epsilon < 0.037$ for $N = 10^4$ and $\epsilon < 0.008$ for $N = 10^5$. Surprisingly, these values correspond to fairly big exit angles (the classical turning points) of 22° and 10°, so

that the tunneling can justifiably be called macroscopic, although it does require rather fine tuning of ϵ, i.e., the applied field **H**.

Let us now include the nuclear spins.[15(a)] We consider only the nuclei of the magnetic atoms, as this is enough to illustrate our central point that nuclear spin dissipation suppresses tunneling. Hyperfine fields at magnetic atoms' nuclei are often ~100 T.[22] Transferred hyperfine fields at the nuclei of nonmagnetic atoms and dipolar fields at nuclei outside the particle are smaller, and their effect is weaker, although it could be included with minor modification of the treatment to follow. Suppose there are N_n magnetic nuclei, each with spin **I**, and magnetogyric ratio γ_n. It suffices to take an isotropic hyperfine tensor, and to neglect the applied and demagnetization fields. The total interaction Hamiltonian for all nuclear spins is then

$$\mathscr{H}_n = -A\sum_k \mathbf{I}_k\cdot\mathbf{s}_k, \tag{2.5}$$

where $\mathbf{s}_k$ is the atomic spin on the kth atom, and A is the hyperfine coupling. The hyperfine field is given by $H_n = As$, and the nuclear Larmor frequency is $\omega_n = AIs/\hbar$. We will only consider the case of zero temperature ($T=0$). The issue of how to correctly calculate $T\neq 0$ escape rates is not completely clear to the author, but if the common procedure of finding the imaginary part of the free energy is used, one can show that the canonically averaged escape rate is always less than the rate in the absence of dissipation.[23] The $T=0$ case thus gives the maximum dissipative suppression of the escape rate, and a comparison of the exponent in this rate with U/k_BT also provides an estimate of the crossover temperature between thermal activation and quantum tunneling.

To calculate the rate Γ with dissipation, we consider an initial state $|\hat{z},\{-I\}\rangle$, where $\hat{\mathbf{z}}$ is the orientation of $\hat{\mathbf{M}}$, and $\{-I\}$ indicates that $I_z=-I$ for all nuclear spins. We then calculate the quantity

$$Q(T) = \langle \hat{\mathbf{z}},\{-I\}|e^{-(\mathscr{H}+\mathscr{H}_n)T/\hbar}|\hat{\mathbf{z}},\{-I\}\rangle \tag{2.6}$$

as $T\to\infty$, and compare the result with $\exp(-E_0+i\Gamma/2)T/\hbar$. (Note that T is now a time, and not the temperature.) The amplitude for the nuclear spins not to flip for any given **M** trajectory is found to very good approximation by perturbation theory, and the final result is[15(a)] that $Q(T)$ can be written entirely in terms of an effective action $S_{\rm eff}=S_0+S_1$ for **M**, where S_0 is given by Eq. (2.3), and

$$S_1[\theta] = N_n\frac{Is^2}{8\hbar}A_x^2\int_0^T\int_0^T[\theta(\tau_1)-\theta(\tau_2)]^2 \times e^{-\omega_n|\tau_{12}|}d\tau_1 d\tau_2. \tag{2.7}$$

Note that this effective action would also be given by a bath of harmonic oscillators, with a spectral density $J(\omega)\sim\delta(\omega-\omega_n)$. This illustrates the Caldeira–Leggett argument[4] that as long as any one bath degree of freedom is weakly perturbed, the bath can be regarded as a collection of harmonic oscillators for understanding the dynamics of the system. We shall see that this description of the nuclear breaks down completely for the case of MQC.

The new rate $\Gamma\propto\omega_p\exp(-S_{\rm eff}^{\rm cl})$, where $S_{\rm eff}^{\rm cl}$ is the least value of $S_{\rm eff}$. (The change in the prefactor in Γ is much less important and will be ignored.) Following Refs. 4(b) and 24, we define $u=\omega_p\tau$, $\theta(\tau)=2\epsilon^{1/2}z(u)$, and

$$\sigma[z] = (\hbar\omega_p/4U)S_{\rm eff}[\theta(\tau)]. \tag{2.8}$$

The problem is characterized by two dimensionless parameters, given by

$$\mu = N_nI\epsilon(\hbar\omega_p/U), \quad \eta=\omega_n/\omega_p, \tag{2.9}$$

in terms of which, we can write

$$\sigma[z] = \int du(\dot{z}^2+z^2-z^4) + \frac{\mu\eta^2}{8}\int\int[z(u)-z(u')]^2 \times e^{-\eta|u-u'|}du\,du'. \tag{2.10}$$

We shall denote the minimum value of $\sigma[z]$ by $b(\mu,\eta)$. Thus, without dissipation, $b=4/3$, and the bounce, or best trajectory, is $z=\operatorname{sech} u$. Taking $H_n\sim$1–100 T, and $\omega_p\sim10^{10}$ s^{-1}, we get $\eta\sim$0.01–1. To estimate μ, let us take $\epsilon\sim10^{-3}$, and $\hbar\omega_p/U\sim1/5$ (any smaller value would lead to a very small bare tunneling rate). If the magnetic nucleus has a high abundance, so that $N_n\simeq N\sim10^5$, we get $\mu\gtrsim10$. If, on the other hand, $N_n/N\sim10^{-2}$, as is the case for natural isotopic mixtures of Fe and Ni, $\mu\simeq0.1$

[Before minimizing Eq. (2.10), we address a recent opinion by Chudnovsky[17(a)] stating that nuclear spin dissipation can largely be ignored. For weak or moderate dissipation, the relevant combination of μ and η turns out to be $\mu\eta/2$, which as we can see from above can be of order unity in many cases. Chudnovsky rewrites $\mu\eta/2=h_{hf}/H_c\epsilon$, where h_{hf} is the field at the atomic moments due to the nuclei. As $h_{hf}/H_c\sim10^{-2}$ for systems with high abundance of magnetic nuclei, a value of order unity for $\mu\eta/2$ can arise only if $\epsilon\lesssim0.01$, a condition which is thought to be not realistic by Chudnovsky. We have shown earlier, however, that small values of ϵ are compelled upon us by the need to have $S_0<30$. Since the second term in Eq. (2.10) is positive, we see that the WKB exponent is always increased by dissipation—in fact, $b(\mu,\eta)$ is a monotonically increasing function of μ—the restrictions on ϵ apply with even greater force. Far from being unrealistic, small values of ϵ are a necessary precondition for observing MQT.]

The Euler–Lagrange equation for the least action trajectory is

$$\frac{d^2z}{du^2} = z-2z^3+\frac{\mu\eta^2}{4}\int_{-\infty}^{\infty}[z(u)-z(u')]e^{-\eta|u-u'|}du', \tag{2.11}$$

and the boundary conditions are $z(u)\to0$ as $u\to\pm\infty$. Denoting Fourier transforms by tildes, Eq. (2.11) can be rewritten in the frequency domain as

$$\tilde{z}(\omega) = 2\widetilde{z^3}(\omega)G(\omega), \tag{2.12}$$

$$G^{-1}(\omega) = 1+\omega^2+\frac{\mu\eta}{2}\frac{\omega^2}{\omega^2+\eta^2}. \tag{2.13}$$

Note that $\widetilde{z^3}(\omega)\neq\tilde{z}^3$. The inverse Fourier transform of Eq. (2.12) gives

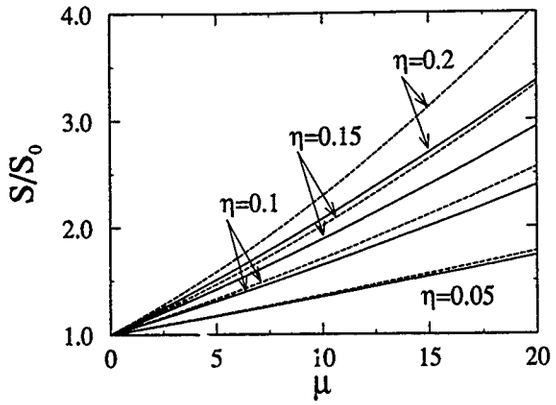

FIG. 2. Multiplicative dissipative correction to the WKB exponent (solid lines), and upper bound from Ref. 17(b) (dashed lines).

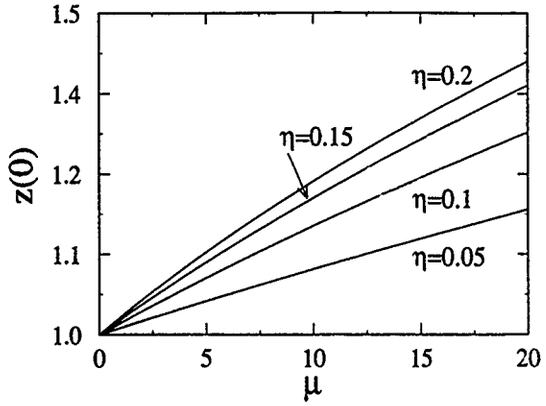

FIG. 3. Maximum excursion of the bounce with dissipation.

$$z(u)=\sum_{j=\pm}\int_{-\infty}^{\infty}z^3(u')R_j e^{-\beta_j|u-u'|}du', \tag{2.14}$$

where

$$\beta_\pm^2=\tfrac{1}{2}(1+\tfrac{1}{2}\mu\eta+\eta^2)\mp\tfrac{1}{2}[(1+\tfrac{1}{2}\mu\eta+\eta^2)^2-4\eta^2]^{1/2},$$
$$R_\pm=(\eta^2-\beta_\pm^2)/\beta_\pm(\beta_-^2-\beta_+^2). \tag{2.15}$$

In a large interesting part of parameter space, we have $\eta\ll 1$, but $\mu\eta$ is arbitrary. In this limit, to leading order in η we have

$$\beta_+=\eta u_b,\quad \beta_-=u_b^{-1},$$
$$R_+=\tfrac{1}{2}\mu\eta^2u_b^2,\quad R_-=u_b, \tag{2.16}$$

where $u_b=(1+\mu\eta/2)^{-1/2}$. From Eqs. (2.14)–(2.16) we see that $z(u)$ varies on two quite different time scales. The short time scale β_-^{-1} and associated amplitude (which is governed by R_-) are both of order unity. The long time scale diverges as $\eta\to 0$, but the amplitude, which is governed by R_+ is $O(\eta)$. In fact we can show that asymptotically, as $u\to\infty$,

$$z(u)\approx z_\infty e^{-\beta_+u};$$
$$z_\infty=2R_+\int_0^\infty z^3(u)\cosh(\beta_+u)du. \tag{2.17}$$

The integral is clearly convergent and of order unity. The approximation B of Ref. 15(a) is obtained by simply neglecting the R_+ term in Eq. (2.14), and using Eq. (2.16) for R_- and β_-.

To solve for $z(u)$ numerically, we iterate Eq. (2.14). [This is better than iterating Eq. (2.12), as $\tilde{z^3}(\omega)$ entails a double integral.] As noted by Chang and Chakravarty,[24] however, one must beware of a dangerous relevant direction in this iteration, but this can be efficiently eliminated following their procedure. At the nth iteration, we insert the solution $z_n(u)$ on the right-hand side of Eq. (2.14) and multiply it by a parameter λ_n to get $z_{n+1}(u)$. The only difference with Ref. 24 is that we must choose $\lambda_{n+1}=\lambda_n\xi^{-3}$, where $\xi=z_{n+1}(0)/z_n(0)$. Once the pair $[\lambda_j,z_j(u)]$ has converged, we scale to $\lambda=1$ via the equation $z(u)=\lambda_j^{1/2}z_j(u)$.

In Fig. 2 we show the calculated multiplicative correction to the nondissipative action $[S/S_0=3b(\mu,\eta)/4]$. The dashed lines are the upper bounds from the method of Ref. 17(b). In Fig. 3, we plot the maximum value $z(0)$, which, multiplied by $2\epsilon^{1/2}$ gives the typical exit angle with dissipation. By choosing different meshes for integrating Eq. (2.14) and different points beyond which the asymptotic form (2.17) is employed, we estimate that our numerics are accurate to about 1%.

As an illustration, for $\mu=10$ and $\eta=0.1$, $S/S_0=1.65$, and so if $S_0/\hbar$ were 25, the escape rate would be reduced by the rather large factor of $10^{-7.0}$. In the author's opinion, the best hope for seeing MQT lies in using materials—natural or isotopically enriched—with few nuclear moments, for which $\mu\approx 0.1$. If $\mu\eta\ll 1$, a useful formula is $S/S_0\approx 1+3\mu\eta/4$.

III. NUCLEAR SPINS AND MQC

The setup for MQC[15(b)] is the same as that for MQT, except that now there is no external field. In other words, we consider an isolated, insulating, ferro- or antiferromagnetic (FM or AFM) particle at nearly zero temperature, with $N_e\lesssim 10^4$ atomic moments. Suppose anisotropy (crystal and/or shape) creates an easy direction for $\mathbf{M}$ or the Néel vector $\hat{l}$. If there are no external fields, time reversal invariance ensures that the opposite direction is also easy, and resonance between these directions then becomes a possibility. We look at this phenomenon in this section.

The tunnel splitting Δ for a potential such as that labeled MQC in Fig. 1 is generically given in terms of the barrier height U and the small oscillation frequency ω_0 by a WKB formula like that for the escape rate: $\Delta\sim\hbar\omega_0\exp(-cU/\hbar\omega_0)$. Since ω_0 for AFM resonance is generally higher than that for FM resonance, we will get bigger Δ's with AFM particles.[11] We will therefore couch our discussion in terms of AFM particles, although it can be trivially altered to fit the FM case. A significant point, as noted by Barbara and Chudnovsky,[11(a)] is that in the AFM case, due to finiteness of the particle, the number of spins on the two sublattices (in the simplest case) will not be equal, and the particle will have a net moment $\mathbf{M}$. We expect $\mathbf{M}$ to follow $\hat{l}$ adiabati-

cally, and MQC could be detected by measuring the ac susceptibility χ'', which is related by standard formulas to the correlation function

$$C(t)=\langle \mathbf{M}(t)\cdot\mathbf{M}(0)\rangle = M_0^2\langle \hat{l}(t)\cdot\hat{l}(0)\rangle. \tag{3.1}$$

As noted in Sec. I, Awschalom *et al.*[18] claim to have seen just such MQC in particles of ferritin, an iron storage protein[25] in the form of a hollow shell of 75 Å inner diameter, that can be filled with an inorganic compound close in composition and structure to ferrihydrite or hydrated α-Fe_2O_3. This core is believed to be antiferromagnetic, and Awschalom *et al.* ascribe the peak in their χ'' to resonance of the Néel vector. Some relevant parameters as given by them are as follows: The sample has $N_g=38\,000$ ferritin particles, each containing $N_e=4500$ Fe^{3+} ions, of which 43 are uncompensated, giving $M_0=|\mathbf{M}|=217\ \mu_B$. At $T=29.5$ mK, the resonance frequency is $\nu_r=\Delta/h=940$ Hz, the peak susceptibility $\chi''(\nu_r)=3.8\times10^{-11}$ emu/G, the full width at half maximum intensity (FWHM) is $\simeq$50 kHz, and the ac field used to see the resonance is $H_{ac}=10^{-5}$ G.

We consider a two-sublattice uniaxially anisotropic antiferromagnetic particle with N_e atomic moments or spins, each of magnitude s. Denoting the spin directions on the sublattices by unit vectors $\hat{\mathbf{n}}_1$ and $\hat{\mathbf{n}}_2$, we have the obvious hamiltonian[11(b),26,27]

$$\mathscr{H}_e=J\hat{\mathbf{n}}_1\cdot\hat{\mathbf{n}}_2-K(\hat{\mathbf{n}}_{1z}^2+\hat{\mathbf{n}}_{2z}^2), \tag{3.2}$$

where $J\gg K>0$. (We will use the subscripts e and n to denote electronic and nuclear spin quantities.) By integrating out[11(b)] $\mathbf{M}\propto(\hat{\mathbf{n}}_1+\hat{\mathbf{n}}_2)$ we get the following Euclidean action for $\hat{l}$:

$$S_0[\hat{l}(\tau)]=\frac{N_e^2s^2}{8J}\int(\dot{\theta}^2+\sin^2\theta\,\dot{\phi}^2)+2K\int\sin^2\theta, \tag{3.3}$$

where θ and ϕ are the polar angles of $\hat{l}$. Standard instanton or WKB methods[11,26] give the tunnel splitting as $\Delta_0=(\hbar\omega_e/\pi)e^{-B}$, where $\omega_e=4(JK)^{1/2}/N_es$ is the AFM resonance frequency, and $B=2N_es(K/J)^{1/2}$ is the action for one instanton. Note that ω_e^{-1} is the instanton width or the "time spent under the barrier." For typical values of J and K, $\omega_e/2\pi\sim10^{11}$–10^{13} Hz. Even for a weak ferromagnet such as α-Fe_2O_3, $\omega_e/2\pi\sim10$ GHz. Because the WKB exponent $B\propto N_e$, Δ will be unlikely to exceed a few MHz if $N_e\gtrsim5000$.

Next, as in Sec. II, let N_n of the magnetic ions have magnetic nuclei. The total interaction Hamiltonian is the same as Eq. (2.5):

$$\mathscr{H}_{en}=-A\sum_{i=1}^{N_n}\mathbf{I}_i\cdot\mathbf{s}_i. \tag{3.4}$$

For simplicity we consider only $I=1/2$. For ferritin, the relevant nucleus is ^{57}Fe, I *is* 1/2, and Mössbauer data[25] give a hyperfine field of 50 T, a typical value for magnetic ions.[22] This yields $\omega_n=As/\hbar=(2\pi)68.5$ MHz. We thus have three well separated frequency scales in the problem: $\omega_e\gg\omega_n\gg\Delta_0/\hbar$.

Because $\omega_e\gg\omega_n$, the nuclear spins are essentially static during the time it takes for $\hat{l}$ to tunnel, and they act almost like a c-number external field. If we map our system onto an equivalent pseudospin 1/2, with the states $|\hat{l}\|\pm\hat{z}\rangle\rightarrow|\pm\rangle$, Eq. (3.2) becomes the tunneling term $\Delta_0\sigma_x$. Equation (3.4) is equivalent to a magnetic field along the z axis proportional to the nuclear polarization $p=2\Sigma_k\zeta_kI_k^z$, where $\zeta_k=\pm1$ depending on the sublattice, and the total Hamiltonian becomes

$$\mathscr{H}_0=\Delta_0\sigma_x/2-\hbar\omega_np\sigma_z/2. \tag{3.5}$$

Since $\omega_n\gg\Delta_0$ and since p changes in steps of unity, it follows that there is negligible mixing between $|+\rangle$ and $|-\rangle$ unless $p=0$. To put it another way, suppose $p\neq0$ and $\hat{l}\|\hat{\mathbf{z}}$ initially. If $\hat{l}$ were to now switch to $-\hat{\mathbf{z}}$, Eq. (3.4) implies that the energy of the nuclei (and hence the total system) would change by $Asp=p\hbar\omega_n\gg\Delta_0$. Since resonance occurs only between nearly degenerate states, we must have $p=0$.

Thus, unlike an ohmic bath, the main effect of nuclear spins is not to renormalize Δ_0. Instead, the amplitude of $C(t)$ is reduced from its non dissipative value (which we shall calculate below) by f_0, the probability for having $p=0$:

$$f_0=(2\pi N_n)^{-1/2}[\cosh(\beta\hbar\omega_n/2)]^{-N_n}, \tag{3.6}$$

where $\beta=1/k_BT$. Since f_0 decreases rapidly with increasing N_n, it pays to work with an element with almost no nuclear magnetism. For ferritin, although the abundance of ^{57}Fe is 2.25%, giving $N_n=101$, we get $f_0=0.034$ at 29.5 mK and $\omega_n/\gamma_n=50$ T.

To include relaxation we argue that coherence will persist from time 0 to time t only if there are no nuclear T_1 processes in this interval. If the T_1 time for one nuclear spin is T_{1n}, $C(t)$ will decay as the probability for no T_1 processes, i.e., as $\exp(-t/N_nT_{1n})$. With $N_n\simeq100$, T_{1n} must be of order a few seconds for the resonance to be observable.

[What about a state with $p\neq0$? Such a state can resonate only if at least p nuclear spins flip along with $\hat{l}$. The frequency for this can be shown[15(b)] to be of order $\Delta_0N_n^{p/2}(\omega_n/\omega_e)^p\ll\Delta_0$. This resonance also decays as $\exp(-t/N_nT_{1n})$, so most of the spectral weight in χ'' is shifted into a broad background near $\omega=0$.]

We now find χ'' and the resonant power absorption. As the ac field $|\mathbf{H}_{ac}(t)|\ll H_a$, the anisotropy field, it cannot cause direct $|+\rangle\leftrightarrow|-\rangle$ transitions. Instead it shifts the $|\pm\rangle$ energies by $\mp M_0H_{ac}^z(t)$. Adding a perturbation term $-M_0H_{ac}^z(t)\sigma_z$ to Eq. (3.5) we obtain a standard NMR Hamiltonian. Introducing T_1 and T_2 for the MQC resonance itself (note that $T_1\neq T_{1n}$), and including the nuclear polarization reduction factor, we get

$$\chi''(\omega)=f_0N_g\frac{\beta\Delta}{\hbar}\frac{M_0^2T_2}{1+(\delta T_2)^2}, \tag{3.7}$$

where δ is the detuning.

From Ref. 18 (see especially the erratum), we have the actual power absorption as $\pi\nu_r\chi''(\nu_r)H_{ac}^2=1.1\times10^{-21}$ W. On the other hand, Eq. (3.7) predicts a peak power of 7.1×10^{-25} W, 1500 times too small. In fact, we have overestimated the expected signal size. First, there is randomness in the angle between $\mathbf{H}_{ac}$ and $\mathbf{M}$'s of different ferritin grains. Then, there are $N_p\simeq8000$ protons per ferritin. If we take the local field at the protons to be about 100 G, which is not unreasonable, the Zeeman splitting is 0.43 MHz, not so different from ν_r. Hence, the net proton spin polarization must

also be quite small for MQC to occur, which reduces χ'' further. [The reduction factor is $11(2\pi N_p)^{-1/2}=0.05$, if we assume that states differing in energy by less than 2Δ can mix, which implies that the proton polarization must be less than 5.] There are simply not enough two-level systems in the MQC interpretation of the data in Ref. 18 to give the large absorption seen. A microscopic interpretation would not suffer from this problem, and seems less remote to the author.[19]

ACKNOWLEDGMENTS

It is a pleasure to thank W. P. Halperin for his sustained interest in this work, and for many useful discussions. This work was supported by the National Science Foundation through Grant Nos. DMR-9102707 and DMR-9306947.

[27] J.-M. Duan and A. Garg (unpublished) have noted that under Eq. (3.2), $\mathbf{M}\cdot\hat{z}$ is rigorously conserved, and to describe its tunneling, one must include transverse anisotropy. Although Eq. (3.2) is seriously limited in its describing experiments, we will still use it here, as the detailed form of the instanton is unimportant; only that $\omega_e \gg \omega_n$ matters.

Evidence for quantum mesoscopic tunneling in rare-earth layers

M. J. O'Shea and P. Perera
Department of Physics, Cardwell Hall, Kansas State University, Manhattan, Kansas 66506-2601

We report on finite size effects and evidence for quantum mesoscopic tunneling (QMT) in thin isolated rare-earth layers prepared in the form of R/Mo multilayers where R represents Tb, Dy, or $Dy_{50}Co_{50}$. The magnetic transition temperature T_c decreases with decreasing magnetic layer thickness and is discussed within a finite size scaling theory. Evidence for QMT is found in magnetic relaxation measurements in these systems with a sharp crossover to a temperature-independent magnetic relaxation regime at low temperatures. The Tb system has a crossover temperature T_0 of 20 K, the largest value reported so far for this crossover.

When magnetic materials are prepared with one or more dimensions close to atomic dimensions, their properties are significantly modified by finite size effects and effects associated with their interface. New phenomena, not seen in the bulk, may also appear. In this work we discuss the properties of ultrathin rare-earth based layers and will show (i) that the transition temperature T_c is depressed in thin layers due to finite size effects[1,2] and (ii) that there is evidence for quantum mesoscopic tunneling[3] via magnetic relaxation measurements. This latter phenomenon is the subject of much current research[3,4] and we find a crossover temperature T_0, below which the magnetic viscosity is temperature independent, of 20 K for the Tb system. This is the highest crossover temperature reported so far.

The systems we report on here are of the form $R(d$ nm)/Mo (18 nm) with at least five bilayers and are prepared by sputtering. R represents Dy, $Dy_{50}Co_{50}$, or Tb. Both Tb and Dy are ferromagnetically ordered at low temperatures,[5] while $Dy_{50}Co_{50}$ is ferrimagnetically ordered.[6] The Mo layer is thick enough that no interactions can occur between neighboring rare-earth layers so that they are magnetically isolated. We have previously reported on the magnetic anisotropy associated with the interface in some of these systems.[7] Examples of x-ray diffractometers using Cu $K\alpha$ radiation at small angles and large angles are shown in Fig. 1 for selected Dy/Mo multilayers. A thinner Mo layer is used for the small-angle diffraction measurement so that the small-angle maxima associated with the bilayer spacing may be seen. The Dy layers are polycrystalline as can be seen from the presence of all the significant large angle peaks associated with the Dy hexagonal structure (peaks in the range 28°–36°). The peak at 41° is associated with the Mo body centered cubic structure. For Dy layer thickness below about 30 nm the crystalline peaks associated with hexagonal Dy become broad indicating structural disorder within the layer. The x-ray diffractograms for the Tb and $Dy_{50}Co_{50}$ systems confirm that they are also layered. While the intralayer structure in Tb is polycrystalline like Dy, the intralayer structure for the $Dy_{50}Co_{50}$ system is amorphous for all layer thicknesses with only a broad maximum in the x ray diffractogram at large angles.

Figure 2 shows field-cooled (FC) and zero-field-cooled (ZFC) magnetizations for selected samples from the Dy series measured with increasing temperature. The applied field is in the plane of the multilayer so that demagnetization effects are negligible. The value of T_c, the magnetic transition temperature, is estimated from the initial rise in magnetization. A Curie–Weiss plot is shown as an inset in Fig. 2 and the Curie–Weiss temperature T_{cw} is determined by extrapolating the high-temperature linear portion of the plot to the temperature axis. Both T_c and T_{cw} agree within experimental error with the bulk values for Dy. Figure 3 shows a plot of T_c versus Dy layer thickness. T_c shows a gradual decrease with decreasing layer thickness and at about 10 nm decreases more rapidly. For systems with no anisotropy, T_c should go to zero in the 2-d limit since it has been shown that no magnetic ordering exists for a 2-d Heisenberg system of spins.[8] Inclusion of anisotropy modifies this result and allows magnetic ordering to occur in 2-d.[9] It is expected from finite size scaling arguments that as the thickness of a magnetic layer is reduced, its transition temperature T_c should show a reduction.[1] Such effects have been seen in some transition metal thin-film systems.[2] The dependence of T_c on film

thickness for thin films is expected to follow the finite size scaling relation[2]:

$$[T_c(\infty)-T_c(n)]/T_c(n)=[(n-n')/n_0]^{-\lambda}, \qquad (1)$$

where $T_c(\infty)$ is the bulk value of T_c and $T_c(n)$ is the value of T_c for a film of thickness n monolayers. n_0 and n' are microscopic lengths of order the size of a unit cell, and λ is an exponent to be determined. This exponent can also be calculated and is ~ 1.5 for a thin film assuming Ising spins.[10] The measurement of λ serves as a test of the finite size model used to calculate it. The solid line of Fig. 3 represents a fit to Eq. (1) using data with $d>5$ nm ($n>17$). The values of λ, n_0, and n' are 1.5, 1.2, and 0.3 nm, respectively (assuming a monolayer is 0.3 nm) with error bars of 20%. The λ is in agreement with the approximate theoretical prediction. The data deviate from the fitted curve at small t most likely because the structure of the layer changes from crystalline to highly disordered as seen in x-ray diffractograms. These fitted values are close to those found for transition metal based thin layers.[2]

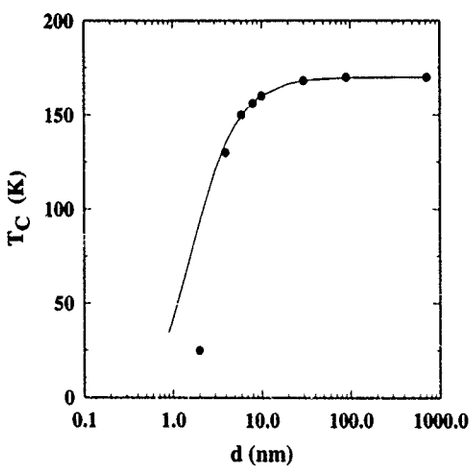

FIG. 3. Magnetic ordering temperature T_c vs magnetic layer thickness for the Dy (d nm)/Mo (18 nm) multilayer series. The solid line represents a curve fit using Eq. (1).

At low enough temperatures quantum tunneling rather than thermal excitation processes are predicted to dominate magnetic reversal. This tunneling process is often referred to as quantum mesoscopic tunneling (QMT) because the number of atomic moments coherently tunneling is inferred to be of order 10^3 in systems studied so far.[4] Magnetic reversal processes involving QMT include magnetic reversal within a single domain and tunneling of a domain wall through a pinning site.[11] These processes are of fundamental interest and are also of practical interest since they may be important in devices of nanometer dimensions.

In our thin films we expect that magnetic reversal is dominated by domain wall movement. Under these circumstances the measured rate of magnetic relaxation when the

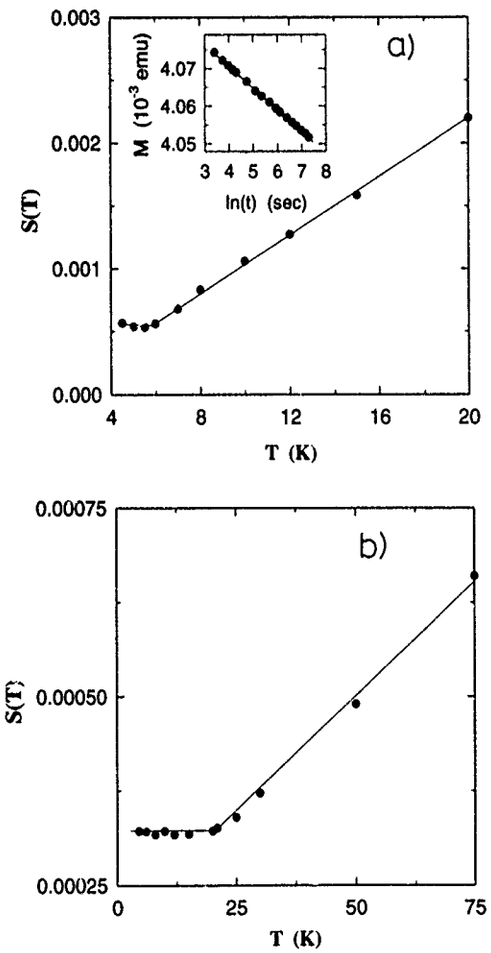

FIG. 4. $S(T)$, the magnetic viscosity, as a function of temperature for (a) Dy (90 nm)/Mo (18 nm) and (b) Tb (77 nm)/Mo (18 nm) multilayers for a measuring field of -100 Oe. The solid lines are guides to the eye. The inset in (a) shows an example of a logarithmic time (t) dependence of magnetization (M) at 8 K. The solid line represents a least-squares fit to the data.

applied field is switched from one value to another should be independent of temperature if domain wall motion occurs by quantum tunneling. We find that the time dependence of magnetization can be parameterized accurately by a logarithmic decay at short times ($<2\times10^3$ s) thus

$$M(t)=M_0[1-S(T)\ \ln(t)]. \tag{2}$$

$S(T)$, the magnetic viscosity, is a measure of the rate of change of magnetization. Both thermal relaxation and tunneling will contribute to $S(T)$. In this experiment the sample is field cooled to a temperature T in an applied field of 1000 Oe. The applied field is then switched to a new value, in our case -100 Oe, and the magnetic relaxation $M(t)$ is measured.

The inset of Fig. 4(a) shows the time dependence of $M(T)$ for the Dy (90 nm)/Mo (18 nm) multilayer at $T=8$ K and as can be seen it conforms to a logarithmic dependence on time. $S(T)=(1/M_0)dM/d\ \ln(t)$ is determined from the slope and the solid line in the insert of Fig. 4(a) is a least-squares fit. Figure 4 shows the calculated $S(T)$ from the relaxation measurements as a function of temperature for a Dy and a Tb multilayer. For the Dy multilayer there is a crossover at 6 K to a regime where $S(T)$ is independent of temperature within our experimental error. In the case of the Tb multilayer where we have data over a wide range of temperatures in the temperature-independent regime, it can be seen that the crossover from the temperature dependent to temperature-independent region is sharp within the accuracy of our experiment. This sharpness, expected from QMT if dissipation is not important, together with the temperature-independent $S(T)$ is strong evidence in favor of a QMT interpretation of these results in these systems.

There is a large difference in the crossover temperatures T_0 for the Tb and the Dy system with Tb, at 20 K, being considerably larger than Dy at 6 K. We note that while we have considered a QMT interpretation of these results, theoretical estimates in the limit of large anisotropy predict T_0 should be proportional to the atomic moment and the square root of the product of the planar and c-axis anisotropy.[11] For Dy and Tb the c-axis anisotropies are 5×10^8 and 5.5×10^8 ergs/cc, respectively, and the planar anisotropies are 7.5×10^6 and 2.4×10^6 ergs/cc, respectively.[12] Since the magnetic moments of Tb and Dy are within 8% of each other this simple model suggests that Dy should have a higher T_0 and Tb and so is unable to explain the large value of T_0 for Tb compared to Dy. We are currently preparing other anisotropic elemental rare earths in layer form to determine if any correlation exists between the microscopic magnetic anisotropy and the measured T_0.

Bloch states of a Bloch wall

Hans-Benjamin Braun and Daniel Loss
Department of Physics, Simon Fraser University, Burnaby, British Columbia V5A 1S6, Canada

Bloch walls in mesoscopic ferromagnets can tunnel between periodically arranged pinning sites leading to a Bloch band. The quantum spin phase gives rise to a spin parity dependent shift in the dispersion. Static external magnetic fields induce magnetization oscillations and provide a magnetic analogue of the Josephson effect.

The possibility of macroscopic quantum tunneling in small magnetic particle has attracted much interest both theoretically[1,2] and experimentally.[3,4] Susceptibility measurements[4] on small antiferromagnetic grains of diameter $\simeq 70$ Å have shown coherent quantum tunneling of the sublattice magnetization through an anisotropy barrier. On the other hand, ferromagnetic domain walls exhibit a high mobility and low coercivities, facts that renders them suitable candidates for displaying macroscopic quantum phenomena (MQP). It has been proposed[5] that domain walls can collectively tunnel out of a single pinning potential by applying an external magnetic field.

In this paper we focus on another possible manifestation of MQP: the coherent tunneling of a Bloch wall between periodically arranged pinning centers in an insulating ferromagnet. Such pinning centers can be caused by the discreteness of the lattice itself or by a magnetic superlattice created, e.g., by ion substitution. We show that there is a finite tunneling probability of the Bloch wall between pinning sites and that, as a result, the low-energy states will form a Bloch band. The topological term gives rise to a shift in the band structure depending on spin quantum number and pinning separation. We determine the bandwidth and show that the decohering effect of the spin waves is negligible below 100 mK for typical material parameters. In addition we demonstrate that a constant magnetic field induces magnetization oscillations in analogy to Bloch oscillations of a Bloch electron in a uniform electric field. This "magnetic Josephson effect" does not have a classical counterpart and thus provides a unique signature of macroscopic quantum coherence. To observe domain wall tunneling, the wall area has to be small. Thus we consider elongated particles (or ferromagnetic "wires") of length L with a cross-sectional area of about 100 nm^2. For these lateral dimensions and at temperatures of interest, transverse spin waves are completely frozen out and the system behaves effectively one-dimensional.

Consider a Heisenberg Hamiltonian with anisotropies on a simple cubic lattice with lattice constant a

$$\mathcal{H}=-\tilde{J}\sum_{\langle i,j\rangle}\mathbf{S}_i\cdot\mathbf{S}_j-\tilde{K}_y\sum_i (S_i^y)^2+\tilde{K}_z\sum_i (S_i^z)^2, \tag{1}$$

where $\mathbf{S}_i$ is the spin operator at the ith lattice site. The first term describes nearest-neighbor interaction with exchange constant $\tilde{J}$; the next terms represents easy- and hard-axis anisotropies with constants $\tilde{K}_z>\tilde{K}_y>0$. For thin long slabs of materials like YIG, $\tilde{K}_z$ originates from shape anisotropy. For the 1D approximation to hold, the sample should have lateral dimensions smaller than the minimal length scale $a[\tilde{J}/\tilde{K}_z]^{1/2}$. Next, we introduce coherent spin states defined by $\mathbf{\Omega}_i\cdot\mathbf{S}_i|\mathbf{\Omega}_i\rangle=S|\mathbf{\Omega}_i\rangle$, where S is the spin quantum number (units such that $\hbar=1$) and $\mathbf{\Omega}=(\sin\theta\cos\phi,\ \sin\theta\sin\phi,\ \cos\theta)$ is a vector on the unit sphere.

To find the tunneling rate it is appropriate to consider the imaginary time transition amplitude between two coherent state configurations expressed as a path integral,

$$\langle\{\Omega_b\}|e^{-\beta H}|\{\Omega_a\}\rangle=\int\mathcal{D}\phi\mathcal{D}(\cos\theta)e^{-S_E[\phi,\theta]}. \tag{2}$$

The Euclidean action is given by

$$S_E[\phi,\theta]=\int_0^\beta d\tau\int_{-L/2}^{L/2}dx\left[iN_A\frac{S}{a}\partial_\tau\phi(1-\cos\theta)+\mathcal{H}\right], \tag{3}$$

and contains the energy density

$$\mathcal{H}=N_A\{J[\sin^2\theta(\partial_x\phi)^2+(\partial_x\theta)^2]-K_y[\sin^2\theta\sin^2\phi-1]+K_z\cos^2\theta\}, \tag{4}$$

where $J=\tilde{J}S^2a$, $K_{y,z}=\tilde{K}_{y,z}S^2/a$. The first term in the integrand of Eq. (3) arises from the overlap of the coherent spin states at adjacent imaginary time steps. For a single spin and for closed trajectories it has the form of a Berry phase. The term $\propto\cos\theta\partial_\tau\phi$ together with the energy density $\mathcal{H}$ reproduces in saddle point approximation $\delta S_E=0$ the micromagnetic Landau–Lifshitz equations. According to our microscopic derivation, there is an additional term $\propto\partial_\tau\phi$ which, as a total derivative, does not affect the classical equations of motion. However, in quantum mechanics all paths contribute to the transition amplitude Eq. (2) and therefore this term can lead to interference effects.[6]

The Bloch wall

$$\phi_0(x)=-\pi/2+2\tan^{-1}(e^{x/\delta}), \tag{5}$$

is confined to the easy-plane $\theta=\pi/2$ and is a solution of $\delta S_E=0$ which connects two different easy-axis anisotropy minima within the wall width $\delta=\sqrt{J/K_y}$. It is degenerate with all Bloch walls $\phi_0(x-X)$ that arise by a rigid translation by X which have the energy $E_0=4N_A\sqrt{JK_y}$.

We now focus on the decohering influence of the spin waves on the motion of the domain wall. A moving Bloch wall induces scattering between the spin wave states and thus affects the quantum coherence of the system. To investigate this effect quantitatively, we can introduce small fluctuations around the moving Bloch wall and construct an effective action for the Bloch wall position X. For simplicity and since the hard-axis anisotropy is large in high-purity materials such as YIG, we first eliminate the out of easy-plane degree of

 0021-8979/94/76(10)/6177/3/$6.00 © 1994 American Institute of Physics

freedom. Expanding Eq. (3) to second order in $p \equiv \cos\theta - \pi/2$ and performing the resulting Gaussian integrals, the transition amplitude Eq. (2) takes the form $\int \mathscr{D}\phi \exp\{-S_{SG}\}$ with the sine-Gordon (SG) action

$$S_{SG}[\phi] = N_A \int d\tau dx \left[i \frac{S}{a} \partial_\tau \phi + \kappa (\partial_\tau \phi)^2 + J(\partial_x \phi)^2 + K_y \cos^2 \phi \right], \tag{6}$$

including a topological term $\propto \partial \phi$. The elimination of the out of easy-plane fluctuations gives rise to the kinetic term $\kappa(\partial_\tau \phi)^2$ with $\kappa = S^2/(4K_z a^2)$. The action of Eq. (6) correctly reproduces the long-wavelength excitations of Eq. (3) to order $\mathscr{O}(K_y/K_z)$. The "velocity of light" $c \equiv \sqrt{J/\kappa}$ in the SG model is the asymptotic spin wave velocity.

Spin wave fluctuations around the Bloch wall Eq. (5) (which also satisfies $\delta S_{SG} = 0$) are described by

$$\phi(x,\tau) = \phi_0(x - X) + \varphi(x - X, \tau). \tag{7}$$

Here $X(\tau)$ represents the instantaneous position of the Bloch wall. Since a rigid translation of the Bloch wall is already described by the coordinate X in the first term on the rhs of Eq. (7), the spin waves φ do not contain the zero energy "Goldstone mode" $d\phi_0/dx$. Maintaining this constraint, Eq. (7) can be inserted into S_{SG} and the transition amplitude $\int \mathscr{D}\phi \exp\{-S_{SG}\}$ can be brought to a form with X and φ as independent variables. Note that this constraint gives rise to a nontrivial Faddeev–Popov determinant, which, however, leads to a correction of order $O(1/N_A S)$.[8] In contrast to the standard Caldeira–Leggett model which contains a coupling which is linear in both the system and environment variables, the coupling occurs here to second order in the spin wave amplitudes. Nevertheless, we can eliminate the spin waves[8] and obtain the following effective action for the Bloch wall coordinate

$$S_X = \int_0^\beta d\tau \left\{ -i\pi S \frac{N_A}{a} \dot{X} + \frac{M}{2} \dot{X}^2 \right\} + \frac{1}{2} \int_0^\beta d\tau \int_0^\tau d\sigma K(\tau - \sigma)[X(\tau) - X(\sigma)]^2. \tag{8}$$

The first term is the topological term while the second term is the kinetic energy of the Bloch wall where $M = 4N_A \kappa/\delta$ is the Döring mass. The third term is the damping term due to the scattering of spin waves. For low temperatures, the damping kernel takes the Caldeira–Leggett form $K(\tau) = (1/\pi)\int_0^\infty d\omega J(\omega) D_\omega(\tau)$ with $D_\omega(\tau) = e^{-\omega|\tau|}$. The spectral function is given by $J(\omega) = (\omega/2\delta c)\Theta(\omega - 2c/\delta)\sqrt{\omega^2 - (2c/\delta)^2}$ and reflects the anisotropy gap of the spin wave excitations. Thus the damping effect of the spin waves can indeed be treated within a Caldeira–Leggett model although the underlying microscopic coupling involves term which is second order in the magnons (see also Appendix C of Ref. 7).

As we shall see below, the characteristic time scale of X is much larger than the decay time $\tau_c = \delta/(2c)$ of the damping kernel. In this case damping leads to a small renormalization of the Döring mass of the order $O(1/N_A S)$ and shall therefore be neglected henceforth.

We now turn to the tunneling of a Bloch wall in a periodic array of pinning sites with distance d that is assumed to be an integral multiple of a. Such pinning sites can be incorporated into the action (6) by substituting K_y with the term $K_y - K_v \Sigma_n \delta(x - nd)$. If the domain wall center (at which the easy-axis anisotropy is maximally frustrated) coincides with one of these pinning sites, the energy will be lowered and the domain wall becomes pinned. Then inserting Eq. (7) with Eq. (5) into this new action and assuming that $d \ll \delta$, we recognize that pinning can be described by adding the potential $2V_0 \int d\tau \sin^2(\pi X/d)$ to Eq. (8). The resulting action is now equivalent to the action of a single particle in a periodic potential, e.g., like an electron in a crystal potential. The topological term then plays the role of the electromagnetic gauge potential. Performing an instanton calculation[9] we can then extract the dispersion relation for Bloch wall states

$$\epsilon(k) = -\Delta/2 \cos(kd + \pi S N_A d/a), \tag{9}$$

where the bandwidth is given by $\Delta = 4\omega_I \sqrt{S_0/2\pi} \times \exp(-S_0)$ with instanton action $S_0 = (4/\pi) d\sqrt{V_0 M}$ and frequency $\omega_I = (2\pi/d)\sqrt{V_0/M}$. The topological phase thus induces a shift in the dispersion by $\pi S N_A d/a$.

To give some quantitative estimates of this effect we consider material parameters (at $T = 0$) of YIG: $J = 1.65 \times 10^{-21}$ erg cm, $K_y = 9.61 \times 10^{-11}$ erg/cm, where a cell with lattice constant $a = 6.2$ Å contains one $S = 5/2$ spin implying a saturation magnetization of $M_0 = 194$ Oe (i.e., $K_z = 2\pi M_0^2 a^2 = 9.1 \times 10^{-10}$ erg/cm), wall width $\delta = 414$ Å, and spin wave velocity $c = 6 \times 10^4$ cm/s.

An external field in the direction of the easy axis induces a Zeeman coupling term $-2\mathscr{A} M_0 H_{ext} X$ which has to be added to the action Eq. (8). The potential strength is related to the coercivity H_c, at which the barrier vanishes, via $V_0/\mathscr{A} = M_0 H_c d/\pi$. If we choose $d = 3a$ and $H_c = 2$ Oe, we have $\omega_I = 1.45 \times 10^{10}$ s^{-1}, and $|\dot{X}/c| \leq 2\omega_I \tau_c d/\pi\delta \simeq 2 \times 10^{-2}$. For $N_A \simeq 260$, the domain wall contains $N_A \delta/a \simeq 1.7 \times 10^4$ tunneling spins, and the bandwidth is $\Delta/\hbar = 5 \times 10^5$ s^{-1}. For $d = a$, the bandwidth becomes $\Delta/\hbar = 6 \times 10^9$ s^{-1}.

Next, we address some striking experimental consequences resulting from this Bloch band structure: Bloch oscillations and the magnetic equivalent of the Josephson effect where a constant external magnetic field H along the easy axis induces an oscillatory magnetization.

Let us recall that the effective behavior of the domain wall in the presence of a periodic pinning array corresponds to the behavior of a single Bloch particle in the presence of a periodic potential and can be described by an effective Hamiltonian, $P^2/2M + 2V_0 \sin^2(\pi X/d)$, where P is the momentum operator conjugate to the wall position X, and V_0 is given above. We choose $d = 3a$ and for simplicity we assume $SN_A d/a$ to be an even integer and thus drop the topological term. The corresponding kinetic energy of the unperturbed ($V_0 = 0$) Bloch particle at the zone boundaries, $k = \pm \pi/d$, is given by $\epsilon_0 = (\hbar^2/2M)(\pi/d)^2 = 10$ mK k_B, for the particular parameter values chosen above for YIG. Thus we find that $\epsilon_0/V_0 = 0.06$, and hence we are in the tight binding limit (as

opposed to the nearly free limit) where the Bloch particle is strongly localized around the potential minima, and with band structure Eq. (9). The lowest band gap E_G is of the order of $\sqrt{2\epsilon_0 V_0} = 0.35V_0$, and thus much larger than the band width Δ, since $\Delta/V_0 = 2.5\times10^{-5}$. Next we consider a dynamic situation and apply to the sample an external magnetic field with H the component along the easy axis. This field drives the domain wall via the Zeeman term, $FX = 2\mathcal{A}M_0HX$. From the standard semiclassical equation of motions for a Bloch particle,[8,10] given by

$$v = \frac{1}{\hbar}\frac{\partial \epsilon}{\partial k} = v_0 \sin[k(t)d],$$

where $v_0 = \Delta d/(2\hbar)$, and $\hbar\dot{k} = F$, we then find that for constant H the domain wall position $X(t)$ performs Bloch oscillations of amplitude $\delta X = \Delta/F$ and Bloch frequency $\omega_B = Fd/\hbar$. These Bloch oscillations result then in oscillations of the magnetization along the easy axis, with amplitude $\delta M = 2N_A g\mu_B(S/a)\delta X$, and with the same Bloch frequency ω_B. Let us now give some illustrative numbers for the set of values $(H, \omega_B, \delta X, \delta M)$: $A = (2\times10^{-5}$ Oe, 5×10^6 s^{-1}, $a = 6.2$ Å, 2600 μ_B), $B = (10^{-5}$ Oe, 5×10^5 s^{-1}, $d = 3a = 18.6$ Å, 7800 μ_B), $C = (7\times10^{-7}$ Oe, 2×10^4 s^{-1}, $\delta = 414$ Å, 2×10^5 μ_B), and $D = (10^{-10}$ Oe, 8 s^{-1}, 0.2 mm, 10^9 μ_B). Thus we see that the smaller the applied field, the larger is the oscillatory response, clearly a striking and unique quantum signature without classical counterpart. Note that these Bloch oscillations are the magnetic analogue of the Josephson effect: a driving constant field (H) results in an oscillatory response (magnetization). Moreover, if the external field is oscillatory in time we expect to see resonance effects in the magnetization.

Very similar to recent experiments on magnetic grains,[4] observations could be performed on ensembles consisting of many identical particles (say 10–100 for case B), by using superconducting quantum interference device (SQUID) magnetometers. If the particles are well separated, the Bloch oscillations are independent and in phase. Thus the magnetization oscillations add up coherently irrespective of the individual easy-axis orientations. To minimize a broadening of the Bloch period the spread of the particle size distribution should be small.

We emphasize that for the above field values Zener interband transitions can be safely ignored even for astronomically long observation times. Indeed, the Zener tunneling probability is given by $P = e^{-A}$, with WKB exponent $A = \pi^2 E_G^2/(4\epsilon_0 Fd) > 8\times10^4$, if $H < 4\times10^{-5}$ Oe, and thus $\omega_B P$ is virtually zero for the above values. Zener transitions occur when P becomes of order one, i.e., $H \approx H_c = 2$ Oe; in this case the Bloch oscillations vanish and the domain wall runs down the pinning "washboard potential."

Finally, preliminary theoretical results[8] suggest that the presence of dissipative effects due to magnons and phonons is negligible also for the dynamics of Bloch oscillations. The fact that damping can be expected to be weak is also supported by the recent observation of macroscopic quantum coherence in small magnetic grains over very long times.[4]

A short review is made of the key magnetic properties of dilute cubic $R_xY_{1-x}Al_2$ (R=Tb, Dy) intermetallics, in order to show their main magnetic features. Dilution by Y introduces a weak random magnetic anisotropy (RMA). The rich magnetic phase diagram is described, including paramagnetic (P), spin glass (SG), correlated spin glass (CSG), random ferromagnetic (RFM), and ferromagnetic (F) phases, with a triple point and two multicritical ones. The paper deals with the induced macroscopic magnetic anisotropy cooling in a magnetic field below T_{SG} or T_{CSG} transition temperatures, which can be either unidirectional or uniaxial or both. High-field (3 T) magnetostriction in Tb series shows, for x=0.48, 0.59, 0.87, a decrease of the Callen α exponent ($\lambda_t \sim m^{\alpha}$, m=reduced magnetization) below 3. The Sompolinsky irreversibility parameter Δ has been determined for the Tb series in the SG regime, and a replica model is presented to explain the $\Delta(T)$ dependence. The character of the P→SG or P→CSG transitions is addressed, through the scaling of nonlinear susceptibility (SG regime) or a ferromagnetic-like scaling of magnetization, respectively. From quasielastic neutron scattering around $\mathbf{Q}$=[1,1,1] we determine the temperature dependence of the magnetic correlation length in $Dy_{0.8}Y_{0.2}Al_2$, which peaks, but does not diverge at T_c. A magnon excitation at 3.5 meV is reported for x=0.8.

I. INTRODUCTION

$R_xY_{1-x}Al_2$ (R=Dy, Tb) are *crystalline* cubic Laves phase compounds. We have extensively studied their magnetic properties using as probes: low- and high-field magnetization, ac magnetic susceptibility, ferromagnetic-like scalings, law of approach to saturation,[1] Arrott plots, observation of transition lines, existence of Edwards–Anderson (EA) parameter,[2] hysteresis,[3] magnetic anisotropy measurements,[4] Bragg and small-angle neutron scattering (SANS),[5] and magnetostriction.[6] These measurements have revealed the compounds as *weak* random magnetic anisotropy (RMA) systems, exhibiting a very rich variety of magnetic phases and transitions,[7] likely never observed together in a RMA system. Of the possible origins for the RMA, the most likely is the strong magnetoelastic coupling, because of the local strains introduced by the Y^{3+} substitutions.[1] In Fig. 1 we show the magnetic phase diagrams (MPD) for the Dy and Tb series. The Dy system exhibits paramagnetic (P), spin glass (SG), and correlated spin glass (CSG) phases, with a triple point (TP) at x_{tr}=0.30.[1] At 0 K a first-order transition from CSG to ferromagnet (FM), driven by coherent cubic anisotropy, is observed at x_t=0.62, remaining up to x_t' = 0.87, where the FM phase extends up to the line boundary FM-P, with a tricritical point at T_t' = 45.4 K.[7] At x_t=0.62, a boundary between CSG and a quasiferromagnetic or random ferromagnetic phase (RFM) appears, with an ending tricritical point at T_t=29.5 K. For $x>x_t$ the line of transitions RFM-P shows a crossover exponent ϕ_Δ=0.80±0.08.[7] Law of approach to saturation allows an estimation of D/J_0, e.g., ≈0.04 for x=0.83, between the strength of the random crystal field (CEF) D, and the *positive* exchange interaction J_0 according to positive paramagnetic Curie temperature θ. An increase of such ratio with decreasing x is likely.[1,7] The MPD of $Tb_xY_{1-x}Al_2$ has not been yet explored in such detail, only up to x=0.50, showing P, SG, CSG phases (see Fig. 1), with a TP at x_{tr}=0.27, T_{tr}=8.6 K.[8]

The aim of this paper is to present the magnetic properties of the RMA system $R_xY_{1-x}Al_2$ (Dy, Tb), showing some previous work and adding new results recently obtained. In particular: the field-induced macroscopic anisotropy in $Dy_xY_{1-x}Al_2$, together with rotational hysteresis found (Sec. II); CEF origin magnetostriction, showing that in Callen's[9] mp law in $Tb_xY_{1-x}Al_2$, $p<3$ (Sec. III); the Sompolinsky[10] irreversibility order parameter Δ in Tb series (Sec. IV); aspects of the critical behavior at the P-SG and P-CSG transitions in Tb series, from magnetization measurements, together with neutron scattering around T_C (P→CSG or RFM)

in the Dy series, and the magnetic correlation length temperature dependence. The amount of work reported is large, and the presentation is succinct.

II. FIELD-INDUCED MACROSCOPIC ANISOTROPY AND ROTATIONAL HYSTERESIS

We will address three points: the symmetry of the field-induced macroscopic anisotropy (FIMA), the rotational hysteresis of anisotropy torque, and the differences in the torque curve symmetries, when cooling above or below the coercive field. The samples were single crystals of $Dy_xY_{1-x}Al_2$ (x =0.3, 0.4, 0.6), i.e., at the CSG phase. The anisotropy torque L_k was measured from the magnetization perpendicular to the rotating magnetic field **B** on plane (110), because $L_k=M_\perp B$. A complication is the coherent cubic anisotropy (CA), which was averaged out by measuring in fields so weak as to have the crystals divided in six ⟨100⟩ domains, so that $\langle \mathbf{M}_s\rangle=0$, for the sample average spontaneous magnetization. We developed[4] a model, based on Henley *et al.* and Saslow[11] ones, which predicts the appearance of FIMA anisotropy both unidirectional (UD) and uniaxial (UA). Starting with the Hamiltonian,

$$H=J_0\sum_{\substack{\alpha,\beta\\ i<j}} S_i^\alpha S_j^\beta+D\sum_{i,\alpha}(\hat{a}_i^\alpha S_i^\alpha)^2, \tag{2.1}$$

where $\hat{a}_i$ are the local RMA easy axes (EA), i stands for sites, and α for spin components. It is possible to show[4] from Eq. (2.1) that the FIMA energy becomes,

$$E_k^{\mathrm{RMA}}=-K_{\mathrm{RMA}}\cos\theta-2K_{\mathrm{RMA}}\cos^2\theta, \tag{2.2}$$

with $K_{\mathrm{RMA}}=(4/15)N(D^2/J_0)$ (N, ion number per unit volume). To this energy me must add the CA, so the total anisotropy torque becomes

$$\Gamma(\theta)=-K_{\mathrm{RMA}}(\sin\theta+2\sin 2\theta)-(K_1/4+K_2/64)$$
$$\times\sin 2\theta-(3K_1/8+K_2/16)\sin 4\theta+\cdots, \tag{2.3}$$

where K_1, K_2 are CA constants, about 10^3 higher than K_{RMA}.

We did two experiments: cooling in the low measuring field, H_m and cooling in a larger field $H_{\mathrm{FC}}>1$ kOe and measuring in the lower one ($\mathbf{H}_{\mathrm{FC}}\|\langle 100\rangle$, easy axis). In addition H_{FC} can be larger or smaller than the coercive field H_c,[1,2] which makes two different situations. The magnetization will be $\mathbf{M}=\chi\mathbf{H}+\mathbf{M}_r$, where χ is the isotropic cubic susceptibility and $\mathbf{M}_r$, the remanent magnetization after FC, which can be a complicated object. (i) We first address the case when both UD and UA FIMA's have been produced. In Fig. 2(a) we show the torque curves for x=0.30, 0.40 below T_C for FC and H_m=0.25 kOe, above H_c. At this field, K_1 and K_2 are very small. Fourier analysis of Γ shows $\sin\theta$ and $\sin 2\theta$ components, indicating the presence of both anisotropies, although for x=0.4 the the UD character is stronger. Extrapolation to H_m=0 of $K_{\mathrm{RMA}}(H_m)$ obtained from the $\Gamma(\theta)\sin\theta$ component amounts to 127 and 225 J/m^3, respectively, at 3.8 K. We notice that the Γ_2 coefficient (of $\sin 2\theta$) is not $2\Gamma_1$ (of $\sin\theta$), because of the CA contamination, which practically disappears below ≅0.70 kOe. In fact a combined plot of $\Gamma_2-2\Gamma_1$ and $(K_1/4+K_2/64)$ gives a linear relation, extrapolating to zero. Model Eq. (2.2) has thus been established. Notice the existence of a constant torque Γ_0 whose origin should be a $\mathbf{M}_r$ component, rotating in phase with **H**, limited by the shortest spin relaxation times. (ii) A second point is that there is a crossover from $H_m<H_c$ to $H_m>H_c$, i.e., from unidirectional plus uniaxial FIMA's to unidirectional alone [π and 2π periods in $\Gamma(\varphi)$ curves, respectively, where φ in the rotating field angle]. These experiments were done with $H_{\mathrm{FC}}\gg H_c$. This is shown in Fig. 2(b) for x=0.6, where H_c=0.39 kOe at T=3.8 K and H_{FC}=3 kOe, in going from H_m=0.23 to 1.0 kOe. The same behavior is observed for the other concentrations. In the first situation ($H_m<H_c$), $\mathbf{M}_r$ remains fixed along ⟨100⟩ cooling direction, whereas in the

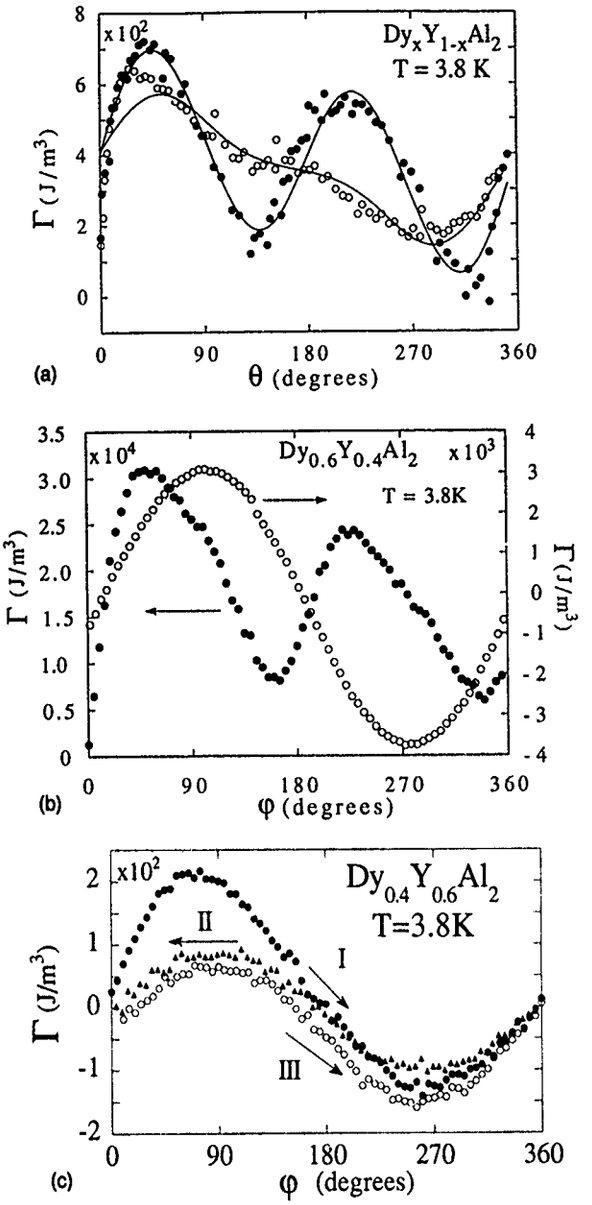

FIG. 2. (a) Magnetic anisotropy torque vs θ angle curves for $Dy_xY_{1-x}Al_2$: x=0.30, (●); x=0.40 (○). The full lines are the theoretical fits, according to Eq. (2.3). (b) Torque curves vs φ angle for $Dy_{0.60}Y_{0.40}Al_2$, for applied fields: (○) 0.23 kOe, (●) 1.0 kOe. The cooling field was 3 kOe (see meaning of φ in text). (c) Torque curves vs φ angle for $Dy_{0.40}Y_{0.60}Al_2$ for applied field 80 Oe. The arrows show the sense of successive rotations. The cooling field was 1 kOe.

second one $\mathbf{M}_r$ splits in three components: one fixed to $\langle 100\rangle$ (Γ_1 torque), a rotating one out of phase with $\mathbf{H}$ (Γ_2 torque), and one at a constant angle with $\mathbf{H}$ (Γ_0 torque), due to the mechanism suggested.

From K_{RMA} one obtains D^2/J_0 (=0.007 and 0.01 K for x=0.3 and 0.4, respectively), which allows a *separate* estimation of D and J_0. Since we found above that $D/J_0 \cong 0.04$, we now have $D \cong 0.2$ K and $J_0 \cong 5$ K. (iii) We now consider the rotational hysteresis, which suggests metastable states in these RMA systems. In Fig. 2(c) we notice, for x=0.4, H_{FC}=1 kOe and H_m=0.080 kOe, at 3.8 K, a strong hysteresis (φ=0 to π) between the first clockwise rotation and the second counterclockwise rotation, the hysteresis disappearing afterwards. An explanation for the transient in the initial $L_k(\varphi)$ curve is that the spins with the shortest relaxation times easily follow the field, the slowest ones following it later on (curves II and III). The hysteresis increases strongly when $H_m > H_c$, as expected. Similar behavior is found for the other concentrations.

III. MAGNETOSTRICTION: VIOLATION OF m^3 LAW

It has been predicted[12] that when the local RMA field satisfies $H_{\mathrm{RMA}} > H$, but $H \ll H_{\mathrm{ex}}$ (H and H_{ex} are the applied and exchange fields, respectively), so one is in the ferromagnet with wandering axis regime (FWA),[13] that noticeable deviations from the Callen and Callen[9] law for CEF-origin shape magnetostriction λ_t are expected: $\lambda_t \sim m^p$, with $p<3$, $m=M(T)/M(0)$ being the reduced magnetization. It can be shown that[12]

$$\frac{\lambda_t(T)}{\lambda_t(0)} = \frac{\langle\langle O_2^0(\mathbf{J})\rangle\rangle_c}{\langle O_2^0(\mathbf{J})\rangle_c}, \quad \frac{M(T)}{M(0)} = \frac{\langle\langle O_1^0\rangle\rangle_c}{\langle O_1^0\rangle_c}, \tag{3.1}$$

where O_2^0 and O_1^0 are Stevens operators, functions of the angular momentum $\mathbf{J}$, $\langle\cdots\rangle$ is the thermal average and $\langle\cdots\rangle_c$ is the average over the local easy axis disorder. For large J, we express O_n^0 in terms of site spin wave (sw) deviation operators, a, a^+, but introducing c and c^+ numbers representing the static spin deviations, writing $a=(1+u)\alpha+v\alpha^++c$, where the (u,v) numbers account for sw scattering by the RMA disorder, and α are Bose operators. Then it can be shown that in the FWA regime, where sw are proper:

$$\frac{M(T)}{M(0)} = \frac{1-J^{-1}\langle\langle a^+a\rangle\rangle_c}{1-J^{-1}\{\langle cc^+\rangle_c+\langle v^2\rangle_c\}},$$

and

$$\langle\langle O_{20}(T)\rangle\rangle_c = 3J^2-J(J+1)-3(2J-1)\langle\langle a^+a\rangle\rangle_c + 6J^2[1-m(T)]^2,$$

with $m(T)=\langle\langle J_z\rangle\rangle_c/J$. Combining the above four equations gives[12]

$$\frac{\lambda_t(T)}{\lambda_t(0)} = \left[\frac{M(T)}{M(0)}\right]^p, \tag{3.2}$$

where

$$p = \frac{3[J(2J-1)-6\delta J+\delta(1+4\delta)]}{[J(2J-1)-6\delta J+3\delta(1+2\delta)]},$$

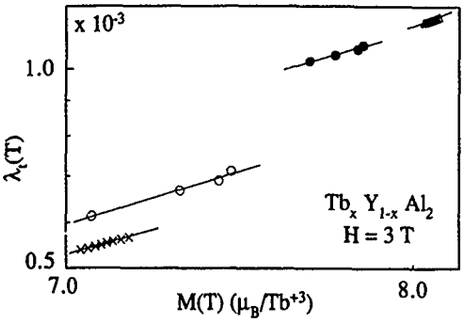

FIG. 3. Double logarithmic plots of magnetostriction $\lambda_t(T)$ vs $M(T)$, at H=3 T, and for $T<20$ K, for $Tb_xY_{1-x}Al_2$, for x=0.49 (x), 0.60 (○), 0.87 (●), and 1(Δ) compounds. The slopes give the exponent p [see Eq. (3.2)].

with $\delta=J[1-m(0)]$, proportional to the RMA disorder 0 K magnetization quantum defect $\Delta(0)=1-m(0)$. The important result is that $p<3$.

We have searched for this m^3 violation in $Tb_xY_{1-x}Al_2$ (x=0.49, 0.60, and 0.87) compounds, measuring $\lambda_t(T)$ and $M(T)$ up to 12 T, from 1.5 K. In Fig. 3(a) we show low-temperature ($T<20$ K) plots of λ_t vs M at H=3 T, where we can assume $H > H_{\mathrm{RMA}}$. From them we obtain the p values: 2.3 (x=0.49); 2.7 (x=0.60); 2.65 (0.87), smaller than for the good ferromagnet $TbAl_2$, $p=3.0\pm0.1$. As expected, p increases with H, becoming quite close to 3 for H=12 T. Also, from p expression we can evaluate $\Delta(0)$:0.24 (x=0.49); 0.16 (x=0.60); 0.18 (x=0.87). These values are slightly higher than those obtained from the ratio $M(0,H)/Ng J\mu_B$:0.19, 0.16, and 0.12 respectively, this reduction likely being due to the magnetization induced by the strong cubic anisotropy. Notice that the extrapolated 0 K Tb^{3+} magnetic moment in $Tb_xY_{1-x}Al_2$ is unquenched,[14] (9.0±0.3) μ_B, allowing us to take $M(0)=NgJ\mu_B$, i.e., excluding RMA effects.

IV. FC AND ZFC MAGNETIZATION IRREVERSIBILITY: ASSOCIATED ORDER PARAMETER Δ

Our best studied system demonstrating the irreversibility between FC and ZFC magnetizations is Tb, for $0.15 \leqslant x \leqslant 0.50$. The behavior is quite different in the SG and CSG regimes. At CSG regime one observes [Fig. 4(a)] a branching point between FC and ZFC magnetizations at T_C, followed by a broad maximum for the ZFC isofield, both magnetizations rapidly decreasing when approaching T_{SG}. For SG regime, only a branching point is observed coincident with the cusp [Fig. 4(b)]. The $M_{\mathrm{ZFC}}-M_{\mathrm{FC}}$ difference decreases with increasing field, finally merging. Strong relaxation was found for $H \cong H_c$, at the ZFC branch, for both SG and CSG regimes.

The usual order parameter considered for SG systems is that of Edwards–Anderson (EA), q, conveniently redefined[15] for RMA systems. Although useful, there are difficulties with q: it has nonzero value for $T > T_{\mathrm{SG}}$ even at zero applied field, and there are subtle theoretical difficulties with the replica method. Therefore it seems worthwhile to use the FC-ZFC irreversibility to define an additional order parameter, in the way proposed by Sompolinsky[10] using a dynamical model

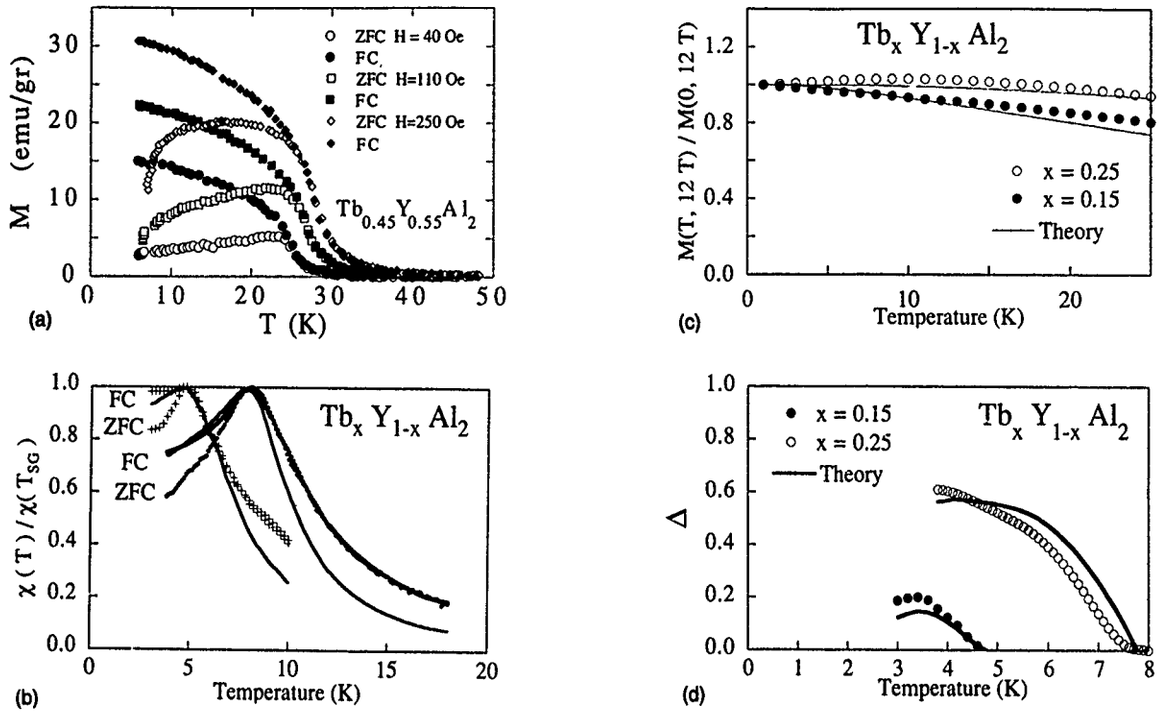

FIG. 4. (a) Field-cool (FC) and zero-field-cool (ZFC) isofield curves for $Tb_{0.45}Y_{0.55}Al_2$ compounds at increasing fields. (b) The same as (a) for $Tb_xY_{1-x}Al_2$: (●), $x=0.25$ at $H=26$ Oe; (+), $x=0.15$ at $H=3.6$ Oe. The full lines are the theoretical calculations for the χ_{FC} susceptibility. (c) Reduced magnetization $M(T,12\,T)/M(0,12\,T)$ for $Tb_xY_{1-x}Al_2$: (●), $x=0.15$; (○), $x=0.25$. The full lines are the theoretical fits (see text for details). (d) Irreversibility order parameter Δ vs temperature for $Tb_xY_{1-x}Al_2$: $x=0.15$ (●), $H=3.6$ Oe; $x=0.25$ (○), $H=26$ Oe (see text for details). The full line is the theoretical calculation.

where time-variable spin noise and time-persistent noise due to RMA are combined with TAP[16] theory. The resulting irreversibility parameter Δ becomes

$$\Delta=\frac{T}{C}(\chi_{FC}-\chi_{ZFC}), \tag{4.1}$$

where χ_{FC} and χ_{ZFC} are low field susceptibilities and C is the Curie constant. The equilibrium χ_{FC} susceptibility is amenable to calculation as (M/H) for very small H(few Oe). We developed a replica-MF model for RMA systems[15] where $M(T,H)=Ng\mu_B\langle\langle J_z\rangle\rangle_c$ has the form

$$\langle\langle J_z\rangle\rangle_c=\int_{-\infty}^{\infty}\frac{dx}{\sqrt{2\pi}}e^{-x^2/2}\frac{\mathrm{Tr}(J_z\exp\{\alpha J_z^2+[\gamma x+\beta\theta(g-1)^2\,m/g+\beta g\mu_B H]J_z\})}{\mathrm{Tr}\exp[\cdots]} \tag{4.2}$$

with $\beta\equiv 1/K_BT$ and $m=M(N\mu_B)^{-1}$. The parameters α and γ depend[15] on the CEF parameter D, on the quadrupolar moment $p=\langle\langle J_z^2\rangle\rangle_c$, and on $q=\langle\langle J_z\rangle^2\rangle_c$. $\theta=zJ_0$ is the paramagnetic Curie temperature, and z is the R^{3+} NN number. Then, to evaluate M, p, and q, we need a knowledge of the parameters J_0 and D. We obtain D from the condition $q(T_{SG},0)=0$ by extrapolation, and we obtain J_0, together with a refinement of D, from a self-consistent calculation of M, q, and p, and fitting $M(T,H)$ to the experiment. In Fig. 4(c) we show the high-field (12 T) measurements of $M(T)$ for $x=0.15$ and 0.25, together with the best theoretical fits. The resulting values were for $x=0.15$, $D=0.5$ K, and $J_0=16$ K ($z=0.6$), and for $x=0.25$, $D=0.7$ K, and $J_0=18$ K ($z=1$). In Fig. 4(d) we present $\Delta(T)$ for both x, at $H=3.6$ and 26 Oe, respectively: note that $\Delta(T_{SG},H)=0$. Figure 4(b) shows $\chi_{FC}(T)$, calculated from Eq. (4.2) for those fields. From Eq. (4.1) we have calculated $\Delta(T)$ for both compounds, the agreement with experiment is reasonably good [Fig. 4(d)].

V. CRITICAL BEHAVIOR, PHASE TRANSITIONS, AND NEUTRON SCATTERING

A still open question is if a RMA spin glass undergoes at T_{SG} a phase transition. The answer can be obtained by a scaling analysis of the nonlinear susceptibility χ_{NL}, which is proportional to the singular component of q.[2,17] Similarly for the CSG or RFM phases one is tempted to see if the magneti-

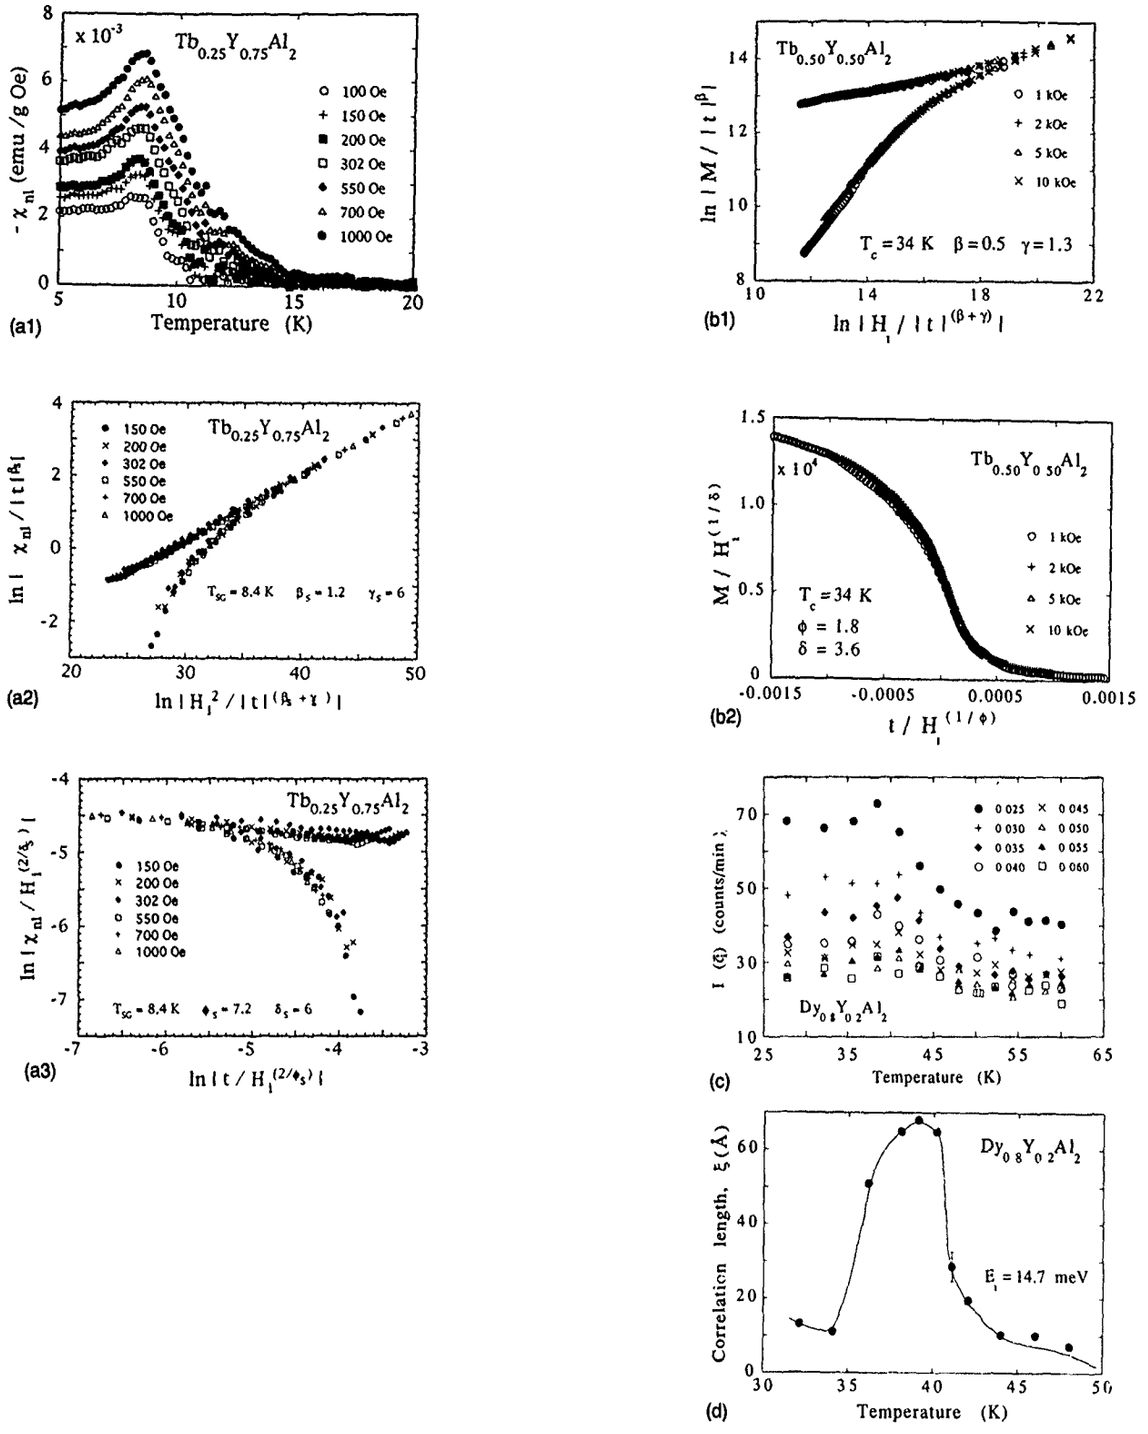

FIG. 5. (a1) Nonlinear susceptibility χ_{NL} vs temperature for $Tb_{0.25}Y_{0.75}Al_2$ at increasing magnetic fields; (a2) double logarithmic (β_s, γ_s) scaling for $x=0.25$; (a3) the same as (a2), (δ_s, ϕ_s) plot. H_i is the internal field. (b1) Double logarithmic ferromagnetic-like (β,γ) scaling plot for $Tb_{0.50}Y_{0.50}Al_2$. The upper branch is for $T<T_c$. H_i is the internal field. (b2) The same as (b1) scaling plot (δ,ϕ) for $Tb_{0.50}Y_{0.50}Al_2$. (c) Scattered neutron intensity, $I(\mathbf{q})$, vs temperature for different momentum transfer $\mathbf{q}=(2\pi/a)$ $[\xi,\xi,\xi]$ (ξa^* values are shown within the graph), around $\mathbf{Q}=(2\pi/a)$ [1,1,1], for $Dy_{0.80}Y_{0.20}Al_2$ (a, the lattice constant). (d) Magnetic correlation length temperature dependence for $Dy_{0.80}Y_{0.20}Al_2$ (see text for details). The line is an eye guide.

zation satisfies a critical scaling similar to ferromagnets and a ferromagnetic-like neutron scattering around T_c. We will address these points in $Tb_xY_{1-x}Al_2$ compounds, together with neutron scattering around T_c for $Dy_{0.8}Y_{0.2}Al_2$.

(i) Critical scaling of χ_{NL} of $Dy_xY_{1-x}Al_2$ has been extensively studied elsewhere[2] and we will focus here on the Tb series at SG regime. The nonlinear susceptibility was obtained as $\chi_{NL}=\chi(H)-\chi_0$, where the linear one χ_0 was

TABLE I. Nonlinear susceptibility χ_{nl} scaling exponents for the series $Tb_xY_{1-x}Al_2$ at the SG regime (s label). Ferromagnetic-like exponents at the CSG regime (no label). The transition temperatures and fractal dimensionality $d_f=d\phi_s/(\phi_s+\beta_s)$ are included. For χ_{nl} exponents: (*) are from (β_s,γ_s) scaling, (+) from (δ_s,ϕ_s), ($) from scaling at T_{SG}, and (#) from scaling laws. Error bars are ±0.1 in β_s and ±0.5 in γ_s, δ_s, and ϕ_s.

Compound	T_c (K)	β	γ	δ		ϕ
$TbAl_2$	97	0.40±0.05	1.25±0.05	4.1±0.01		1.65±0.01
0.50	34	0.5±0.5	1.3 ±0.1	3.6±0.1		1.80±0.1

accurately measured at a few Oe. In Fig. 5(a1) we show $\chi_{NL}(T)$ for $x=0.25$, the variation being similar for $x=0.15$, 0.20. No shift with H is found, signaling T_{SG} as a fixed point. Two kinds of scalings:[17] $-\chi_{NL}/H^{2/\delta_s}=f(|t|/H^{2/\phi_s})$ and $-\chi_{NL}/|t|^{\beta_s}=f(H^2/|t|^{\beta_s+\gamma_s})$ were performed [see Figs. 5(a2) and 5(a3), with the best data "collapses"], in order to determine the pairs of exponents (δ_s,ϕ_s) and (β_s,γ_s), and to verify the scaling laws; also the first scaling was performed at T_{SG}, where $\chi_{nl}\approx H^{2/\delta_s}$ [$t=(T-T_{SG})/T_{SG}$ is the reduced temperature]. All exponents are in Table I, scaling laws being reasonably well obeyed, as well as universality, although exponents markedly differ from MF theory.[17] We conclude that the $P\rightarrow$SG transition is a true phase transition for RMA $Tb_xY_{1-x}Al_2$ compounds, as was shown for the Dy ones.[2]

In the CSG regime we performed a ferromagnetic-like scaling for $x\geq0.40$, akin to such a character according to Arrott plots, where the demagnetizing limit is almost reached at $x=0.35$. The relations were $M/|t|^{\beta}=f(H/|t|^{\beta+\gamma})$ and $M/H^{1/\delta}=f(t/H^{1/\phi})$, in order to check for the scaling laws. For $TbAl_2$, a good $3d$-Heisenberg ferromagnet,[14] we obtain the exponents in Table I. In Figs. 5(b1) and 5(b2) we show the (γ,β) and (δ,ϕ) best data "collapses," with the exponents quoted in Table I, for $x=0.5$. It is clearly not a ferromagnet, because of the nonleveling-off of the $T<T_c$ branch. Those exponents are related to those for a $3d$-Heisenberg ferromagnet (f), using the Arrott–Noakes[1] equation of state: $\delta=(\epsilon+2)\beta_f/(1+2\gamma_f)$, $\beta=[(\epsilon+2)/2]\beta_f$, with $\epsilon=4-d$. These relations are well followed in the Dy series but not in the Tb one, likely due to the stronger cubic anisotropy and weaker RMA of the Tb compounds.

(ii) Zero energy transfer neutron scattering at $E_i=14.7$ meV was performed at the triple-axis $H4M$ spectrometer at BNL for $x=0.8$ compound, around $Q=a^*[111]$ for $q=a^*[\zeta,\zeta,\zeta]$ momentum transfer with $\zeta a^*=0.03$–0.058 $Å^{-1}$, in the range 8.7–66 K. In Fig. 5(c) we see that the scattered intensity peaks around $T_c=38$ K, in agreement with magnetization and χ_{ac} measurements. We tried a Lorentzian (L)[18] fit to the magnetic intensity I_m (after subtracting I at 60 K), i.e., $I_m(q,T)=A/(q^2+\xi^{-2})$, in order to measure the magnetic correlation length ξ. Below 36 K it was necessary to fit by $L+L^2$.[18] This indicates that above and just below T_c, the "critical" fluctuations are spin waves (sw), and that below 36 K static RMA disorder becomes important. In Fig. 5(d) we show $\xi(T)$, not diverging at T_c, an indication of the absence of long-range ferromagnetic order. This develops, for the longitudinal magnetization,[18] at finite T only above $x=0.87$.[1] We should mention that we have very recently observed a sw excitation at $\mathbf{Q}=a^*[2,2,-0.4]$ of 3.5 meV for $x=0.8$ at 10 K, a confirmation of the predicted existence of spin waves in weak RMA quasiferromagnets.[18]

Correlation decay in low-dimensional spin glasses

A. N. Kocharian[a)]

A. S. Sogomonian
Yerevan Physics Institute, Yerevan 375036, Armenia

A new method to investigate the two-point correlation function decay in a finite size random spin system and at finite temperatures is proposed. It is applicable to systems with cyclic boundary conditions and in any local or uniform magnetic field. The efficiency of this method is presented in the case of an isotropic XY spin glass model with Gaussian bond distribution in external field. Using unitary $U(1)$ gauge transformation and operator inequalities we have obtained explicit upper bounds for generalized spin-glass susceptibility $\kappa(T,R)$ that describes off-diagonal transverse magnetization in two dimensional random XY spin lattices at finite temperatures. It is found that the slowest possible decay for susceptibility in random XY spin glass is of the Kosterlitz–Thouless-type with power-law decay in 2D, and the exponential type in 1D, at low temperatures. These upper bounds rule out the possibility of the corresponding magnetic ordering in 1D and 2D isotropic XY spin glasses at finite temperatures.

INTRODUCTION

During the last two decades, the problem of random spin systems have attracted the interest of many physicists. This is because among the systems considered there are simplest examples of the random models such as Ising spin glasses or random XY model with nearest neighbor or long-range interactions.[1,2] These systems are characterized by a competition between ferromagnetic and antiferromagnetic interactions and a huge number of their experimental examples have been studied. As a result, conventional magnetic long-range order is impossible. In the mean field approach we can obtain numerous thermodynamic states and suggest the existence of the line of phase transitions at finite temperatures in the presence of a magnetic field.[3] On the other side, there is evidence that the nature of the random spin system (planar XY model with spin dimensionality n equals 2) at finite temperatures and in low dimensions may be close to the classical XY model in the 2D case and correspondingly quite different from the simple mean field picture. The essential difference is in the properties of the low temperature phase.

There are many doubts about the possibilities of obtaining real phase transitions in such systems at sufficiently low temperatures. For all these models, one believes, an upper critical dimension exists, and the critical properties associated with the transition are modified due to fluctuations below this critical dimension. In other words, the main problem is whether or not phase transitions are possible in real three dimensional space at finite temperatures for random spin systems. This circumstance depends on lowest critical dimensionality d_c; and if $d_c>3$, then phase transitions are ruled out, and if $d_c\leqslant 3$, then there is a possibility of obtaining a real finite temperature transition. Unfortunately, there are no exact results corresponding to the value of parameter d_c in spin glasses. The same question can be stated also in two dimensional spin glasses, where it would be possible to obtain the finite temperature transition, in the case when spins are frozen randomly and we have neither ferromagnetic nor antiferromagnetic states, but more of the spin liquid type.

In this paper, we propose a new method for investigation of the upper bound behavior of two-point correlation functions of such random systems as the isotropic XY spin glass model with long-range interactions with the Gaussian bond distribution at sufficiently low temperatures and in an arbitrary magnetic field in one and two dimensional lattices. Below, we show that the upper bound for generalized spin susceptibility at low temperatures in 2D lattices is power-law like. These results rigorously rule out any possibility of the corresponding long-range ordering in 1D and 2D random XY models at nonzero temperatures. The suggested approach has been used before to obtain upper bounds for correlation function decay in low dimensional Hubbard model as well as for correlation functions in anisotropic Heisenberg–Ising like models with arbitrary spin.[4,5]

SPIN-GLASS MODEL

As is known, the Hamiltonian of the random XY model with long-range interactions in the presence of local longitudinal magnetic field is represented in the form

$$H_{S.G.}=\sum_{i,j} J_{ij}(S_i^xS_j^x+S_i^yS_j^y)-\sum_i H_i,S_i^zV. \tag{1}$$

The main distinction from the usual XY model is that the value of the exchange integral J_{uv} in (1) is random and given by a Gaussian bond distribution function $\phi(J_{uv})$, where each J_{uv} is statistically independent of all others,

$$\phi(J_{uv})=\frac{1}{\sqrt{2\pi\sigma_{uv}}}\exp\left(-\frac{J_{uv}^2}{2\sigma_{uv}}\right), \tag{2}$$

where $\sigma_{uv}=\langle J_{uv}^2\rangle-\langle J_{uv}\rangle^2$ is the dispersion of the system.

For the random spin lattices all physical and thermodynamical expectation values for correlation functions $\langle....\rangle_T$ must be averaged also by parameter J_{uv} with distribution function:

[a)]Permanent address: Yerevan Physics Institute, Yerevan 37503, Armenia

$$(\langle \ldots. \rangle_T)_J = \int \langle \ldots. \rangle_T \phi(J_{uv}) dJ_{uv}. \quad (3)$$

The thermal expectation in (3) is defined by $\langle \ldots \rangle_T = \lim 1/N \, \mathrm{Tr}(\ldots \exp[-\beta H])/\mathrm{Tr}(\exp[-\beta H])$, where we replace the infinite lattice with a finite one of linear dimension N with periodic boundary conditions and take the limit $N \to \infty$.

To prove the restrictions on the correlation functions we use unitary $U(1)$ gauge transformation $T(\theta) = \Pi \exp[\theta_i(S_{iz})]$, where θ is an arbitrary function on the hypercubic lattice, and the identity $\mathrm{Tr}[A \exp(-\beta H)] = \mathrm{Tr}[T(\theta) A T^{-1}(\theta)] \exp[-\beta T(\theta) H T^{-1}(\theta)]$ with $\beta = 1/T$. In the following[4] we also let $\theta = i\varphi$ be pure imaginary, and in this case the transformation is no longer unitary. To get upper bound for different correlation functions we also use some operator inequalities.[4-6]

The transverse susceptibility in the regular XY model, which is defined from the two-point correlation function, can be represented in the form

$$A_{ij} = \lim_{N \to \infty} 1/N \langle S_i^x S_j^x + S_i^y S_j^y \rangle_T \leq B_{ij}, \quad (4)$$

where upper bound $B(R)$ for two-point correlation function $A(R)$ at sufficiently large distances $R = i - j$ in regular lattices is defined by

$$B = \exp\left[-2 \ln R + 2T^{-1} \left(\sum_{uv} \left| J_{uv} [\cosh(\varphi_u - \varphi_v) - 1] \right| \right) \right]. \quad (5)$$

This expression depends on the exchange parameter J_{uv} and variables φ_u and φ_v, which are unique solution of Poisson equation $-\Delta \varphi_u = q(\delta_{x,v} - \delta_{y,u})$ on the hypercubic lattices and they satisfy the same conditions as in Ref. 4. The positive charge q is defined later from optimization condition and constants δ and L exist depending on parameters of the system and lattice dimensionality, so when for arbitrary u and v with $|u - v| \leq L$, $|\varphi_u - \varphi_v| \leq q\delta$.[6]

Correspondingly, for the XY spin glass model, the generalized susceptibility is defined by

$$\chi = \lim \frac{1}{2N} \sum_{ij} [\langle S_i^+ S_j^- + S_i^- S_j^+ \rangle_T^2]_J, \quad \text{when } N \to \infty, \quad (6)$$

and interesting two-point correlation function must be averaged by parameter J_{uv}. Then, using integral inequalities after a Gaussian integration with (2), we obtain the upper bound for correlation function for 2D random spin glass system:

$$[\langle S^+(R) S^-(0) + h.c. \rangle_T^2]_J \leq D \exp\left(-4 \ln R + 4T^{-2} \sum_{uv} \sigma_{uv} [\cosh(\varphi_u - \varphi_v) - 1]^2 \right). \quad (7)$$

Using the properties of the parameters φ_u and φ_v, we get a restriction on the expression $\alpha = \cosh(\varphi_u - \varphi_v) - 1$ and obtain the final upper bound relation for 2D spin glass correlation function, when $N \to \infty$ and $\varphi_R \geq q \ln R / 2\pi J$:

$$[\langle S^+(R) S^-(0) + h.c. \rangle_T^2]_J \leq D \exp[-f(T,Q) \ln R], \quad (8)$$

where

$$f(T,Q) = \frac{1}{2\pi} \left(Q - \frac{J^2}{4T^2} (\cosh Q - 1) \right).$$

The parameter D in (7) and (8) weakly depends on the temperature, which appears to be due to a Gaussian integration:

$$D = (2\pi\sigma)^{-1/2} \int dJ_{uv} \exp[-(J_{uv} - 2\sigma_{uv}\beta\alpha)^2 / 2\sigma_{uv}].$$

The expression $f(T,Q)$ depends on the effective dimensionless parameter $Q = 4q/J$. The optimization of the bound relation (7) by the parameter Q gives the condition

$$1 - \frac{J^2}{2T^2} \sinh Q \cdot (\cosh Q - 1) = 0. \quad (9)$$

The same type of calculations gives the upper bound for the 1D case, where $\varphi_r \geq qr/J$:

$$[\langle S^+(r) S^-(0) + h.c. \rangle_T^2]_J \leq D \exp[-f_1(T,Q) r], \quad (10)$$

where

$$f_1(T,Q) = 4Q - \frac{4J^2}{T^2} (\cosh Q - 1)^2.$$

The main result contained in Eqs. (8) and (9) does not depend on magnetic field and shows that when the parameter R goes to infinity the two-point correlation function for off-diagonal transverse magnetization goes to zero. This means that it is impossible to obtain a phase transition in 2D random lattices at any finite temperature and for an arbitrary value of magnetic field (local or uniform). On the other hand, the investigation of the upper bound in Eqs. (8) and (9) shows that the slowest possible decay at low temperatures is power-law like, which in principle does not exclude the possibility of a Kosterlitz–Thouless-like phase transition in 2D spin glass.[7] But in contrast to Ref. 7, the critical exponent $f(T)$ in (8) at low temperatures is proportional to T.[2/3] This means that in random lattices transverse magnetization of the correlation function decays faster than in regular spin lattices.[4,5] The indication about Kosterlitz–Thouless-like behavior can also be obtained from the comparison of changing characters for correlation functions under the temperature for upper bound correlation length of our system with those known for the classical XY model. Indeed, in both cases we have similar logarithmic behavior for correlation lengths at high temperatures. The correlation length, which is a power function at low temperatures and becomes logarithmic at high temperatures, apparently reflects a nonmonotonic variation of the thermodynamic state with the temperature.

On the other hand, from Eq. (8) one can obtain that in the zero field the upper bound for susceptibility diverges at low temperatures, when the corresponding critical exponent becomes less then 2. Such a behavior indicates the possibility of a certain phase transition similar to the Kosterlitz–Thouless-type, even in the random two-dimensional spin system at nonzero temperature.

Corresponding investigations in the 1D case from Eq. (10) show that the upper bound decays exponentially with

the distance, in spite of the fact that the high temperature behavior remains as in the 2D case with large spin. The obtained upper bounds do not exclude the possibility of some kind of long range ordering for a two dimensional random spin system at zero temperature. Corresponding lower bound relations until now have been obtained only for the regular Heiseberg–Ising-like 2D systems in the ground state.[8] It is believed that vector Heisenberg spin glasses with $n=3$ do not have an equilibrium phase transition in the 3D case, but that the observed experimental transitions result from small anisotropicity, which causes a crossover to an Ising-like transition. The approach suggested here is applicable for both randomness and long-range interaction simultaneously and can be used for investigations of critical behavior in the presence of the magnetic field for a large class of random spin quantum systems, which are invariant under the global rotation around the z axis.

Thus, the method developed for finding upper bounds gives results sharpening the Mermin–Wagner theorem for regular lattices as well as for a random system with long-range interactions.

Relaxation and spin correlations in ^{119}Sn-doped a-$Fe_{90}Sc_{10}$

D. Wiarda and D. H. Ryan
Centre for the Physics of Materials and the Department of Physics, McGill University, Rutherford Building, 3600 University Street, Montréal, Québec, Canada H3A 2T8

Combined ^{119}Sn and ^{57}Fe Mössbauer measurements have been made on a Sn-doped sample of a-Fe-Sc both around T_{sg} (117±2 K) to examine the onset of order, and at 12 K to investigate spin correlations. The different time scales probed by the Sn and Fe Mössbauer transitions allow us to confirm that cluster relaxation effects do not contribute to the ordering at T_{sg}, while the large transferred hyperfine field (B_{hf}) at the Sn sites, in an alloy known to exhibit isotropic spin freezing, is inconsistent with the simple view of the transferred field arising as a vector sum over the nearest-neighbor moments.

I. INTRODUCTION

Amorphous iron-rich Fe-Sc alloys are unique among the iron-rich early transition metal-iron glasses, in that they do not exhibit a strong dependence of the magnetic ordering temperature on composition.[1] In contrast to a-Fe_xZr_{100-x} where the ordering temperature drops from 260 K at $x=88$ to 160 K at $x=93$,[2] the ordering temperature in a-Fe_xSc_{100-x} is essentially constant at 105 K in the range $89 \leqslant x \leqslant 91$ accessible by melt spinning.[3] Examination of the scaling behavior of the susceptibility around T_{sg} indicates that the material is a borderline spin glass, just sufficiently frustrated to destroy the ferromagnetic order,[4] a result that is confirmed by in-field Mössbauer measurements[5] which show that the system directly enters a noncollinear state at T_{sg}, and does not pass through the intermediate ferromagnetic phase seen in less frustrated materials.[1] More recent magnetization measurements have demonstrated that the system does not exhibit a spontaneous moment at any temperature.[6] An alternative view of the ordering proposes the existence of superparamagnetic clusters, which block in random orientations at T_{sg}.[7] This seems extremely unlikely in view of the close agreement between χ_{ac}[4,8] and Mössbauer[3] determinations of the ordering temperature, measurements with vastly different characteristic time scales.[5]

We present here a combined ^{57}Fe and ^{119}Sn Mössbauer study of a ^{119}Sn-doped a-Fe-Sc alloy. The two Mössbauer measurements are made in the same way, and on the same equipment, thus eliminating instrumental and calibration differences; however, the lifetime of the ^{119}Sn excited state is a factor of 5.5 times shorter than that of ^{57}Fe, so that the two measurements probe very different time scales, allowing us to examine the possible role that cluster freezing may play in the ordering at T_{sg}. Furthermore, as Sn has no local moment, the transferred hyperfine field at the ^{119}Sn nuclei contains information about the magnetic correlations among the neighboring Fe moments.

II. EXPERIMENTAL METHODS

Ingots for melt spinning were prepared in an arc furnace under titanium-gettered argon. The Sc (99.9%) was first premelted and then alloyed with the ^{119}Sn. Enriched ^{119}Sn (isotopic purity 82.9%) was used in order to get ~8 mg ^{119}Sn per 1 g sample weight and ensure a convenient absorption in the ^{119}Sn spectra. The Sc-Sn alloy was then added to an appropriate quantity of Fe (99.98%), and melted several times to ensure homogeneity. Melt spinning was done under a helium atmosphere onto a copper wheel, and yielded ribbons ~1 mm wide and ~10 μm thick. The amorphous structure of the sample was verified by x-ray diffraction and room-temperature Mössbauer spectroscopy. Differential scanning calorimetry showed that the crystallization temperature for this material was 810 K, close to the value of 822 K reported for a-$Fe_{90}Sc_{10}$,[3] confirming that the addition of 1% Sn does not significantly affect the glass. The amorphous ribbons were mounted on tape in order to make a Mössbauer absorber. A single thickness was used for the ^{57}Fe spectra while six layers were used for the ^{119}Sn measurements. The Mössbauer spectra were taken using a conventional constant acceleration spectrometer with a ^{57}CoRh source for the ^{57}Fe spectra and a $Ca^{119}SnO_3$ source for the ^{119}Sn spectra. The temperature was varied by means of a vibration-isolated closed-cycle He cryostat.

The ^{57}Fe spectra were fitted using two Gaussian distributions to describe the hyperfine field distribution. For the ^{119}Sn spectra a single Gaussian distribution with different widths on the low- and high-field side of the peak field was used. As the sample is an amorphous ribbon, the relative intensity of lines 2 and 5 cannot be fixed *a priori* to its powder average value. Therefore it was fitted in the ^{57}Fe spectra and then set to 2 (the value found in the fits to the ^{57}Fe spectra) for the ^{119}Sn spectra. A linear correlation between the isomer shift and the hyperfine field was assumed in order to fit the slight asymmetry in the spectra.

III. RESULTS AND DISCUSSION

A conventional method for determining magnetic ordering temperatures is to record the transmitted intensity of Mössbauer radiation at zero velocity as a function of temperature. As the spectrum broadens at T_{sg}, the peak absorption falls, and the zero-velocity count rate increases. The data for the ^{57}Fe thermal scan are shown in Fig. 1. T_{sg} is identified with the marked change in slope at 119±1 K. The procedure has to be modified for ^{119}Sn as the isomer shift displaces the peak absorption above T_{sg} to +1.8 mm/s relative to the source at rest. The spectrometer is therefore run at a constant velocity chosen to maximize the absorption at room temperature, and the observed drift in count rate on cooling above

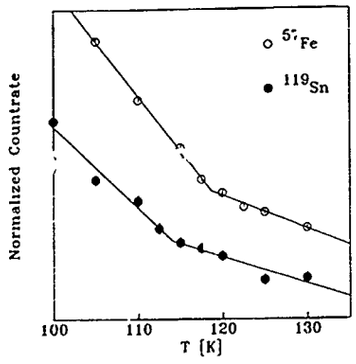

FIG. 1. Mossbauer thermal scans for a-$Fe_{90}Sc_9Sn_1$ at zero velocity for ^{57}Fe (○) and at ~1.8 mm/s for ^{119}Sn (●), showing the discontinuity at T_{sg}.

T_{sg} seen in Fig. 1, is due to the spectrum center moving as a result of the second-order Doppler shift. A clear break in slope is observed at 114±2 K.

Given that ^{119}Sn samples on a shorter time scale than ^{57}Fe, we would expect the Sn data to give a significantly higher ordering temperature if blocking of superparamagnetic clusters were the origin of the magnetic order. Such clusters would appear frozen at higher temperatures when observed at higher frequencies. However, the two Mössbauer measurements yield the same ordering temperature within error (it is interesting to note that the Sn value is actually slightly lower, rather than significantly higher). Assuming that T_{sg} does reflect a blocking of superparamagnetic clusters, we can calculate the energy barrier for magnetization reversal[9] and thus the change in blocking temperature on going from ^{57}Fe to ^{119}Sn. This calculation indicates that the ^{119}Sn transition would be at ~150 K if such a model were appropriate, rather than 114 K as observed. We can therefore rule out relaxation effects or cluster blocking as contributing to the ordering of a-Fe-Sc.

Unlike earlier work on Sn-doped a-Fe-Zr which showed no effect of the Sn additions on the magnetic ordering temperature,[10] the Sn-doped sample does exhibit a slightly higher ordering temperature than that of earlier materials; however, we do not believe that the ~14 K increase reflects a significant modification of the magnetic structure. The most convenient way to modify the magnetic properties of a-Fe-Sc is to add hydrogen. This leads to profound changes in both T_c (rises to ~310 K) and the iron moment (increases to $\sim 2.2\mu_B$, the average hyperfine field rises to 31.3 T),[3] but the material still lacks the critical behavior characteristic of a ferromagnet.[4] Therefore it seems reasonable to conclude that if a 200 K increase in T_c leaves the system still in a strongly spin-glass like state, a 14 K increase will have negligible effects on the magnetic structure.

The Mössbauer spectra obtained at 12 K for the two transitions are shown in Fig. 2. Both are clearly magnetically split, reflecting the ordering of the iron moments. The fit to the ^{57}Fe spectrum yields an average hyperfine field of 22.8 T, indistinguishable from previous values obtained on Sn-free materials,[3,5] and further reinforcing the view that the addition of Sn has not significantly affected the magnetic ordering. Curiously, the ^{119}Sn spectrum also yields a large average

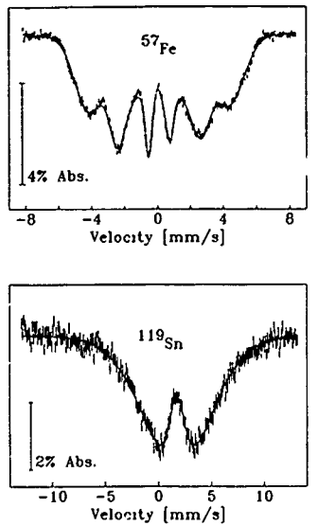

FIG. 2 Mossbauer spectra measured at 12 K a-$Fe_{90}Sc_9Sn_1$ for ^{57}Fe (top) and ^{119}Sn (bottom).

field: 5.1±0.2 T. If the local magnetic order were essentially isotropic, as would be expected in a spin glass, the contributions from the neighboring Fe moments would be random and therefore largely cancel at a Sn site. Such a situation would then yield a small ratio between the observed transferred Sn field and the Fe field (assumed proportional to the Fe moments). The value obtained here is 0.22±0.01, essentially the same as that found in the less frustrated a-$Fe_{92}Zr_7Sr_1$ (Ref. 10) and the almost ferromagnetic a-$Fe_{90-x}Ni_xZr_9Sn_1$.[11] Assuming that the transferred field at the ^{119}Sn results from a vector sum over the moments on the Fe nearest neighbors, and that the coordination number in the glass is ~12, then going from fully collinear to isotropic order should lead to a factor of 4 drop in the Sn/Fe hyperfine field ratio, a prediction that is completely inconsistent with our observations. Similar measurements on Mn-containing spin glasses[12,13] have also reported large transferred fields, leading to the rather unlikely speculation that the spin glass is dominated by significant ferromagnetic short-ranged correlations.[13] Since it is highly unlikely that the addition of 1 at % Sn makes the a-Fe-Sc alloy essentially ferromagnetic, without increasing either T_c or the iron moment, we are forced to conclude that even in an isotropically ordered material (i.e., a spin glass), the ^{119}Sn nuclei measure the magnitude of the average iron moment, rather than the vector sum of the randomly oriented neighboring moments.

Field-dependent susceptibility aging in CuMn spin glasses

P. W. Fenimore and M. B. Weissman
Department of Physics, University of Illinois at Urbana–Champaign, 1110 West Green Street, Urbana, Illinois 61801-3080

A "hole" is found to develop in the dc field-dependent ac susceptibility of CuMn spin glasses when the material is cooled or aged in a field. Comparisons are made with analogous experiments on structural glasses at low temperature. The hole is not compatible with independent two-level systems. The significance of the width (in H) of this hole is discussed.

Recent work on aging of the ac dielectric susceptibility $\epsilon(f)$ in several dissimilar insulating glasses found that a "hole" can form in $\epsilon(f)$ versus applied dc electric field **E** when the dielectric is aged in an electric field at low temperatures for times in the range 10^3–10^5 s.[1] The detailed time and frequency dependence of this hole has been shown to be inconsistent with a model consisting of a simple superposition of quantum two-level systems (TLS).[2] The most plausible source of such aging effects lies in multistate relaxations, such as those responsible for the well-known (but not well understood) large aging effects in spin glasses.[3] In this paper we describe experiments, analogous to the dielectric experiments, on the time and magnetic field dependence of the magnetic susceptibility, $\chi(f)\equiv\chi'(f)+i\chi''(f)$, in metallic spin glasses.

Spin glasses are good candidates for these experiments for several reasons. (i) Previous work has clearly established that there are large aging effects below the spin-glass temperature.[3] (ii) In metallic spin glasses there is almost certainly a continuous phase transition at the spin-glass freezing temperature T_G,[4] which provides a well-defined energy scale for interactions in spin glasses. Since the low-temperature excitations of the structural glasses do not have a known phase transition, an appropriate energy scale for interactions in glasses is unclear. (iii) Spin-glass experiments may be conducted in the classical (high-temperature) regime. Dielectric aging has been studied in the tunneling regime and comparison with spin glasses should shed light on the importance of quantum mechanical effects.

We have examined CuMn with 4 at. % Mn and 12 at. % Mn and CuMnAu with 4 at. % Mn and 1 at. % Au. We have also measured a CuSiMn (4.2 at. % Si, 0.3 at. % Mn) sample as a control. The spin-glass temperature of the control sample is lower than the temperature range in which we took data (T_G<5 K). The 4% samples are cylindrical and have two overlapping cuts along their length to reduce the contribution to χ'' from eddy currents.[5] The 12% sample is a small segment of an annulus about 2 cm in radius. The overall dimensions of this sample are comparable to the 4% samples. The control sample is a ~1-cm-long section of the body of a silicon-bronze screw. All the samples have masses near 1 g. The measurements were made in a 1 T commercial (Quantum Design) ac susceptometer. The measurements were made at 3 Hz, about the highest frequency (allowing fastest data collection) for which the eddy current background could be accurately subtracted.

The spin glass is initially field cooled (usually at 300 Oe) from $\sim 2T_G$ to a working temperature below T_G. A non-zero cooling field is used to make sure that the effects of equilibrating at a particular field are not confused with any special properties of $H=0$. The fields used were always small enough to stay the strongly irreversible spin-glass regime at the measurement temperature.[5] The sample is then aged at that field for about 5000 s. The field is then changed to a new (second) field for a few minutes. during which time the initial values of χ' (3 Hz) and χ'' (3 Hz) are measured. The applied field is then changed back to its initial value and the sample is allowed to age before the next measurement is performed. By repeating this **H**-cycling procedure, all at fixed T, we make a map of initial χ vs **H**. Since, empirically, this map does not depend substantially on the order in which we cycle to the measurement fields, long-term distortion of the curve caused by the field history at the measuring temperature does not seem to be a problem.

All three of these spin glasses show a substantial hole in $\chi(f,H)$ versus magnetic field (H) (see Fig. 1). To a first approximation, the center of the hole is simply shifted by cooling in different fields. The hole in $\chi(f,H)$ for these SGs is short lived, compared with the lifetime of the hole in $\epsilon(f,E)$ of structural glasses (except SiO_2).[1] (Because of this effect slow scans of the applied field are not feasible.)

The hole depth for χ'' is ~30% of the initial value of χ'' and for χ' it is ~3% of the initial value. These numbers contrast with the structural glasses where the hole depth in ϵ' is only ~0.1%. Monitoring χ'' allows us to separate slow, relaxational spin dynamics from fast spin dynamics (e.g., spin dynamics near the attempt rate) that contribute to χ'. This is important because there is no guarantee that the

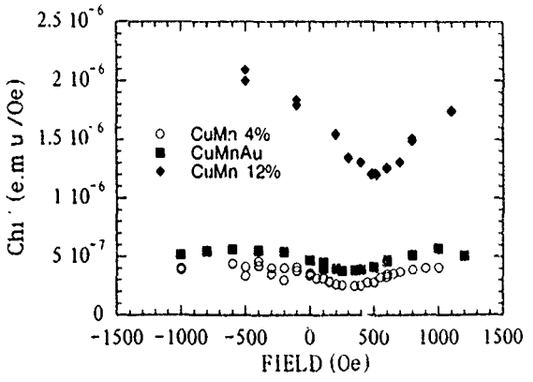

FIG. 1 The hole in χ'' vs field for three different spin glasses at $0.5T_G$. The measurements were made at 3 Hz

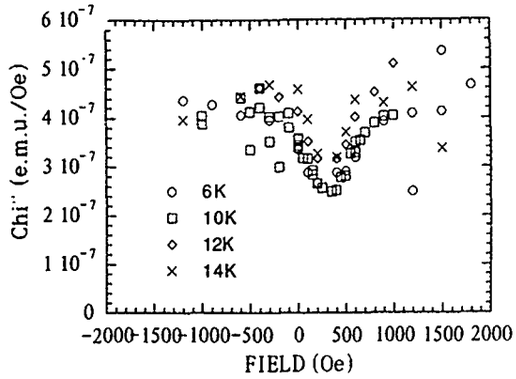

FIG. 2. The hole in χ'' vs field for four temperatures in CuMn 4 at. % Mn. The data were taken at 3 Hz.

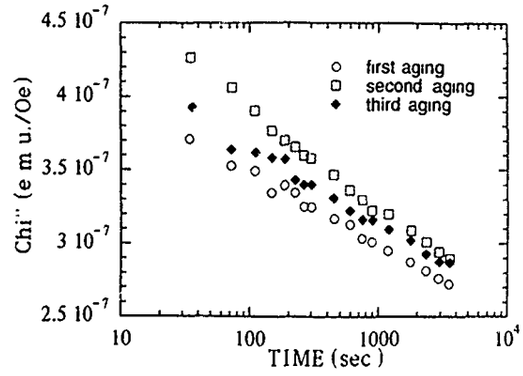

FIG. 3. Time dependence of the relaxation of χ'' in CuMn 4 at. % Mn at 10 K. The data were taken at 3 Hz.

"fast" spin dynamics have the same aging properties as those near 1 Hz.

The width of the hole in χ'' is ~300 Oe at 10 K and is slightly narrower at higher temperatures (see Fig. 2). The weak T dependence of this width, from 0.3 to $0.7T_G$, contrasts with the strong temperature dependence of the $\epsilon(f,\mathbf{E})$ hole between 50 and 500 mK.[1]

For sufficiently large ΔH (~300 Oe), the increase in χ saturates, indicating that nearly all the spin configurations whose fluctuations give χ'' (3 Hz) are sufficiently changed by fields of ~300 Oe to cease to contribute to χ'' (3 Hz). That is, by changing H by 300 Oe, one sees a different set of fluctuators, ones which have not had a chance to relax to the smaller values of χ'' (3 Hz). Further change of H simply gives a different set of new fluctuators, which are still not aged.

One expects that H has little effect on the dynamics of active spin clusters until $\mu\Delta H$ becomes greater than k_BT, where μ is the net magnetic moment of the rearranging spin cluster. (When, however, $\mu\Delta H > k_BT$, a new set of fluctuating objects will be responsible for χ''.) Since the net moment of a spin cluster in a spin-glass scales as the square root of the number of spins, and since a Mn ion in Cu has a moment about $2\mu_B$, the characteristic number of spins involved in the clusters as $\mathbf{H}$ is changed is about 10^5 at 10 K. This number of spins is fairly constant in the samples we have examined. However, the relations among this number, the number of spins involved in individual coherent thermal flips at fixed H,[6] and the number of spins which are within a volume throughout which such coherent groups interact[6] are not yet clear to us.

If instead of briefly visiting other fields and building up a map of initial, unaged χ vs $\mathbf{H}$, we field cool in $+\mathbf{H}_1$, age the sample, change to $-\mathbf{H}_1$ and allow the sample to age further, we can see the long time behavior of the hole. The relaxations are roughly logarithmic in time (Fig. 3). Observing this second relaxation (and also a third relaxation, this time back at $+\mathbf{H}_1$) allows us to compare the field-cooled behavior with field-jump behavior.

For equal aging times the second aging does not reach as low a χ'' value as the first. Even a brief excursion from the field cooled $+\mathbf{H}_1$ to $-\mathbf{H}_1$ mostly resets the (third) aging of χ'' on return to $+\mathbf{H}_1$. Nonetheless, at long times the third aging (at $+\mathbf{H}_1$) is intermediate to the first and second, indicating that some small part of the $+\mathbf{H}_1$ hole survives to long times at $-\mathbf{H}_1$.

In contrast, the aging of χ' at $+\mathbf{H}_1$ is not mostly restarted by brief excursions to $-\mathbf{H}_1$ (see Fig. 4). For times shorter than about 1000 s at $-\mathbf{H}_1$, the initial χ' on return to $+\mathbf{H}_1$ is still lower than any value of χ' recorded at $-\mathbf{H}_1$. We assume that this behavior indicates that the very fast relaxations which contribute substantially to χ' age in a very different way than the clusters responsible for χ''.

In conclusion, conventional spin glasses in a classical temperature regime show field-dependent aging effects similar to those of structural glasses in the quantum regime. The spin-glass susceptibility holes, however, are deeper than those of the structural glasses, and generally show more rapid relaxation. Our results strongly reinforce the theoretical conclusion[2] that the main explanation of dielectric aging will be found in multisite cooperative effects, such as are known to be present in spin glasses, rather than in the simple TLS picture.

Several prior pieces of evidence strongly support this view. The decay in $\epsilon'(f)$ is very strongly dependent on f.[1] Thus the frequency dependence of ϵ' strongly ages. Since,

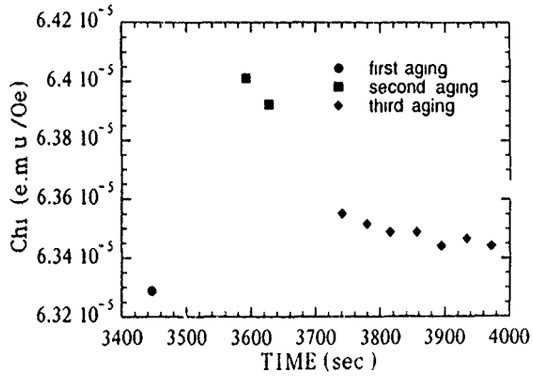

FIG. 4. χ' vs time for CuMn 4 at % Mn at 10 K. The data point at early times is in the first part of the aging. Note that χ' drops between the second and third aging fields. The data were taken at 3 Hz.

by Kramers–Kronig, the frequency dependence of ϵ' is essentially ϵ'', ϵ'' must also show very strong aging effects (as does χ'' in spin glasses). At frequencies much less than the attempt rate, it is very unlikely that χ'' or ϵ'' comes from anything other than relaxational effects (i.e., tunneling processes at low temperature and activated processes at higher temperatures). Since a simple noninteracting two-state system with a characteristic rate comparable to the measurement frequency does not have some other longer time associated with it, it cannot produce a slowly aging χ'' or ϵ''.

It is known from fluctuation experiments in mesoscopic samples of metallic glasses that their low-temperature structural fluctuations (in both the tunneling and activated regimes) are not strictly two-state systems.[7] Interactions lead to slow fluctuations in the characteristic rate and duty cycle of the individual (configurational) fluctuations. These fluctuations are probably the equilibrium analog of the dielectric aging. Since the detailed properties of the fluctuators vary over long times, one expects long time relaxations into configurations with minimal free energy. Unless some unexpected symmetry precludes average differences in susceptibility between the high free-energy configurations and the minimum, the susceptibilities will slowly relax. The sign of the relaxation (toward lower susceptibilities) is consistent with a simple correlation: the barrier heights seen from a low free-energy configuration tend to be higher than those seen from a high free-energy configuration, as would be expected if energies of the transition states did not differ from each other. It is probably no coincidence that similar mesoscopic experiments on CuMn show extremely strong interactions, to the point that nothing like two-state systems exists,[6] and that CuMn shows much stronger aging effects.[3]

In the mesoscopic noise experiments on amorphous metals, a whole new set of fluctuating objects could be obtained by thermal cycling to ~50 K and back,[7] just as a whole new fluctuation pattern can be obtained by cycling a mesoscopic spin glass to T_G.[6] If the analogy between interacting TLS in amorphous materials and interacting spins in spin glasses turns out to be meaningful, then the ~100 mK temperature scale of the dielectric hole measurements probably corresponds to a similar low temperature in the spin-glass experiments. It will be interesting to investigate whether the quantitative differences between the aging in the two types of systems are primarily the result of this different experimental temperature scale or of some more fundamental factor, such as the strength of the interactions versus the local energy asymmetries. At any rate, the quantum mechanical nature of the TLS does not seem to be an essential aspect of the aging.

Quantum tunneling in magnetic particles (invited) (abstract)

D. P. DiVincenzo
IBM Research Division, T. J. Watson Research Center, P.O. Box 218, Yorktown Heights, New York 10598

Recent advances both in materials preparation techniques for ultrafine magnetic particles, and in low-temperature magnetometry, have made possible the observation of a new kind of collective quantum-mechanical phenomenon. In our studies[1] of horse-spleen ferritin particles (naturally occurring 75 Å iron-oxide crystallites), a resonance in the magnetic susceptibility is observed at low temperature (<200 mK) and exceedingly low ambient magnetic fields (of order 10^{-3} Gauss and below). I will discuss the accumulation of evidence which indicates that this resonance arises from the quantum tunneling of the magnetization between the ferritin particles's two easy-axis states. This involves a unique collective effect: the orientation of the thousands of spins in the particle flip over as a unit, passing through an energy barrier. I will discuss various new theoretical results which have been stimulated by these recent experiments. For example, quantum mechanics predicts that the tunneling behavior is radically different for particles with even and odd number of iron atoms,[2]—in particular, tunneling is predicted to be forbidden in the odd case. Finally, I will discuss the possibilities for quantum effects in a new class of nanoscopic Fe particles, produced by a novel STM deposition technique by A. Kent. It is clear that new materials preparation techniques will continue to provide novel testing grounds for quantum theory.

Remanent magnetization of AgMn spin glasses (abstract)

Emily Engle and E. Dan Dahlberg
School of Physics and Astronomy, University of Minnesota, Minneapolis, Minnesota 55455

Plots of the dc demagnetization remanence, I_d, versus the isothermal remanent magnetization, I_r, have been used to determine the presence of interactions in concentrated magnetic systems.[1] In terms of interacting entities within the system, the standard interpretation of these plots is that positive (negative) curvature indicates the presence of demagnetizing (magnetizing) interactions between the magnetic entities.[2,3] We will report the first such analysis made on a spin glass (the archetypal spin glass system AgMn, with three Mn concentrations). As prescribed, I_d and I_r were normalized and plotted against each other. All of the plots of zero-field quenched specimens have positive curvature, indicating the presence of demagnetizing interactions. In these measurements the sample shape dependent demagnetizing field was not a factor because the magnetizing field was applied parallel to the long axis of the foils (0.50 in. × 0.15 in. ×~0.005 in.). These results are consistent with a recent model for slow relaxation[4] wherein interactions, not disorder, determine the quasilogarithmic time dependence of relaxation processes in these systems.

Calculated field cooled and zero field cooled magnetizations of the three-dimensional Ising spin glass using Monte Carlo hard-spin mean-field theory (abstract)

Edwin A. Ames and Susan R. McKay
Department of Physics and Astronomy, University of Maine, Orono, Maine 04469-5709

We have studied the $\pm J$ Ising spin glass in a uniform magnetic field by using Monte Carlo hard-spin mean-field theory,[1] implemented on a $24\times24\times24$ lattice with periodic boundary conditions. This method modifies the conventional mean-field approach to retain frustration by placing a spin of unit magnitude at each nearest neighbor. Each spin's direction is chosen using the hard spin condition, which preserves the site's average magnetization. The method yields an average magnetization at each site and permits the exploration of stable and metastable states within the spin-glass phase and their overlaps. By direct calculation of the free energy of each final state, stability and metastability can be distinguished. The resulting average magnetizations display realistic history dependence. For example, the calculated field cooled magnetization remains roughly constant below the freezing temperature, T_g, whereas the zero field cooled magnetization rises to a cusp as temperature is increased below T_g, as is observed experimentally. Aging phenomena are also reproduced within this method, since varying the number of Monte Carlo steps at each temperature and field corresponds to altering the waiting time.

Giant magneto-impedance and magneto-inductive effects in amorphous alloys (invited)

L. V. Panina, K. Mohri, K. Bushida,[a] and M. Noda
Department of Electrical Engineering, Nagoya University, Nagoya 464, Japan

Recent experiments have discovered giant and sensitive magneto-impedance and magneto-inductive effects in FeCoSiB amorphous wires. These effects include a sensitive change in an ac wire voltage with the application of a small dc longitudinal magnetic field. At low frequencies (1–10 kHz) the inductive voltage drops by 50% for a field of 2 Oe (25%/Oe) reflecting a strong field dependence of the circumferential permeability. At higher frequencies (0.1–10 MHz) when the skin effect is essential, the amplitude of the total wire voltage decreases by 40%–60% for fields of 3–10 Oe (about 10%/Oe). These effects exhibit no hysteresis for the variation of an applied field and can be obtained even in wires of 1 mm length and a few micrometer diameter. These characteristics are very useful to constitute a highly sensitive microsensor head to detect local fields of the order of 10^{-5} Oe. In this paper, we review recently obtained experimental results on magneto-inductive and magneto-impedance effects and present a detailed discussion for their mechanism, developing a general approach in terms of ac complex impedance in a magnetic conductor. In the case of a strong skin effect the total wire impedance depends on the circumferential permeability through the penetration depth, resulting in the giant magneto-impedance effect.

I. INTRODUCTION

Recently, much work has been done on giant magnetoresistance because of its importance for applications in various magnetic sensors and especially in magnetic heads for recording. The problem, however, is not well understood, and experimental results are far from practical applications, as the effect is observed at rather high magnetic fields and suffers strong hysteresis. On the other hand, giant and sensitive magneto-inductive (MI) and magneto-impedance (**MI**) effects have been found in soft magnetic FeCoSiB amorphous wires[1–6] and ribbons.[7,8] These effects include a sensitive change in an ac voltage in these materials with the application of a small dc magnetic field, and are thus an ac analog of giant magnetoresistance. The effects have been reported to be the strongest for an amorphous wire of a composition $Fe_{4.3}Co_{68.2}Si_{12.5}B_{15}$. In a low frequency range of 1–10 kHz, which is typical of the MI effect, the inductive component of an ac wire voltage decreases by 50% for a longitudinal field of 2–5 Oe. At higher frequencies (0.1–10 MHz) where the skin effect is essential the giant **MI** effect occurs: the amplitude of the total wire voltage decreases by 40%–60% under the influence of a longitudinal field of 3–10 Oe. No hysteresis has been observed. The giant MI and **MI** effects can be observed in wires with a few micrometer diameter and 1 mm length. These results suggest establishing a new microsized sensitive magnetic head and a sensor head for information storage devices.

In this work we present a comprehensive study of the MI and **MI** effects in FeCoSiB amorphous wires including both a brief review of the recently obtained experimental results and their analysis on the basis of the ac complex impedance of a magnetic wire with a domain structure. Some new results for FeCoMoSiB amorphous ribbons are presented as well. We demonstrate that both effects have a classical electromagnetic origin and, hence, are not connected with the conventional magnetoresistance. All the experimental data can be explained in terms of a field dependence of impedance as a result of the transverse magnetization (with respect to current direction) and the skin effect.[6,9–11] In general, large and giant magneto-impedance effects are possible in many other soft magnetic materials of various geometries.

Because of the skin effect, an ac current, $I=I_0\exp(-j\omega t)$, tends to be concentrated near the surface of a conductor, changing its impedance $\hat{Z}$. The current distribution depends not only on the shape of the conductor and frequency but also on the transverse permeability μ. If μ is a sensitive function of an external field H_{ex} in a high frequency region this dependence reveals itself in the impedance behavior through the penetration depth, resulting in a sensitive voltage response: $V(\omega,H_{ex})=\hat{Z}[\omega,\mu(\omega,H_{ex})]I$. At low frequencies, when the skin effect is negligible, the first order term in an expansion of $\hat{Z}(\omega)$ in powers of frequency is responsible for the voltage field dependence. This term is represented by the internal inductance, which is proportional to the static transverse permeability. The general approach of impedance is thus helpful to explain both the low and high frequency field effects on ac voltage.

An FeCoSiB amorphous wire can be considered as one of the most suitable material to observe the magneto-impedance effects. It has fine soft magnetic properties because of its nearly zero magnetostriction constant $\lambda\cong-10^{-7}$. The negative magnetostriction results in a circumferential anisotropy and, consequently, a domain structure with circu

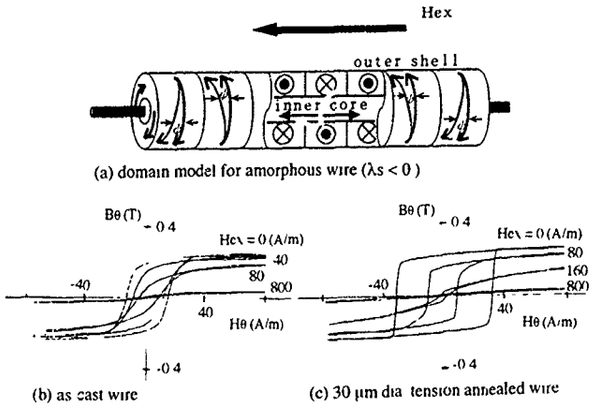

FIG. 1 Magnetic structure (a) and circular hysteresis loops (b), (c) of FeCoSiB amorphous wires in the presence of a longitudinal field.

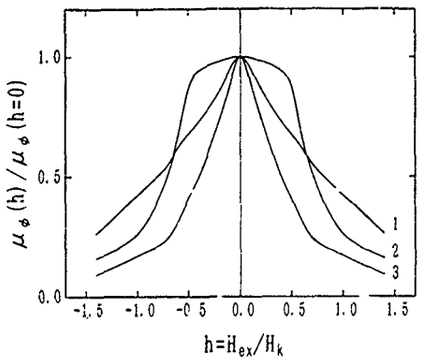

FIG. 2. Theoretical dependencies (obtained on the basis of hysteresis loop calculations, Ref. 9) of the maximal circumferential permeability on a reduced longitudinal field $h=H_{ex}/H_K$. The anisotropy axis deviations $2\Delta\alpha$ are: 1—45°, 2—10°, 3—20°.

lar domains situated along the wire. The current flowing through the wire generates an easy axis driving field which causes a circular magnetization by the domain wall movement. The external longitudinal field H_{ex}, being a hard axis field with respect to the circular magnetization, suppresses the circular flux change. As a result, the circumferential permeability having a high value of the order of 10^4 for $H_{ex}=0$, decreases rapidly with the application of the field. This sensitive field dependence of the circumferential permeability, which maintains till high frequencies at which the skin effect is essential (but the domain wall motion is not completely damped by eddy currents), is responsible for the magneto-impedance effects in wires.

This paper is organized as follows: In Sec. II we review the existing experimental and theoretical results on the static magnetic properties of negative magnetostrictive amorphous wires since they eventually determine the field dependence of the impedance. In Sec. III the experimental magneto-inductive and magneto-impedance characteristics recently obtained by the present authors are summarized. For comparison, new data for FeCoMoSiB amorphous ribbons are presented. In Sec. IV the concept of the magneto-impedance effect is put forward. In Sec. V the calculated magneto-impedance characteristics for wires are presented, and the analysis of the experimental results is given, showing a reasonable agreement.

II. STATIC MAGNETIC PROPERTIES OF FeCoSiB AMORPHOUS WIRES

The magnetic structure of amorphous wires made by rapid quenching process is dominated by stress induced anisotropy.[12–14] In the case of negative magnetostrictive wires ($\lambda<0$), the stress distribution results in a core and sheath magnetic structure with magnetization parallel to the wire axis in the inner core and circular in the outer shell. The corresponding magnetic structure with ring domains spaced along the wire is shown in Fig. 1(a). This structure is retained even for slightly negative ($\lambda=-10^{-7}$) magnetostrictive wires of a composition $Fe_{4\,3}Co_{68\,2}Si_{12\,5}B_{15}$ which are used in the present investigation without loss of generality.

An as-cast wire has a diameter of 120 μm. Smaller diameter wires (down to 30 μm) can be obtained by cold drawing an as-cast one and then tension annealing. During tension annealing a higher circumferential anisotropy is induced. For a relatively high annealing tension (>2 kg/mm^2) the circumferential magnetization is considered to exist in the entire wire However, the effective anisotropy field H_K is still very small (~1 Oe). If the wire is shortened down to 1–3 mm, H_K increases due to the demagnetizing effect and is about several Oe. The length effect on the anisotropy is much stronger for as-cast wires.

The circumferential anisotropy allows the wire to be magnetized by flowing through it a current which creates a circular easy axis driving field H_φ. The circular magnetization proceeds mainly by the movement of circular (or ring) domains along the wire, resulting in a sharp hysteresis with the maximum of the differential permeability of the order of 10^4 for a 1 kHz current (see Fig. 1). Then a sensitive circumferential magnetic flux change can be made to occur due to a small ac wire current. The magnetic field H_{ex} applied along the wire axis suppresses the circular magnetization by wall movement, since H_{ex} is a hard axis field with respect to the circumferential anisotropy. As H_{ex} is increased and the rotational portion of the remagnetization grows, there is a gradual transition from almost a square loop to a linear one[1–3] as can be seen in Fig. 1. This process is accompanied by rapid reduction in the circumferential permeability μ_φ. In Ref. 9 the change in hysteresis loops under the influence of H_{ex} was considered for a practical case of a nonuniform circumferential anisotropy. The result for the maximal differential permeability as a function of H_{ex} for different averaged anisotropy axis inclinations, $\Delta\alpha$, relative to the circular direction, is presented in Fig. 2. For some optimum values of $\Delta\alpha$, the permeability sensitively decreases with increasing h for $h=H_{ex}/H_K<1$. For higher fields ($h>1$) corresponding to the longitudinal saturation, the permeability slowly decreases, being consistent with the pure rotational magnetization. The proper anisotropy can be established by corresponding tension annealing.[3]

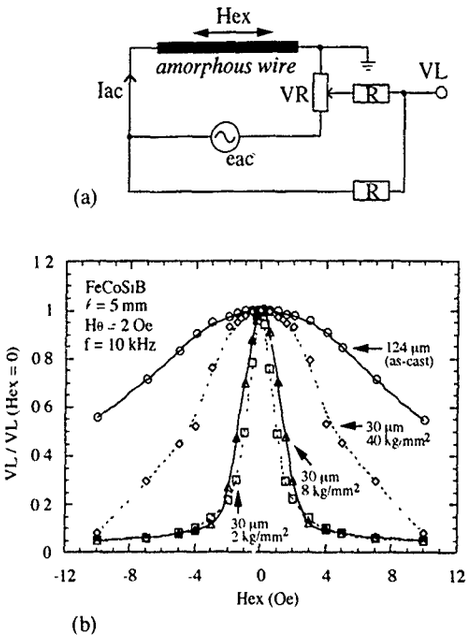

FIG. 3. Experimental circuit for measurement of V_L (a), and reduced amplitude of that voltage plotted as a function of H_{ex} for as-cast and tension annealed amorphous wires (b)

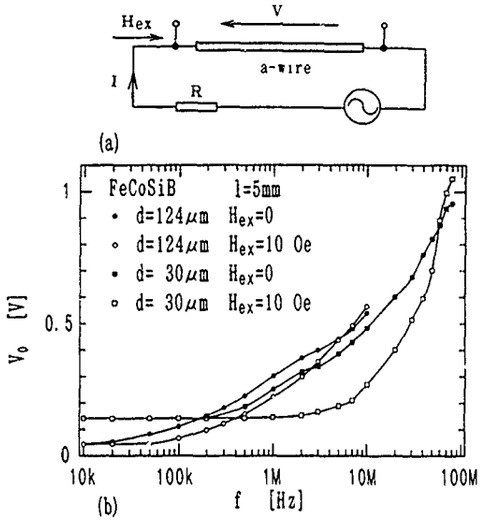

FIG. 4. Experimental circuit (a) and measured frequency dependencies of the voltage amplitude with H_{ex} as a parameter for a 124 μm diameter as-cast wire and a 30 μm diameter tension annealed wire (b).

III. EXPERIMENTAL RESULTS

The unique circumferential magnetic properties of FeCoSiB amorphous wires are attractive for the application of those wires as a sensitive flux detection element, since the change in the circular magnetization due to an ac wire current affects the voltage across the wire ends. In the case of a relatively low frequency current, when the skin effect is negligible, the change in the circular magnetic flux is considered to generate an additional inductive voltage,[15] V_L, which is determined by the internal part of the self inductance of a wire, $L_i = l\mu_\varphi/2$, where μ_φ corresponds to the averaged differential permeability and l is the wire length. The magnetoinductive effect can be measured by utilizing a resistor bridge circuit as shown in Fig. 3(a). A series of narrow peaks periodically spaced on the time axis then can be observed.[1–3] The peak height V_{L0} sharply decreases with the application of a longitudinal magnetic field H_{ex} by 50% at relatively low fields of 2–10 Oe as can be seen in Fig. 3(b). The sharp form of V_L is consistent with the nearly rectangular hysteresis loop for $H_{ex}=0$. There is also a consistency between the experimental dependencies $V_{L0}(H_{ex})$ and calculated dependencies for the maximum permeability $\mu_\varphi(H_{ex})$ shown in Fig. 2. Theoretical curves 2,3 characterized by a smaller anisotropy axis distribution $\Delta\alpha$ correspond to those seen in the case of tension annealed wires with a stronger circumferential anisotropy. Curve 1 is typical for as-cast wires with much broader anisotropy axis distribution.

It was proposed in Refs. 5 and 6 to utilize a high frequency current for which the total wire voltage is sensitive to the magnetic field. As the frequency is increased above some characteristic value ω^*, the amplitude V_0 of the total wire voltage increases as seen in Fig. 4. The value of ω^* increases with the application of the field as well as for a smaller diameter wire ($\omega^*/2\pi$ is about 20 and 200 kHz for 120 and 30 μm diameters, respectively, at $H_{ex}=0$). Such behavior shows that the skin effect is of predominant importance. At frequencies above $\omega^*(H_{ex}=0)$ there is a big difference between the behaviors of $V_0(\omega)$ for $H_{ex}=0$ and in the presence of the field. As a result, for a given frequency above this critical value the voltage amplitude decreases sensitively with the application of the field. For example, a drop in voltage by 50% can be reached by applying a field of about 10 Oe for a 30 μm diameter amorphous wire as seen in Fig. 5. The cut-off frequency of H_{ex} is 1/10 that of the ac wire current.

Figure 6(a) compares the wave forms for a magnetizing current at 1 MHz and the voltage at zero external field and a field of 10 Oe. The wave form of the voltage at zero field clearly exhibits a nonlinear behavior, supporting the idea that at high frequencies the magnetization processes such as domain wall displacement affect the total wire voltage. The voltage form, however, is not so far from the sinusoidal one (especially at higher frequencies), probably because the domain walls are already quite damped by eddy currents. Therefore the concept of a complex impedance $\hat{Z}=Z'+jZ''$, as the ratio between the harmonic complex voltage and cur-

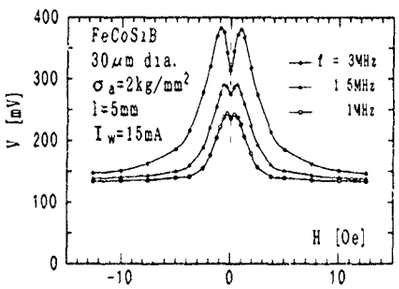

FIG 5. Voltage amplitude as a function of H_{ex} at various current frequencies for 30 μm diameter tension annealed wires.

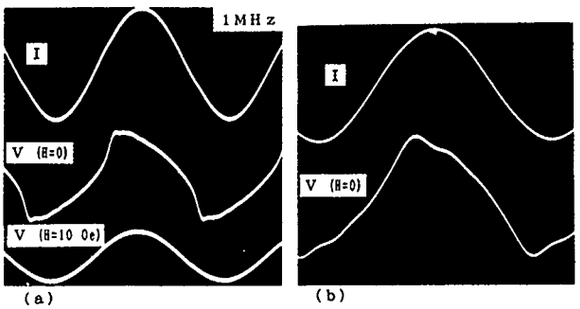

FIG. 6. Wave forms of current and voltage at different fields in (a) and frequencies in (b).

rent, can be employed to describe the observed effects at higher frequencies. Thus, the decrease in the wire voltage by applying the longitudinal field means the corresponding change in $\hat{Z}$. In this sense the effect was named as a magneto-impedance effect.

A giant **MI** effect can be found in various soft magnetic materials. However, in the case of a longitudinal (along the current and field direction) magnetic structure the **MI** effect is less sensitive and observed for higher fields, as in the case of FeCoSiB amorphous ribbons.[8] We measured the **MI** effect in ribbons of a composition $Fe_4Co_{67}Mo_2Si_{15}B_{10}$ as shown in Fig. 7. The voltage drop by 15%–20% is observed for fields of 20–30 Oe.

IV. IMPEDANCE OF A MAGNETIC WIRE

In this section we consider the field dependence of the complex impedance of a magnetic conductor. All the results are given for a wire with a circular domain structure since at present the main experimental data have been obtained in such materials. We employ Gaussian units.

A. Low frequency case

Let us consider a wire in which an ac current $I=I_0\exp(-j\omega t)$ is flowing. The current generates a circular magnetic field $H\varphi$ which magnetizes the wire in the circular direction. This circular magnetization affects the voltage across the wire ends. At low frequencies, when the skin effect is negligible, it is simply written as

$$V=RI+\langle E_z\rangle l. \tag{1}$$

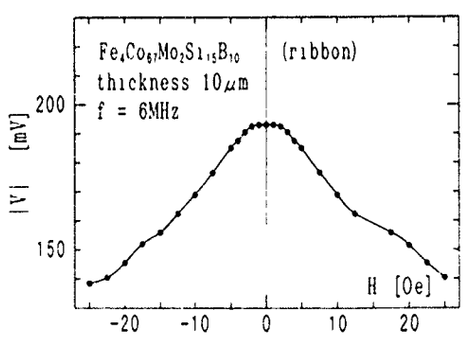

FIG 7 Magneto-impedance effect in $Fe_4Co_{67}Mo_2Si_{15}B_{10}$ amorphous ribbons of 10 μm thickness.

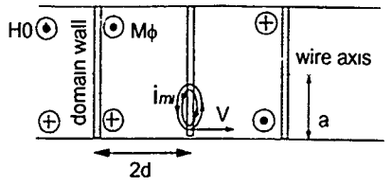

FIG. 8. Circular domain model for eddy current distribution calculations.

Here R is the ordinary resistance, and $\langle E_z\rangle$ is the averaged electric field due to change in the circular magnetization caused by $H_\varphi=2Ir/ca^2$:

$$E_z(r)=-\frac{j\omega}{c^2}I\int_0^r\frac{2r'\,dr'}{a^2}\mu_\varphi(r'),\quad r\leqslant a, \tag{2}$$

where a is the wire radius, μ_φ has to be defined as a differential permeability $\mu_\varphi=dB_\varphi/dH_\varphi$. Averaging Eq. (2) over the wire cross section allows us to represent Eq. (1) in a standard form $V=\hat{Z}(\omega)I$ using the wire impedance

$$\hat{Z}=R-j(\omega/c^2)L_i,\quad L_i=2l\left\langle\int_0^r\mu_\varphi r'\,dr'/a^2\right\rangle. \tag{3}$$

It follows from Eq. (3) that at a low frequency the field dependence of the impedance is attributed to its inductive term which is proportional to the differential circumferential permeability.

B. High frequency case

We can expect that with increasing frequency the dependence of $\hat{Z}$ on the field becomes more essential. In the case of thin wires with homogeneous magnetization changing linearly with an ac magnetizing field, the impedance can be calculated exactly for any frequency, i.e., without neglecting the skin effect:[16]

$$\hat{Z}=-(j\omega/c^2)L_e+RkaJ_0(ka)/2J_1(ka),$$
$$k=(1+j)/\delta_m,\quad \delta_m=c/\sqrt{2\pi\omega\sigma\mu_\varphi}, \tag{4}$$

where $L_e=2l\ln(l/a)$ is the external part of the self inductance of the wire, δ_m is the penetration depth in a magnetic media with the linear permeability μ_φ, σ is the conductivity, and J_0, J_1 are Bessel functions. In the case of a strong skin effect $a/\delta_m\gg 1$, the high frequency expansion of Eq. (4) gives

$$\hat{Z}=R(a/2\delta_m)-j\omega[L_e+L_i(2\delta_m/a)]/c^2. \tag{5}$$

It follows from Eq. (5) that at high frequencies (but L_e can be still neglected) $\hat{Z}\propto(\omega\mu_\varphi)^{1/2}$ since the penetration depth in magnetic materials depends on permeability as $\delta_m=\delta/\mu_\varphi^{1/2}$ [$\delta=c/(2\pi\omega\sigma)^{1/2}$ is a nonmagnetic penetration depth] and the internal inductance is proportional to μ_φ. Thus, in the high frequency region, when the skin effect can not be ignored, the total impedance of a magnetic wire is proportional to the root of the circumferential permeability.

This simple consideration already gives the idea of the **MI** effect and is helpful for the understanding of the experimental data described in Sec. III. However, for a quantitative comparison we have to consider the dynamic character of the

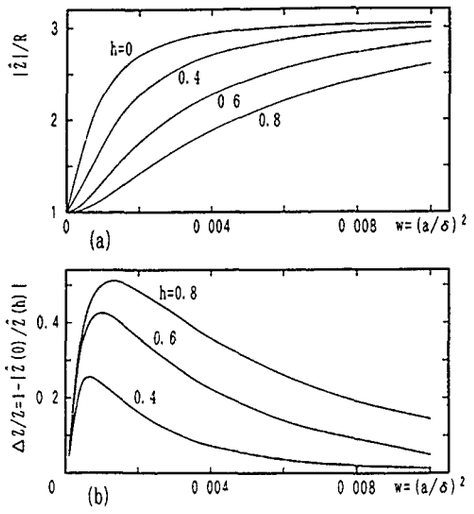

FIG. 9. Frequency dependence of the impedance $[|\hat{Z}|/R$ in (a), and $\Delta Z/Z = 1-|\hat{Z}(h)/\hat{Z}(0)|$ in (b)] with $h=H_{ex}/H_K$ as a parameter. The calculation was done with the theoretical dependence $\mu_\varphi(H_{ex})$ shown in Fig. 2 by curve 3, $\mu_\varphi(H_{ex}=0)=10^4$, $d/a=1/3$, $1/\sigma=130\ \mu\Omega$ cm

magnetization process. In the case of a wire with circular domains, while $H_{ex}<H_K$, the main contribution to the circular magnetization arises from the domain wall motion which generates local eddy currents. In Eq. (4) we ignored these microscopic currents. However, they are known to result in the excess losses[17] and damped domain wall movement. The exact calculation of the total current distribution inside the wire (due to the outer shape and domain wall displacements) cannot be done analytically. This problem can be considered in the effective medium approximation[18,19] in which the microscopic eddy currents i_{mi} are averaged on the domain wall scale. Then classical expression (4) for the impedance can be still used but with the effective permeability $\tilde{\mu}_\varphi$ incorporating i_{mi} and substituting for μ_φ.

The effective magnetic permeability depends on a concrete type of the domain structure. The calculation of $\tilde{\mu}_\varphi$ can be done by considering that the wall motion generating the eddy current field H_{mi} occurs under the influence of the averaged field $\langle H\rangle$ which includes some external field H^0 and the field H_{mi}. Then, if the eddy current field is known, we have the self-consistent condition to calculate $\tilde{\mu}_\varphi: \tilde{\mu}_\varphi H^0=\langle\mu_\varphi(H^0+H_{mi})\rangle$. The analytical solution for the eddy current field distribution is known for some simple domain structures as in the case of a sheath with periodical bar domains.[20] Recently an analytical result has been obtained for a wire with circular domains around it with a periodic spacing $2d$, as shown in Fig. 8. In this case, which is a prime interest here, the effective permeability can be written in the form[10]

$$\tilde{\mu}_\varphi=\mu_\varphi/(1-j\omega/\omega_{rel}), \tag{6}$$

$$\omega_{rel}=c^2/16\pi\mu_\varphi\sigma ad\sum_n g_n, \tag{7}$$

$$g_n=\left(\int_0^{\lambda_n} xJ_1(x)dx\right)^2 \coth(\lambda_n d/a)/\lambda_n^5 J_2^2(\lambda_n),$$

where ω_{rel} is a characteristic relaxation frequency, λ_n are such that $J_1(\lambda_n)=0$. The series in Eq. (7) is rapidly converging and is equal to 0.053 for $d\geqslant a/3.8$. From Eqs. (6) and (7) it follows that if the initial permeability μ_φ is a function of the magnetic field, the parameter $\tilde{\mu}_\varphi$ will also sensitively depend on the field while $\omega<\omega_{rel}$. In the limit $\omega\gg\omega_{rel}$ the effective permeability tends to be $\tilde{\mu}_\varphi\cong jc^2/(0.9\pi ad\omega)$ and is independent of μ_φ and, hence, of the field.

It should be noted that the eddy current losses in the case under consideration prove to be about 3 times lower than that for a bar domain structure.[20] Due to this the permeability maintains its low frequency value till higher frequencies and the condition $\omega^*=c^2/2\pi a^2\sigma\mu_\varphi<\omega<\omega_{rel}$ is easier satisfied, in the case of a wire with circular domains.

V. MAGNETO-IMPEDANCE CHARACTERISTICS

To describe quantitatively the magneto-impedance effect in negative magnetostrictive amorphous wires we will use expression (4) which is valid for any frequency together with the frequency dependent magnetic permeability defined by Eqs. (6) and (7). For the initial permeability entering Eq. (6) we will use the result of Ref. 9 shown in Fig. 2. We can assume that those field dependencies are valid for the linearized permeability as well.

First, let us investigate a high frequency $(a/\delta_m\gg 1)$ expansions of the impedance, substituting the complex permeability in Eq. (5),

$$\hat{Z}=R(a/2\delta)(\sqrt{\mu_R}-j\sqrt{\mu_L})-j\omega L_e/c^2,$$
$$\mu_R=|\tilde{\mu}_\varphi|+\tilde{\mu}''_\varphi,\quad \mu_L=|\tilde{\mu}_\varphi|-\tilde{\mu}''_\varphi. \tag{8}$$

It follows from Eq. (8) that at high frequencies such that $\omega^*<\omega<\omega_{rel}$ both the resistive and inductive components of $\hat{Z}$ depend on the permeability and contribute to the dependence of $\hat{Z}(H_{ex})$. At $\omega/\omega_{rel}\gg 1$ the ratio $\mu_L/\mu_R\approx(\omega_{rel}/2\omega)^2$ and tends to be zero, so the wire behaves as a resistive element (see experimental wave forms in Fig. 6). However, under this condition the dependence of $\hat{Z}$ on H_{ex} disappears since the permeability becomes independent of the field.

The frequency dependence of the impedance in the presence of the external field is shown in Fig. 9. We use the reduced frequency $w=(a/\delta)^2$. The reduced external field $h=H_{ex}/H_K$ is chosen to be $h<1$ since we are concerned with the permeability associated with domain wall displacement. Figure 9(a) shows the module of the impedance $|\hat{Z}|$ as a function of w. The considerable field dependence occurs in some frequency range $1<w\mu_\varphi<\omega_{rel}/\omega^*$ where the skin effect is suitable but the magnetic permeability μ_φ still has relatively high values. As a result, the relative change in the impedance $\Delta Z/Z=1-|\hat{Z}(H_{ex})/\hat{Z}(0)|$ by the external field has a maximum which achieves 50% at $h=0.8$ as shown in Fig. 9(b). Such impedance behavior is consistent with the experimental results. In Fig. 10 the **MI** ratio $\Delta Z/Z$ is compared with the experimental data obtained on amorphous wires of different diameters, showing a satisfactory agreement. In accordance with the skin effect, the maximum of $\Delta Z/Z$ shifts to lower frequencies for a larger diameter wire.

In Fig. 11 the field dependence of $\Delta Z/Z$ is shown for some frequencies. The plot is shown symmetrically since the

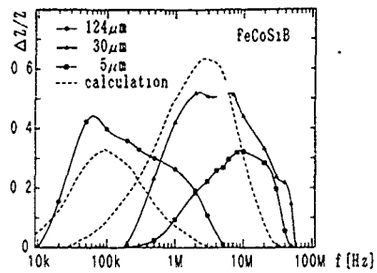

FIG. 10. Experimental and calculated frequency dependencies of $\Delta Z/Z$ at H_{ex}=10 Oe for a 124 μm diameter as-cast wire [$\mu_\varphi(H_{ex}=0)$=9800] and a 30 μm diameter tension annealed wire [$\mu_\varphi(H_{ex}=0)$=13 000]. The data for a 5 μm diameter wire obtained by etching are shown for a comparison.

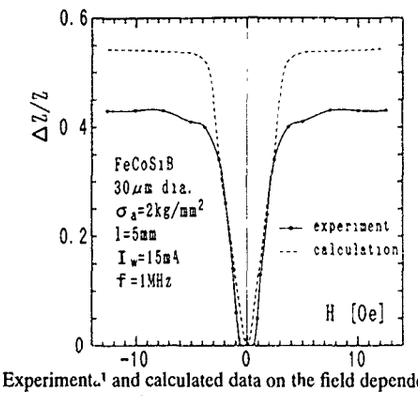

FIG. 12. Experimental and calculated data on the field dependence of $\Delta Z/Z$ for a 30 μm diameter tension annealed wire.

static permeability does not exhibit hysteresis with respect to h. Here the case of $h>1$ is considered as well. At such fields, a wire is longitudinally magnetized and the circumferential permeability is associated with only the magnetization rotation. In the frequency range under consideration it can be assumed to be frequency independent. The **MI** ratio rapidly increases at fields lower than the anisotropy field H_K ($h<1$), and it increases little at fields higher than H_K ($h>1$). Such behavior reflects the field dependence of the static permeability that was used for the impedance calculation (curve 3 in Fig. 2). In Fig. 12 the experimental and calculated curves are shown for a 30 μm diameter tension annealed wire, showing a reasonable agreement.

It should be noted, that with increasing frequency the rotational permeability becomes important even at $h<1$, since the wall motion becomes more and more damped. The longitudinal field stimulates the rotational process while $h<1$, and the corresponding permeability has a maximum at $h=1$. This tendency can be seen in Fig. 5 for higher frequencies.

VI. CONCLUSION

We can conclude that the magneto-impedance effect has a classical electromagnetic origin and is a general phenomenon in soft magnetic conductors. At high frequencies when the skin effect is strong, the impedance is subject to the current distribution which sensitively depends on the transverse magnetic properties. The most sensitive magneto-impedance effect can be expected in soft magnetic materials with domain walls perpendicular to the current and external field direction. In this case the change in $\hat{Z}$ of the order of 50% can be reached with fields of the order of the anisotropy field. This configuration is realized in negative magnetostrictive amorphous wires having a circular domain structure.

Very large magneto-impedance in amorphous soft ferromagnetic wires (invited)

K. V. Rao, F. B. Humphrey,[a] and J. L. Costa-Krämer
Department of Condensed Matter Physics, Royal Institute of Technology, Stockholm, Sweden

Changes in the impedance, ≈600%/Oe, at axial fields less than 1 Oe nave been observed in the presence of a 90 kHz, few mA current through a soft, nearly zero magnetostrictive wire. In this 125 μm diameter CoFeSiB amorphous wire we observe a total change of 160% at the maxima of the impedance in dc fields less than 2 Oe. A systematic study of the role of induced anisotropy in the axial, circumferential, and helical directions on the magneto-impedance shows that the largest effect is seen in the wire annealed to obtain circumferential easy axis using a 15 mA ac current passing through it. Both the axial hysteresis loops and the observed *I-V* characteristics reflect the induced anisotropies. The observed dependence of the inductance change on the type of the anisotropy induced in these wires can be modeled in terms of an interplay between the induced anisotropy, reversing ac field, and the axial dc field.

I. INTRODUCTION

Recently, there has been considerable interest in the giant-magneto-resistive (GMR), phenomena observed in a wide variety of magnetic materials such as multilayers, granular, and other heterogeneous structures. For device applications a large change in GMR per Oe at room temperature and low external fields is of interest.

In this paper we elucidate the role of induced anisotropies to explain the large changes in the magneto-impedance observed[1] in a nearly zero magnetostrictive wire at external fields as low as 1 Oe. Amorphous wires, produced by injecting a melt through a continuously moving fluid,[2]develop a unique microstructure because of the axial direction in which it is cast and the homogeneous radial rapid cooling process during solidification.[3] Such transition metal based amorphous wires are found to possess unique soft magnetic properties which are already used in applications as sensors.[4] In a Co-Fe-Si-B amorphous wire with the absence of crystalline anisotropy it is now possible to tailor[5] a nearly zero magnetostrictive ($\lambda_s < 10^{-9}$) wire in which we can induce axial, circumferential, or helical anisotropies with practically no dispersion and study the response of such a system to external fields. The magne o-inductive properties found in such tailored wires are promising for developing novel low field sensors.

II. EXPERIMENT

In order to study in depth the role of the type of induced anisotropy we have specially prepared the amorphous wires in a well defined magnetic state with axial, circumferential, and helical anisotropies using the following procedure: four 45 cm long, 125 μm diameter wires of nominal composition $(Co_{94}Fe_6)_{72.5}Si_{12.5}B_{15}$, were used. Three of these were annealed in air using a current of 350 mA for 30 min. During this anneal, the field direction on each wire was carefully controlled so that a well defined induced magnetic anisotropy would develop. One wire was annealed in the presence of an axial dc field to obtain an axial anisotropy. Another was annealed with only the ac current to induce a circumferential anisotropy. The third, was annealed using a dc current in the presence of an axial dc field of such a value as to create a 45° helix at the wire surface.

The axial hysteresis loops of the wires were measured with a conventional induction technique hysteresis loop tracer. It uses a primary coil 27 cm long, 3 cm diameter, with a field to current constant of 22.9 Oe/A. A 31 Hz sinusoidal current is fed to the primary, the voltage across a resistor connected in series with the primary coil fed to the *X* channel of an oscilloscope. The voltage induced in a 1000 turn 0.8 cm long secondary, properly compensated for the applied field, is integrated and displayed in the *Y* channel of the oscilloscope where the longitudinal hysteresis loops are monitored.

The *I-V* characteristics of the wires were studied passing an ac current through the wire and a resistor connected in series. We use an oscilloscope to visualize the voltage across 35 cm of the amorphous wire against the voltage across the resistor. The current through the wire creates a circumferential field of about 0.031 Oe per mA at the surface. An FFT spectrum analyzer, model SR760 from Stanford Research Systems, was used to measure the different spectral components of the magneto-impedance. In this work we present the amplitude of the first harmonic of the voltage as a function of the axial field for the above mentioned wires.

III. RESULTS AND DISCUSSION

In Fig. 1 the longitudinal hysteresis loops for the amorphous wires as-quenched, and annealed under different conditions are displayed. The saturation magnetization value for the wire is found to be about 5700 G. The as-quenched wire [Fig. 1(A)] reaches magnetic saturation at a field of about 0.5 Oe with $M_r/M_s \approx 0.61$. The axial anisotropy wire [Fig. 1(B)] clearly displays an axial easy direction of the magnetization ($M_r/M_s \approx 1$) with H_c of about 0.035 Oe. The wire with circumferential anisotropy [Fig. 1(C)] exhibits a hysteretic loop typical when a magnetic field is applied along a hard axis direction ($M_r/M_s \approx 0$) with H_k of about 1.3 Oe. The wire with induced helical anisotropy [Fig. 1(D)] displays a loop with an intermediate behavior for which

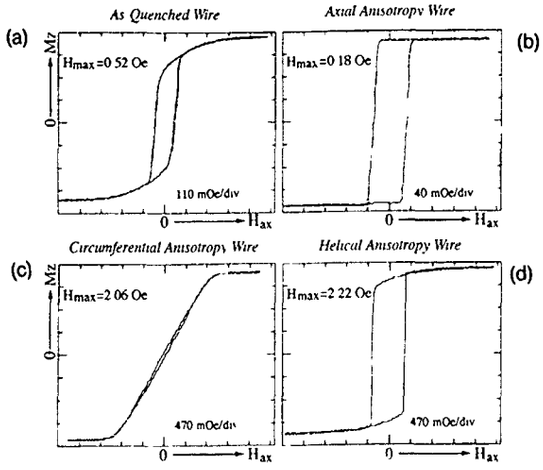

FIG. 1. Longitudinal hysteresis loops for $(Co_{94}Fe_6)_{72.5}Si_{12.5}B_{15}$ wire in the (A) as-quenched, and current annealed under different conditions for induced (B) axial anisotropy, (C) circumferential anisotropy, and (D) helical anisotropy.

$M_r/M_s=0.85$ which corresponds to an average orientation of the magnetization of 32° with respect to the axis. If we assume a 45° orientation of the magnetization at the surface, which decreases monotonically as we proceed radially inwards, to an axial orientation at the center of the wire, we estimate a theoretical average angle to be 30.7°, which is quite close to the measured value of 32°. This wire axially saturates at an external field of about 1.5 Oe.

The frequency dependence of the *I-V* characteristics at zero applied axial magnetic field for the same wire is shown in Fig. 2. On the vertical axis we display the voltage across 35 cm of wire and, on the horizontal axis, the voltage across a resistor in series with the wire which is proportional to the current amplitude value. As observed, at low frequencies in all cases the resistive (linear and reversible) component of the impedance dominates. The slope of this linear part is related to the dc resistance of the wire (about 35 Ω). As the frequency of the ac current is increased, the inductive component of the impedance develops. Notice that the *I-V* loop closes at the current amplitude which saturates the sample along the circumferential direction, proportional to the circumferential anisotropy field. Accordingly, the area under the inductive peak should be proportional to the frequency of the excitation and the amount of circumferential flux which is being switched. The position of the maximum of the peak in the inductive component provides us with the circumferential coercive field at which the maximum flux change takes place.

As seen in Fig. 2(A), the as-quenched wire has a small inductive component of the impedance even for 100 Hz fre-

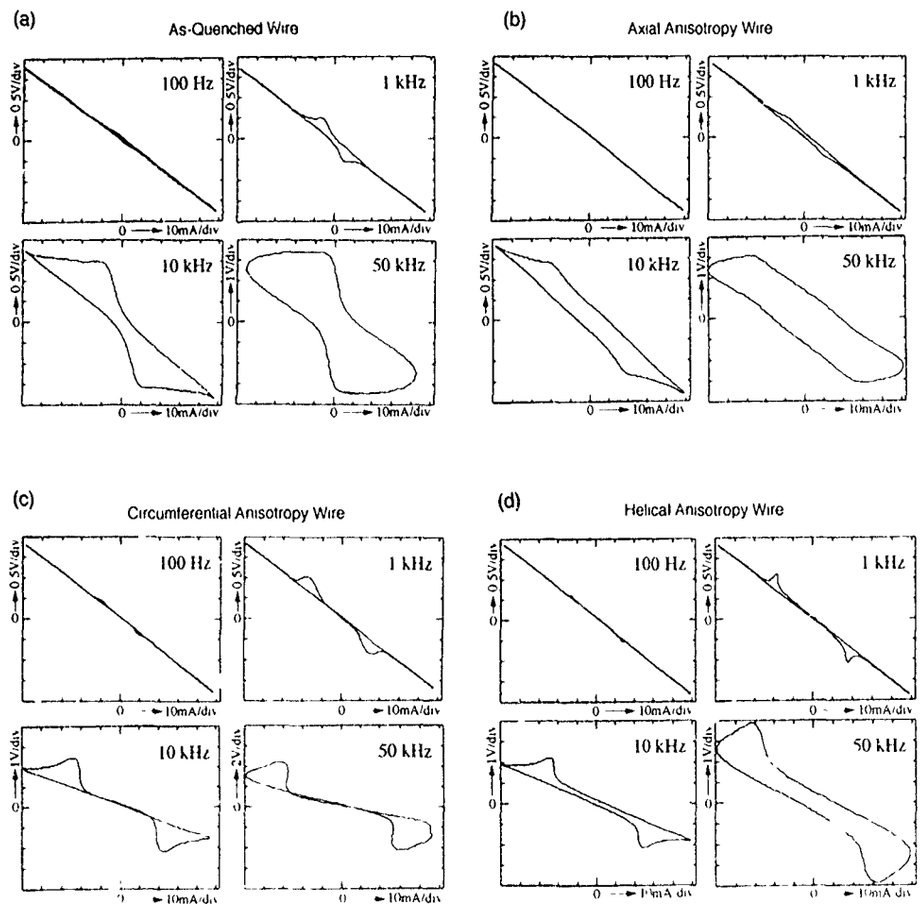

FIG. 2. Frequency dependence of the *I-V* characteristics for $(Co_{94}Fe_6)_{72.5}Si_{12.5}B_{15}$ wire in the (A) as-quenched, and current annealed under different conditions for induced (B) axial anisotropy, (C) circumferential anisotropy, and (D) helical anisotropy.

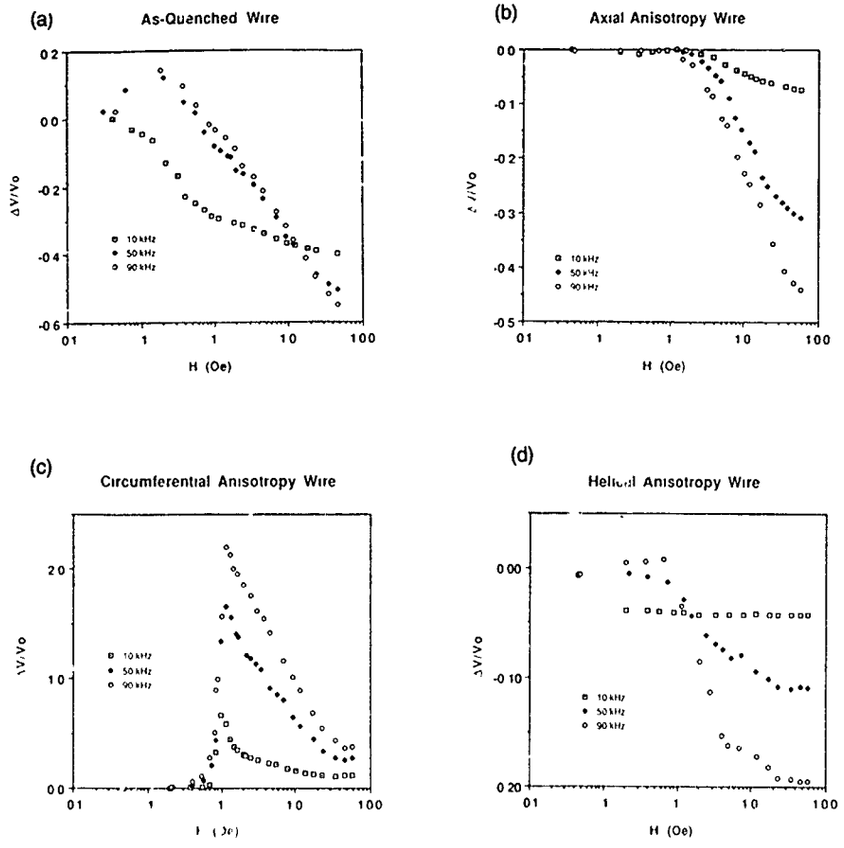

FIG. 3. Magneto-impedance measured with 3 mA at 10, 50, and 90 kHz for $(Co_{94}Fe_6)_{72.5}Si_{12.5}B_{15}$ wire in the (A) as-quenched, and current annealed under different conditions for induced (B) axial anisotropy, (C) circumferential anisotropy, and (D) helical anisotropy.

quency. On increasing the frequency of the current, the inductive component grows and is displaced toward higher current values, indicating the displacement of the circumferential coercive field as we increase the frequency of the excitation. This is concomitant with a decrease of the circular susceptibility. For the induced axial anisotropy wire [Fig. 2(B)] we do not observe a significant inductive component of the impedance at 100 Hz. In a similar fashion to the as-quenched wire, the inductive component increases as the current frequency is increased. The wire with circumferential anisotropy [Fig. 2(C)] displays the inductive bumps separated by a central linear and reversible part up to 50 kHz current frequency. This suggests the existence of a critical circumferential switching field below which there is no significant circumferential flux change and accordingly no axial inductive voltage. At a threshold the circumferential magnetization switches, as noticed by the appearance of the inductive component of the voltage. Notice also that, as before, the inductive component of the impedance displaces to higher current amplitude values on increasing the current frequency. For the wire with induced helical anisotropy [Fig. 2(D)] we observe a mixture of the previous two behaviors, i.e., a displacement of the inductive peaks plus a broadening of the *I-V* loop. The observed behavior could be viewed as a mixture of the axial and circumferential *I-V* characteristics.

The inductive component shown in the various wires of Fig. 2 can be identified by using an axial field. In all the wires, when a 100 Oe axial field is applied, each of the curves collapse to a diagonal resistive line. The inductive component disappears, leaving pure resistive behavior. Consequently, the deviation from the resistive behavior at a given frequency and amplitude of the current, provides a measure of the magnitude of the impedance change from zero to saturation.

We now discuss the evolution of the magneto-impedance in the wire with a well tailored anisotropy. The actual field evolution of the voltage between the ends of the wire depends both on the amplitude of the ac current and on the magnetic anisotropy. In. Fig. 3 the amplitude of the fundamental of the impedance as a function of the axial dc field is presented at three different frequencies (10, 50, and 90 kHz) when a 3 mA ac current is flowing through the wires with different induced anisotropies. A 3 mA current flowing through the wires creates a maximum circumferential field at the surface of about 0.1 Oe. This field will try to oscillate the magnetization circumferentially. The amount of flux change (and accordingly the axial inductive voltage) will depend on the magnitude and relative orientation of the anisotropy and the applied ac field. It will also depend on the magnetic softness of the material which in amorphous materials is primarily determined by the magnitude and sign of the magnetostriction. On applying an axial field, we modify the zero field domain structure tilting the average magnetization toward the axis, and, consequently, change the relative orien-

tation of the average magnetization to the applied circumferential field, resulting in the magneto-inductive voltage changes. This voltage change will thus reflect the change of circular susceptibility at the frequency of the excitation as we proceed towards axial saturation, in the external field.

For the as-quenched wire [Fig. 3(A)] at 10 kHz we observe a continuous decrease of the inductive voltage as a function of the axial field, demonstrating partly a decrease of the circular susceptibility as we align the magnetization axially. On increasing the current frequency the inductive voltage first increases and then decreases. This may be caused by an increase in the average circular susceptibility at that frequency values as we align the magnetization axially. At high enough axial field values a pure resistive behavior is expected, the magneto-impedance is then saturated.

The axial anisotropy wire [Fig. 3(B)] displays the magneto-impedance at the three selected frequencies. Below 1 Oe there is no significant change of the magneto-impedance. As the field increases further, the magneto-impedance starts to decrease, demonstrating the reduction of the amplitude of the circumferential flux oscillations created by the current's self-field.

In the case of the circumferential anisotropy wire, the magnetization is oriented circumferentially in the demagnetized state. Below the circumferential critical switching field there is no circumferential flux change [central part of the *I-V* characteristic, Fig. 2(C)]. However, the situation changes on applying an axial field. When the applied axial field overcomes the effect of the circumferential anisotropy, the magnetization will rotate toward the axial direction. The circumferential susceptibility is expected to increase. The magneto-impedance data for this wire [Fig. 3(C)] is consistent with this picture. A sharp rise in the inductive component of the impedance at about 0.8 Oe, reaching a maximum value at about 1 Oe is observed. On increasing the axial field further, the circular susceptibility decreases, eventually to zero resulting in no inductive voltage. Notably, the maximum change in the impedance is 220% at 90 kHz, with a maximum slope at field values between 0.8 and 1.1 Oe of about 300%/Oe!

The magneto-impedance for the helical anisotropy wire [Fig. 3(D)] displays a behavior qualitatively similar to the as-quenched wire with a lower axial saturation field. At 10 kHz current frequency a continuous decrease of the voltage is observed as the axial dc field is raised, while at higher frequencies the initial slope tends to be positive. The low axial saturation field of the magneto-impedence might be explained in terms of a smaller circumferential susceptibility, as compared with the as-quenched wire case at the same current value. The axial field required to stop the magnetization oscillations in the circumferential direction is accordingly smaller.

The remarkable magneto-impedance behavior for the wire with circumferential anisotropy, can be seen in more detail in Fig. 4. The relative change in voltage is seen as a function of the axial field for different ac currents through the wire at a constant frequency of 90 kHz as a parameter.

As the amplitude of the ac current is increased [see Fig. 4(A)], the impedance threshold is displaced to lower axial

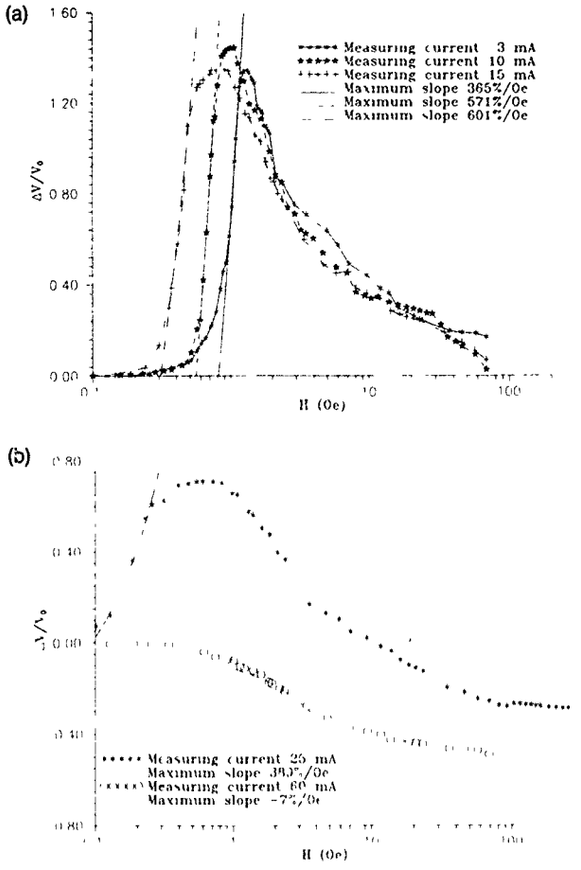

FIG. 4. Dependence of the magneto-impedance on the current amplitude at 90 kHz for a $(Co_{94}Fe_6)_{72.5}Si_{12.5}B_{15}$ wire with induced circumferential anisotropy at (A) 3, 10, and 15 mA and (B) 25 and 60 mA.

fields. This can be understood in terms of the balance between the circumferential anisotropy, the applied axial dc and circumferential ac fields. As the amplitude of the ac circumferential field is increased, the dc field required to tilt the magnetization such that the ac circumferential field manages to set the magnetization to oscillate in the circumferential direction is decreased. On increasing the current amplitude further [as seen in Fig. 4(B)], a value is reached for which all the circumferential flux is oscillating at zero axial field. When this value is reached, the behavior of the magneto-impedance changes to a continuous decrease in amplitude as the axial field is increased as shown by the open circles (60 mA).

IV. CONCLUSIONS

Current annealing proves to be a powerful method to tailor magnetic responses, particularly the magneto-impedance, of amorphous soft ferromagnetic wires.

The magneto-impedance effect has been studied in low magnetostrictive amorphous wires with different easy magnetization axes. The observed current, frequency, and axial field dependencies of the magneto-impedance support the view of an effect related to the soft magnetic properties of

the wire, i.e., voltage changes caused by large circular magnetic flux variations driven by the field generated by the current.

The nature of the magnetic anisotropy is an essential ingredient in the description of the effect. The field and current dependencies of the magneto-impedance are markedly different for axial and circumferential anisotropies, i.e., domain orientations parallel and perpendicular to the applied dc field. As expected, the characteristics of the changes in the impedance are found to be maximum in the wire with induced circumferential magnetic anisotropy. A maximum change of +220% in the impedance value at an external field of about 1 Oe, and a slope of 600%/Oe at axial field values below 1 Oe in the presence of a 15 mA, 90 kHz current are found in this wire. A quantitative analysis of the magneto-impedance and its dependence on the applied external dc fields in the presence of ac currents through the wires will be presented elsewhere.

Sensitive field- and frequency-dependent impedance spectra of amorphous FeCoSiB wire and ribbon (invited)

R. S. Beach and A. E. Berkowitz[a)]
Center for Magnetic Recording Research, University of California, San Diego, La Jolla, California 92093

Conflicting reports of large magnetoresistive and magnetoinductive effects in amorphous FeCoSiB wires and ribbons prompted the impedance measurements reported here. The spectra ($0 \leq f \leq 3.2$ MHz) were obtained at room temperature using a commercial impedance analyzer both as functions of axial magnetic field ($-140 < H_A < 140$ Oe) and sense current ($1 \leq I_{rms} \leq 60$ mA). The phase shift due to the test leads was carefully measured and subtracted from the raw data to resolve the spectra into resistive $R(f)$ and reactive $X(f)$ components. We find for the $Fe_{4.3}Co_{68.2}Si_{12.5}B_{15}$ wire (120 μm diameter) and ribbon (20 μm thick) that both $R(f)$ and $X(f)$ depend strongly on frequency and magnetic field. For $H_A=0$, each component increases monotonically with frequency, with $R(f=0) \approx 1$ Ω/cm and $X(f=0)=0$. In high fields ($H_A=140$ Oe), $R(f)$ and $X(f)$ are nearly frequency independent. The field-dependent response is sharply peaked about $H_A=0$; the full width at half maximum is FWHM$\leq$20 Oe, typically. The change in $R(f)$ and $X(f)$ between these two extremes is extraordinarily large; 4.5 Ω/cm at $f=1$ MHz is a typical value for the wire. The sensitivity of the magnetoresistive response is 44% of the dc resistance per Oe for $f=1$ MHz. Qualitatively similar phenomena were observed for the $Fe_{7.5}Co_{67.5}Si_{15}B_{10}$ ribbon, although the field and frequency dependences of the spectra are less pronounced than for the wire. We discuss a model which describes the spectra quantitatively, using classical electrodynamics.

I. INTRODUCTION

In spite of the fact that amorphous ferromagnetic materials have zero magnetocrystalline anisotropy, magnetic isotropy has not been attained in the laboratory. The small, yet finite coercivities, permeabilities less than simple theoretical predictions, and the unusual domain structures characteristic of these materials demonstrate the presence of anisotropy despite their amorphous microstructure. It is generally believed that the anisotropy observed in amorphous ferromagnets is predominantly due to magnetostriction. Magnetostriction anisotropy is governed by the alloy composition, which determines the value of the magnetostriction coefficient λ, and stress fields which result from the fabrication process. Amorphous ferromagnetic wires are produced by quenching a molten stream in water. This process results in wires with a radially directed stress field and, consequently, anisotropy fields that are either radial or circumferential, depending on the sign of λ.

Due to their potential uses in transformers and transducers, the magnetic properties of amorphous ferromagnets in the frequency domain have been studied extensively. These materials typically exhibit high permeabilities and low losses, characteristics desirable for many high-frequency applications. The permeability, in particular, is dependent upon the anisotropy field, the domain structure, and the magnitude and topology of the magnetic field acting on the material.

Recent work by the authors,[1] by Mohri and co-workers,[2] and several others[3–5] has focused on ac electrical transport phenomena in amorphous FeCoSiB alloys. These researchers have demonstrated firstly that the impedance $Z(f)=R(f)+iX(f)$ of certain amorphous wire and ribbon samples is a very strong function of the frequency f of the drive current, and secondly, that this strong frequency response can be virtually eliminated by the application of a magnetic field H_A of the order of 10 Oe. Such amorphous materials have the potential to be used as simple, extremely sensitive magnetic field detectors.

In our research, we have found that a sensitive magnetoresistance $R(f,H_A)$ accompanies the previously observed[2] field-dependent reactance $X(f)$ of amorphous FeCoSiB wires. At room temperature and for $f \geq 3$ MHz, the net magnetoresistance exceeds 600% of the dc wire resistance. This large response enables us to detect changes in the applied field of less than 0.001 Oe. The impedance spectra of as-cast FeCoSiB ribbon have also been measured, and we observe field-dependent effects that are of the same order of magnitude, but somewhat smaller than those for wires. For the case of wires, we are able to fit the spectra to a straightforward model that is based on classical electrodynamics.

II. EXPERIMENTAL

All of the data presented herein were obtained using a Schlumberger 1260 impedance analyzer running in constant current amplitude mode. The FeCoSiB ribbon and wire samples were first cut to lengths of 3 cm and cleaned in a solution of HCl and ZnCl. Two current leads were attached to the ends of the samples, and two voltage leads, 1.4 cm apart, were attached between these. All the connections were made with Ag paint. The contact resistances were less than 1 Ω. The samples were mounted inside a grounded chassis box which was connected to the analyzer with four coaxial cables. The cables were roughly 40 cm long and permitted the samples to sit within a Helmholtz coil (diameter 30 cm), which produced a dc magnetic field -140 Oe$<H_A<140$ Oe

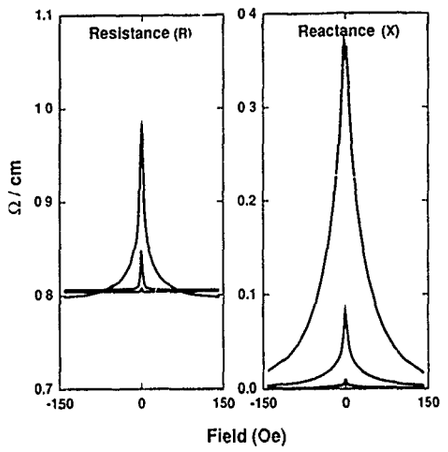

FIG. 1. The impedance of an amorphous $Fe_{75}Co_{67.5}Si_{15}B_{10}$ ribbon $Z=R+iX$ vs magnetic field ($-140<H_A<140$ Oe) for three sense current frequencies, $f=10$ kHz, 100 kHz, and 1 MHz. The peak at $H_A=0$ grows dramatically with increasing f. Note also the frequency dependence of the peak widths.

along the lengths of the samples. The samples were aligned with their long axes (parallel to the current) normal to the earth's magnetic field. All the data were collected at room temperature.

The measured impedance spectra $Z(f,H_A)$ were resolved into resistive R and reactive X components by subtracting the previously determined impedances of the instrumentation and test leads from the raw data. This null correction amounted to approximately 10% of the measured wire signal for $f=1$ MHz. Frequency sweeps (100 Hz$<f<$3 MHz) and current amplitude sweeps (0.5 mA$<I_{rms}<$60 mA) were controlled by computer. Field sweeps were performed manually. The applied field had no direct observable effect on the experimental apparatus.

III. IMPEDANCE $Z(f,H_A)$ OF AMORPHOUS FeCoSiB RIBBON AND WIRE

A. Ribbon

In this paper we discuss the impedance spectra $Z(f,H_A)$ obtained from FeCoSiB ribbon and wire samples under the influence of an axially applied magnetic field H_A. We expect that these materials are very soft ferromagnets, with dc coercivities considerably less than 1 Oe, although this was confirmed only for the ribbon sample.

The 0.9-mm-wide by 20±3-μm-thick $Fe_{75}Co_{675}Si_{15}B_{10}$ ribbon was prepared by melt spinning by J. L. Walter of the General Electric Research and Development Center. The amorphous structure of the ribbon was verified by x-ray diffraction. The as-cast ribbon has a resistivity $\rho=145$ $\mu\Omega$ cm. It exhibits only a small anisotropic magnetoresistance of $\sim$0.1% at room temperature, and a small linear decrease of $R(H_A)$ for fields $H_A>5$ kOe. This behavior is typical of ferromagnetic $3d$ metals and alloys. In Fig. 1 we show the response of the ribbon impedance (in units of Ω/cm ribbon) to a magnetic field applied along the ribbon's length, at drive current frequencies of 10 kHz, 100 kHz, and 1 MHz. The drive current amplitude used in collecting these data was $I_{rms}=10$ mA. The dc impedance (not shown) is flat on this scale, and is purely real. For frequencies f other than zero, peaks in both the resistance R and reactance X appear, centered about $H_A=0$. Both the magnitudes *and* widths of the peaks in R and X grow monotonically with frequency. For $f=1$ MHz, the magnetoresistance ratio is $(R_{max}-R_{sat})/R_{sat}=23\%$. The dc resistance $R_{dc}=0.8$ Ω/cm is apparently equal to R_{sat}, the ac resistance in the limit of high H_A. The relative change in reactance for $f=1$ MHz is $\Delta X/R_{sat}=X_{max}/R_{sat}=46\%$. We note that the widths of the resistive and reactive responses are different. The full widths at half maximum of the resistance curves FWHM$=2\Delta H_R$ are less than those for the reactance $2\Delta H_X$ for each value of f shown. The magnitudes of these peaks ΔR and ΔX, and their widths ΔH_R and ΔH_X are given in Table I. Parameters which serve to quantify the sensitivities of the resistive and reactive responses are $(1/\Delta H_R)(\Delta R/R)$ and $(1/\Delta H_X)(\Delta X/R)$. For $f=1$ MHz, these are, respectively, 4.3%/Oe and 1.8%/Oe. We observe relatively little response in either R or X when H_A is perpendicular to the current.

TABLE I. The relative magnitudes and widths of the peaks in R and X for a $Fe_{75}Co_{67.5}Si_{15}B_{10}$ ribbon, taken from Fig. 1. The resistance for $f=0$ is $R_{dc}=0.8$ Ω/cm.

Frequency	10 kHz	100 kHz	1 MHz
$\Delta R/R$	0.4%	5.5%	23%
$\Delta X/R$	1.1%	10.1%	46%
ΔH_R	1.0 Oe	1.8 Oe	5.3 Oe
ΔH_X	3.5 Oe	7.2 Oe	25 Oe

Impedance spectra ($0<f<3$ MHz) in zero field and for $H_A=140$ Oe are displayed in Fig. 2. The zero-field reactance exhibits negative curvature for the entire frequency range, and linearly approaches a value $X=0$ at $f=0$. On the contrary, the resistance displays positive curvature up to $f=1.5$ MHz; for $f>1.5$ MHz, the curvature of $R(f)$ is negative. Similar zero-field behavior, very much smaller in magnitude, was previously observed[6] for FeCoSiMoB ribbons.

The spectra are rendered nearly completely flat by a 140 Oe magnetic field, as shown in the Fig. 2. The resistance

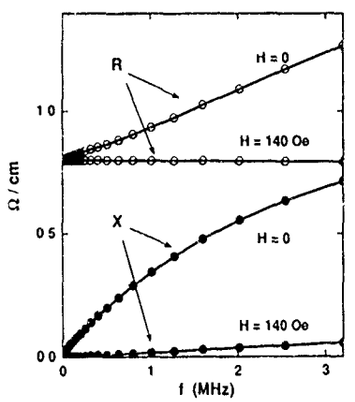

FIG 2. Impedance spectra for the amorphous $Fe_{75}Co_{675}Si_{15}B_{10}$ ribbon for zero applied field, and for an axially applied field of 140 Oe Close inspection of the figure reveals an inflection point at $f=1.5$ MHz The 140 Oe field suppresses the frequency responses almost completely

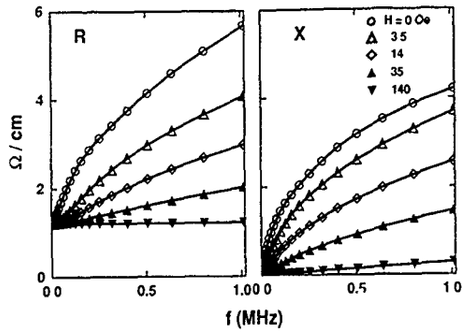

FIG. 3. Impedance spectra of a $Fe_{43}Co_{68.2}Si_{12.5}B_{15}$ wire for axially applied magnetic fields H_A=0, 3.5, 14, 35, and 140 Oe. Solid lines connect points at fixed H_A.

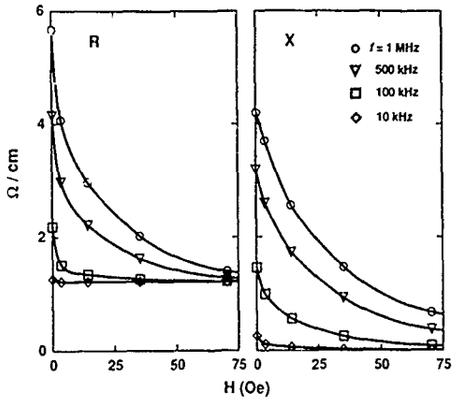

FIG. 5. Data from Fig. 3 plotted vs the applied field ($0<H_A<140$ Oe). (Data for H_A=75 Oe were not included in Fig. 3 for clarity.) We observe little difference between these data and those obtained by scanning H_A with f fixed.

$R(f)$ has no visible slope for this field. One will note a small positive slope in $X(f,H_A=140$ Oe), which is consistent with the different widths of $R(H_A)$ and $X(H_A)$ found in the field scans of Fig. 1. Note that ΔR is less than ΔX for all frequencies $f<3$ MHz. At a frequency of $f=3.2$ MHz, $\Delta R/R=59\%$ and $\Delta X/R=89\%$.

B. Wire

The nominally amorphous $Fe_{43}Co_{68.2}Si_{12.5}B_{15}$ wire sample was fabricated by the technique of quenching in rotating water[7] by the Unitika Corp. of Japan. We are grateful to R. Hasegawa for making it available to us. The wire has a 120 μm diameter, and a resistivity $\rho=135$ $\mu\Omega$ cm. Impedance spectra obtained from this sample in various axially applied magnetic fields are displayed in Fig. 3. These share many characteristics with the ribbon spectra, shown in Fig. 2. Both $R(f)$ and $X(f)$ increase monotonically with frequency, and are driven to lower values by the axial field, but the magnitudes of the responses are $\Delta R/R=370\%$ and $\Delta X/R=350\%$ for a frequency $f=1$ MHz, an order of magnitude larger than for the ribbon. Like the ribbon, $X(f)$ also exhibits negative curvature and vanishes for $f=0$, but the curvature in $R(f)$ is predominantly negative for $0<f<1$ MHz (where that for the ribbon is positive). However, as f approaches zero, the second derivative of $R(f)$ becomes positive. This behavior is clearly evident in Fig. 4, where we show $Z(f)$ for $H_A=1.4$ Oe. At higher frequency, both $R(f)$ and $X(f)$ increase as $f^{1/2}$. For $H_A=0$, the inflection point which separates the two regimes occurs for $f=60$ kHz. A $H_A=140$ Oe applied field virtually flattens the resistive frequency response ($R(f,H_A=140$ Oe)$\cong R_{sat}$), and like the ribbon, only a small positive slope remains in $X(f)$ for $H_A=140$ Oe. This particularly simple form of $Z(f)$ at high field, for which $R(f)\cong R_{sat}$ and $X(f)\cong 0$, is easily explained: when the sample is saturated, the anomalous magnetic effects disappear, and we observe flat spectra (for $0<f<1$ MHz) typical of nonmagnetic materials.

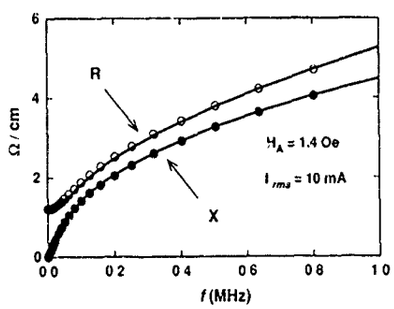

FIG. 4. The impedance spectrum $R(f)$ and $X(f)$ for the $Fe_{43}Co_{68.2}Si_{12.5}B_{15}$ wire subjected to an axial magnetic field $H_A=1.4$ Oe (the amplitude of the sense current is 10 mA rms). Note the inflection point in $R(f)$ for $f\approx 60$ kHz. The solid lines shown are a fit to Eq. (2) using two parameters.

Figure 5 shows data taken from Fig. 3 in the H_A-Z plane (we also show additional points for $H_A=75$ Oe). The lines join data obtained at a fixed frequency. The data display a pronounced increase in R and X as H_A is reduced to zero. For all values of H_A, both R and X increase with increasing frequency, and at high field tend to their respective dc limits. The widths of the curves also increase monotonically with frequency, as for the ribbon. We observe no hysteretic effects associated with sweeping frequency at fixed magnetic field, rather than sweeping field at fixed frequency. Table II displays $\Delta R/R$, $\Delta X/R$, and the widths ΔH_R and ΔH_X obtained from the wire. For $f=3.2$ MHz, $\Delta X/R=470\%$ and $\Delta R/R=620\%$. For the wire, as well as the ribbon, $\Delta H_R<\Delta H_X$. The sensitivities of the resistive and reactive responses for $f=1$ MHz are extraordinarily high: $(1/\Delta H_R)(\Delta R/R)=44\%$/Oe and $(1/\Delta H_X)(\Delta X/R)=16\%$/Oe.

TABLE II. Relative magnitudes and widths for the $Fe_{43}Co_{68.2}Si_{12.5}B_{15}$ wire sample taken from Fig. 5. The resistance at $f=0$ is $R_{dc}=1.2$ Ω/cm.

Frequency	10 kHz	100 kHz	1 MHz
$\Delta R/R$	4%	80%	370%
$\Delta X/R$	21%	120%	350%
ΔH_R	1.5 Oe	1.9 Oe	8.5 Oe
ΔH_X	2.7 Oe	8.3 Oe	21.5 Oe

IV. MODEL FOR SPECTRA

Two characteristics common to the spectra of both wire and ribbon are the negative curvatures of the reactances $X(f)$ and the inflection points in the resistances $R(f)$; the latter separates the low frequency behavior, dominated by positive curvature, from that at high f, where the curves are concave down. For the case of the wire, both R and X increase with $f^{1/2}$ in the high f limit. Such features are characteristic of the impedance of nonmagnetic wires.[8] However, for a wire of the same diameter and resistivity (120 μm and 135 $\mu\Omega$ cm), these features should appear for $f \cong 10$ MHz, not at the onset frequency $f \cong 15$ kHz observed.

The magnetic response to the field produced by the drive current is evidently the mechanism which gives rise to the tremendous frequency dependences of the ribbon and wire impedances. (The effect of Joule heating on the spectra was previously found to be unimportant.[1]) The domain structure[9] of amorphous FeCoSiB wire is determined by its negative magnetostriction coefficient $\lambda \cong -10^{-7}$ in combination with quenched-in radial tensile stress. The resulting magnetic easy direction is circumferential (at least near the wire's surface). The domain structure is broken along the wire's length into alternate left- and right-handed circumferential domains. Evidently, this magnetic structure is highly susceptible to the field of a current flowing in the wire.

We model the impedance spectra of the wire using Maxwell's equations. The response to the field generated by the drive current is governed by the circumferential permeability, denoted μ_ϕ. We assume that μ_ϕ does not depend on position. This is a crude approximation; the core of the wire, very probably, is longitudinally magnetized.[9] Nevertheless, it is correct to first order. From Maxwell's equations we deduce that the skin depth for a wire with circumferential anisotropy is

$$\delta = \frac{c}{2\pi}\sqrt{\rho/\mu_\phi f}, \tag{1}$$

from which follows[8]

$$Z = R + iX = \frac{1}{2} R_{dc} ka \frac{J_0(ka)}{J_1(ka)}, \tag{2}$$

where the J_i are Bessel functions of the first kind, R_{dc} is the $f=0$ resistance of the wire (per cm), a the wire radius, and

$$k = (1+i)\frac{a}{\delta}.$$

The data may be fit to Eq. (2), with μ_ϕ a real constant.[1] Here we include the possibility that μ_ϕ is frequency dependent. We assume that this arises from a damped magnetic response, characterized phenomenologically by a relaxation time τ. The permeability $\mu_\phi = \mu'_\phi + \mu''_\phi$ is then given by[10]

$$\mu'_\phi = 1 + \frac{4\pi\chi_0}{1+\omega^2\tau^2}, \quad \mu''_\phi = \frac{4\pi\chi_0\omega\tau}{1+\omega^2\tau^2},$$

where χ_0 is the susceptibility for $f=0$ and $\omega = 2\pi f$. The solid lines in Fig. 4 are a fit with two parameters, $1+4\pi\chi_0 = \mu_\phi(f=0) = 6074$ and $1/\tau = 10.45$ MHz. A rigorous model of the impedance would include nonlinear terms in the magnetic response to the drive current (saturation of the circumferential magnetization being the most obvious nonlinear phenomenon not contained in the above), as well as a frequency dependent relaxation time. In its present form, the model describes the data extremely well, especially considering the approximations we have made.

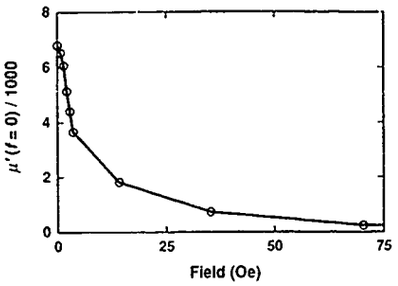

FIG. 6 Field dependence of the fitting parameter $\mu'(f=0,H_A) = 1+4\pi\chi_0(H_A)$ of Eq. (3). The points were obtained by fitting data from Fig. 3 to Eq. (2) using Eqs. (1) and (3).

The permeability was so determined from the $Z(f)$ shown in Fig. 3 for a variety of H_A. Its value at zero frequency $\mu_\phi(f=0)$ (purely real) vs H_A is shown in Fig. 6. The sharp decrease in $\mu_\phi(f=0,H_A)$ for a relatively small increase in H_A parallels that in $Z(f,H_A)$. For $H_A = 140$ Oe, $\mu_\phi(f=0,H_A)$ is reduced from its value of 6805 at $H_A=0$ by a factor of 75. When the magnetization is forced to lie parallel to the wire axis, the circumferential permeability approaches $\mu_\phi = 1$ (Ref. 11 suggests a plausible mechanism for the field dependence of μ_ϕ). We infer that, for a fixed frequency, the skin depth δ grows roughly by a factor of 10 as H_A increases to 140 Oe from zero, and that the wire resistance is subsequently diminished. The relaxation frequency $1/\tau$ appreciably affects the quality of the fit only for $H_A < 3$ Oe. In this range, $1/\tau$ increases sharply from $1/\tau = 3.3$ MHz for $H_A = 0$ and rises to $1/\tau > 40$ MHz, beyond which frequency the addition of a damping term has a negligible effect for the frequency range fit ($0 < f < 1$ MHz). This behavior may possibly be due to the increased importance of rotational processes for higher H_A, and more rapid relaxation.

We believe that the same mechanism is responsible for the impedance of the ribbon sample. Because the domain structure is not known for this sample, we decline to make a quantitative comparison of the ribbon and wire spectra. We may, however, compare the two frequencies for which $R(f, H_A=0)$ exhibits an inflection point; their ratio is 25. Assuming that this is the frequency for which the skin depth is equal to the thickness of the sample, we arrive at a ratio of effective permeabilities which is of the order of one.

V. DRIVE CURRENT DEPENDENCE

The frequency-dependent part of the resistance $R - R_{sat}$ for $H_A = 0$ is shown in Fig. 7 versus drive current amplitude 0.5 mA $< I_{rms} <$ 60 mA (data taken from Ref. 1). Note that the ordinate is set on a logarithmic scale. The current amplitude dependence of X is qualitatively similar.[1] The current scans (I_{rms} increasing) were performed for fixed frequencies $f = 1$ kHz, 10 kHz, 100 kHz, and 1 MHz. For $f = 1$, 10, and 100

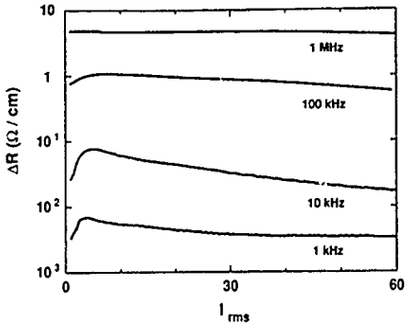

FIG. 7. Dependence of the magnetoresistance $\Delta R(f,I_{rms})$ on the amplitude of the drive current I_{rms}. Note the peak in $\Delta R(f,I_{rms})$ for $I_{rms}<1$ MHz, and the decrease in $\Delta R(f,I_{rms})$ for $I_{rms}>10$ mA at all f. The applied field is $H_A=0$.

kHz, there are peaks evident in the data at $I_{rms}=4.0$, 5.5, and 8.0 mA, respectively. This maximum vanishes for $f\geq 1$ MHz. Each data set also exhibits a gradual decrease for $I_{rms}>10$ mA. The fields at the surface of the wire are $H_\phi=2.5$, 3.0, and 4.5 Oe at the peak positions. Since it is reasonable to expect that the wire magnetizes by domain wall motion at low f, we suggest that the peak in $R(f,I_{rms})$ corresponds to the onset of domain wall motion, i.e., the circumferential coercive force. The absence of a peak in $R(f,I_{rms})$ for $f>1$ MHz is possibly due to the dominance of rotational processes at these relatively high frequencies. The decrease in R for $I_{rms}>10$ mA may result from saturation of the circumferential magnetization for a current-dependent fraction of the cycle. Experiments are in progress that will test these speculations by imaging the magnetization dynamics.

VI. CONCLUSION

A complete picture of the magnetic-field-dependent impedance spectra of amorphous ferromagnetic materials has only begun to take shape. Over the last few years a handful of groups have reported fragments of the whole. The reactance of amorphous wires possessing negative magnetostriction was found to depend sensitively on applied field;[2] a large magnetoresistance for such wires was reported for $f=82$ Hz (Ref. 4) (we observe no magnetoresistance at this low frequency); and an ac magnetoresistance, which scales linearly with f, was reported for FeCoSiB ribbons.[3] In our work we have determined that the impedance spectra of amorphous FeCoSiB wire and ribbon consist both of resistive and reactive components, each of which displays a precipitous decrease in a moderate magnetic field parallel to the sense current. We have been able to describe the effect in wires quantitatively, using a phenomenological model based on classical electrodynamics. The existence of qualitatively similar spectra for amorphous FeCoSiB ribbon demonstrates that the phenomenon is somewhat robust, and that it is not dependent on a particular domain structure.

At high frequency, the resistance is sensitive to smaller fields than the reactance. Why the widths ΔH_R and ΔH_X are different, and why they increase with frequency are unanswered questions at present (we note that the sensitivity increases with f). A possible explanation for the latter is that the circumferential anisotropy K_ϕ (and the resistivity) is dependent on position. Due to the quenching process, one expects this quantity to be greater near the wire surface. The current runs closer to the surface at higher frequencies, and the effective anisotropy field thus increases with frequency

Currently, the most sensitive giant magnetoresistive (GMR) materials have $(1/\Delta H_R)(\Delta R/R_{sat})<1\%$/Oe at room temperature. The sensitivity of the amorphous wire discussed in this paper to an applied field is more than an order of magnitude larger than this for $f=1$ MHz. It is expected that further developments in this nascent field will increase the sensitivity substantially. There is vast technological potential in the phenomenon of magneto-impedance, and many scientific questions still unanswered.

ACKNOWLEDGMENTS

Magnetic and specific-heat studies of U_2T_2X compounds show a frequent occurrence of the γ enhancement in conjunction with the onset of antiferromagnetic ordering. The largest value of 830 mJ/mol K^2 was observed in U_2Pt_2In, which is nonmagnetic down to 1.2 K. Variations of electronic structure are documented by optimized relativistic LCAO calculation.

I. INTRODUCTION

Magnetic and other electronic properties of light actinides in intermetallic compounds are strongly affected by the hybridization of the $5f$ states with electronic states of ligands. In compounds with transition metals, the most significant delocalizing effect comes from the $5f$-d hybridization, which is reduced with filling the d band. The reason follows from electronic structure calculations, which show how the gradual filling of the d states leads to a reduced overlap of the $5f$ states, forming a band pinned at E_F, with the d transition metal states, which are pushed down to higher binding energies. Thus irrespective of stoichiometry or crystal structure we can observe variations of the $5f$ electron magnetism, with a crossover from nonmagnetic to magnetic ground state by the end of transition metal series. There is a common belief that heavy fermion phenomena occur only with very narrow $5f$ bands, which do not order magnetically (or which show very small ordered moments). However, it remains an open question as to why the onset of magnetism is *not* accompanied by a significant γ enhancement in many cases. In other words, the heavy fermion compounds remain rather unique and it is unclear where to place them in the systematics of other uranium intermetallics.

Here we describe results of investigations of the recently discovered compounds of the U_2T_2X type,[1] which can contribute to heavy fermion research due to a systematic occurrence of γ enhancement. The U and Np compounds of the 2:2:1 stoichiometry exist with nearly all transition metals of the Fe, Co, and Ni column. X represents Sn or In. They all crystallize in the tetragonal U_3Si_2 structure type with U-U distances in the range 3.45–3.8 Å.[1]

II. EXPERIMENTAL RESULTS

We studied polycrystalline samples prepared by arc melting stoichiometric amounts of the constituent elements. Most of them were single phase. A several percent contamination was found in U_2Pt_2In (UPt) and in U_2Ir_2Sn and U_2Ir_2In (UIr).

Most of the compounds with Ni, Pd, and Pt display antiferromagnetic (AF) order at low temperatures. The only exception is **U_2Pt_2In**, which exhibits a strongly enhanced susceptibility χ at low temperatures (23×10^{-8} m^3/mol at 4.2 K—note that 1 mol f.u. contains 2 U atoms). No phase transition was indicated in the specific heat down to 1.2 K. The $\chi(T)$ dependence (Fig. 1) can, at high temperatures, be approximated by a modified Curie–Weiss (MCW) law similar to the majority of compounds described here:

$$\chi = C/(T-\Theta_p)+\chi_0, \tag{1}$$

yielding for U_2Pt_2In the parameters $\mu_{\rm eff}=2.4$ μ_B/U, $\Theta_p=-106$ K, and $\chi_0=9.7\times10^{-8}$ m^3/mol. Below 100 K, $\chi(T)$ deviates from the MCW fit towards larger χ values. The low-temperature data are contaminated by the UPt impurity[2] (which has spontaneous magnetization of 0.4 μ_B/U below $T=25$ K[3]), but the large susceptibility at 4.2 K was confirmed by high-field magnetization measurements. The specific heat displays a pronounced upturn of C/T vs T (Fig. 2), which is insensitive to applied magnetic field of 5 T. Although the fit involving a $T^2 \ln T$ term accounts well for the data only in a very limited temperature range (up to 5 K), it can be used to estimate the γ value in the zero K limit, $\gamma\cong830$ mJ/mol K^2.

The highest ordering temperatures were observed in the two Pd compounds, **U_2Pd_2Sn** ($T_N=41$ K) and **U_2Pd_2In** ($T_N=38$ K). The susceptibility analysis in terms of Eq. (1) yields smaller negative Θ_p values (−30 and −32 K for Sn and In, respectively) than in other compounds from this series. The relatively strong $5f$ localization is indicated by sizeable U magnetic moments (1.89 and 1.40 μ_B, respec-

 0021-8979/94/76(10)/6214/3/$6.00 © 1994 American Institute of Physics

tively) determined from neutron-diffraction experiments. They show in both cases a noncollinear AF structure with moments within the basal plane and oriented along directions of the [110] type.[4] Despite magnetic ordering, a pronounced upturn in the C/T vs T dependence was found also for U_2Pd_2In, leading to γ=393 mJ/mol K^2 (65 mJ/mol K^2 is obtained by extrapolation from paramagnetic range). No such upturn was found in U_2Pd_2Sn, but the linear coefficient of the specific heat was still high: γ=203 mJ/mol K^2. The $5f$ local-moment magnetism in the Pd compounds is corroborated by the magnetic entropy estimate ($1-2\times R$ ln ?).

Unlike U_2Pt_2In, **U_2Pt_2Sn** is magnetically ordered (T_N=15.5 K). A much smaller magnetic entropy (about 0.2 $\times R$ ln 2) is suggestive of itinerant magnetism. γ=334 mJ/mol K^2 was extracted from the low-temperature range, whereas 390 mJ/mol K^2 can be obtained above T_N.

U_2Ni_2In exhibits a similar behavior (T_N=15 K). Magnetic susceptibility analysis in terms of Eq. (1) yields $\Theta_p=-80$ K and μ_{eff}=2.0 μ_B/U. The low-temperature γ=200 mJ/mol K^2 is substantially smaller than the high-temperature value of 350 mJ/mol K^2. The magnetic entropy is about 0.4$\times R$ ln 2.

U_2Ni_2Sn orders below T_N=25 K. In the paramagnetic range, μ_{eff} can be described by Eq. (1) yielding μ_{eff}=2.3 μ_B/U, $\Theta_p=-110$ K, and $\chi_0=1.8\times10^{-8}$ m^3/mol. We are aware that the presence of the χ_0 term can be an artifact due to the averaging the anisotropic χ values in polycrystal.

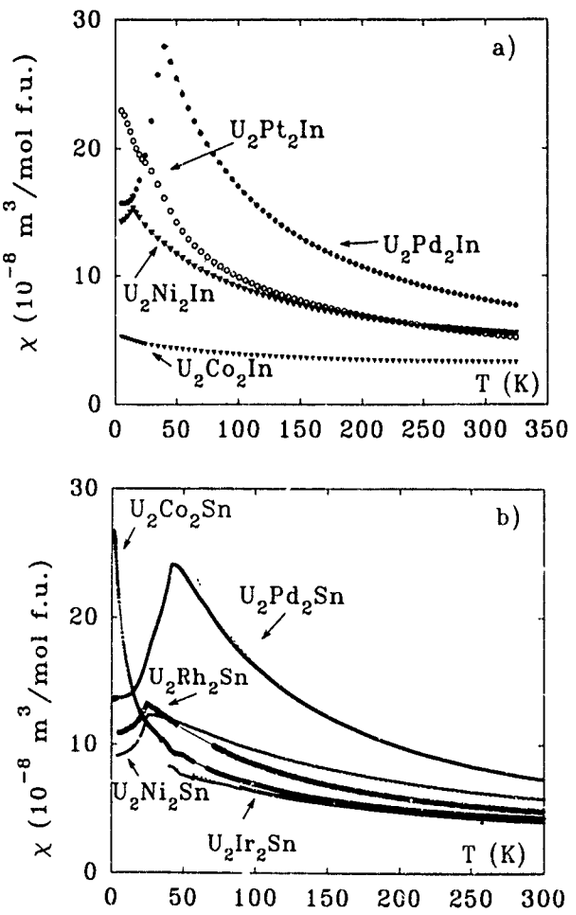

FIG 1 Temperature dependence of magnetic susceptibility of (a) U_2T_2In and (b) U_2T_2Sn The dotted lines shown in some cases are the MCW fits

Regarding other compounds, we have found magnetic ordering in **U_2Rh_2Sn** with T_N=24 K. A weak magnetic entropy of 0.4×R ln 2 is again indicative of a strongly itinerant $5f$ magnetism, but the γ value is rather low (131 mJ/mol K^2).

Besides U_2Pt_2In, some other nonmagnetic compounds exhibit spin-fluctuation features: **U_2Co_2Sn**, **U_2Ni_2In**, and **U_2Ir_2Sn**. They display γ values ranging from 130 (U_2Ir_2Sn) to 280 mJ/mol K^2 (U_2Rh_2In) (a strong upturn in C/T is found in U_2Co_2Sn and a weaker one in U_2Rh_2In). Finally, the presumably most itinerant $5f$ states cause a weak itinerant paramagnetism in **U_2Co_2In** (γ=32 mJ/mol K^2) and **U_2Ru_2Sn** (20 mJ/mol K^2).

Assessing variations of properties in the group of U_2T_2X compounds, we can deduce the following trends: (i) The $5f$ localization increases within each transition metal series towards the right end of the periodic table. This is similar to findings in other groups of light actinide compounds. (ii) The U_2T_2In compounds have a weaker tendency to magnetic ordering than their U_2T_2Sn counterparts.

III. ELECTRONIC STRUCTURE CALCULATIONS

To follow electronic structure variations in the system of U_2T_2In compounds, we performed calculations using the optimized HLCAO[5] method in a fully relativistic version.[6]

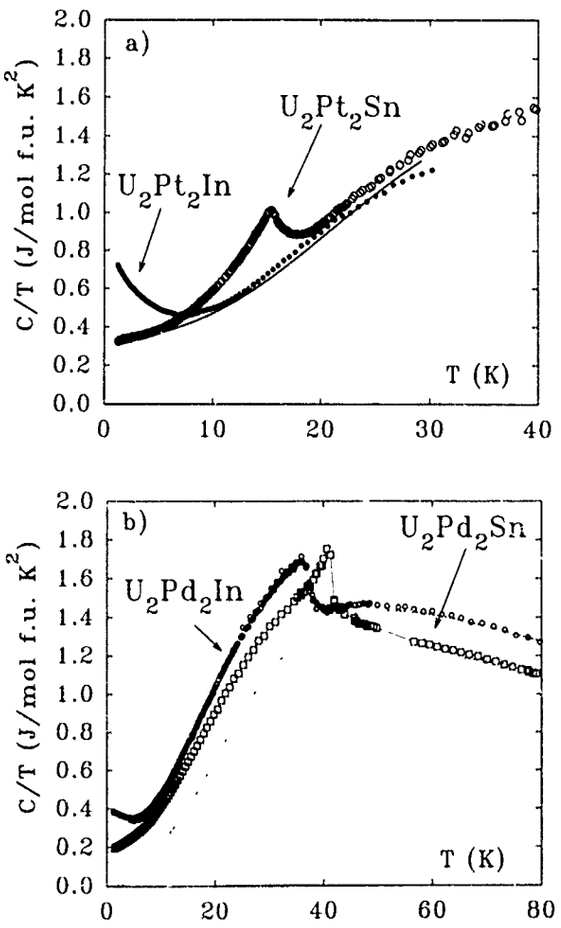

FIG. 2. C/T vs T plots of (a) U_2Pt_2X and (b) U_2Pd_2X The dotted lines show the Debye background approximating the high-temperature specific heat. For U_2Pt_2Sn (full line) it is shifted down to fit to the low-temperature γ.

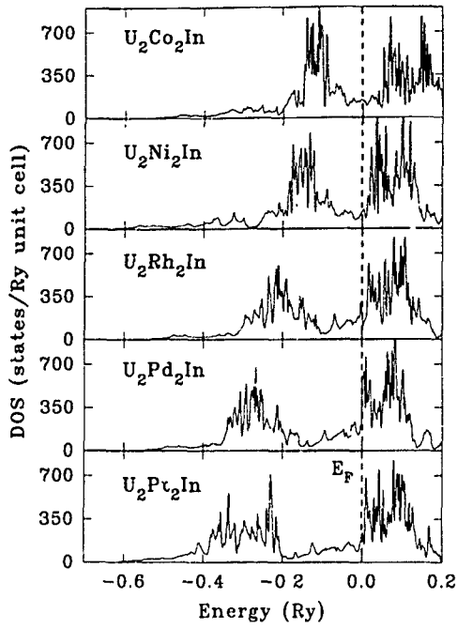

FIG. 3. Calculated total density of states of U_2T_2In.

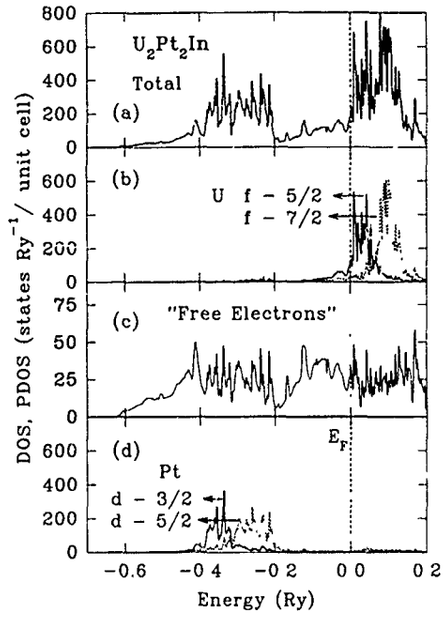

FIG. 4. Calculated total and orbital-projected density of states for U_2Pt_2In.

Self-consistency is treated by the Kohn–Sham density-functional theory in the local-density approximation (LDA).

The total densities of states (DOS) for U_2T_2In (T=Co, Ni, Rh, Pd, Pt) calculated fully relativistically are displayed in Fig. 3. The obtained spectra are characterized by a nearly free-electron background of s-, p-, and uranium $6d$ electrons, which extends to about 0.6 Ry below E_F. In all cases bonding and antibonding band groups are well separated by a broad and deep minimum around E_F. The orbital-projected DOS for the $5f$ and T-d orbitals (see, e.g., U_2Pt_2In shown in Fig. 4) indicate that the bonding (antibonding) states are predominantly T-$d(5f)$. There is, however, an appreciable amount of covalency—the $5f(T$-$d)$ contribution to the bonding and the antibonding states, respectively. The estimate of the contribution of a direct $5f$-$5f$ overlap to the width of the f-projected DOS proved that the $5f$-d hybridization appreciably enhances the $5f$ bandwidth.[6]

Practically no electron transfer from U to T was found in U_2Pd_2In. But it does increase with decreasing population of the d states. As expected, the spin-orbit splitting of Co- and Ni-$3d$ states is small, with moderate spin-orbit splitting in Rh- and Pd-$4d$ states (0.02 Ry), and the largest splitting in Pt-$5d$ and U-$5f$ states (0.1 Ry).

The Fermi level gradually shifts from the top of the bonding band in U_2Co_2In to the bottom of the antibonding band in U_2Ni_2In, U_2Rh_2In, and U_2Pt_2In, and finally into the antibonding band in U_2Pd_2In, which displays much weaker transfer of $5f$ (and $4d$) electrons into free-electron states. This reduced transfer may be understood as the result of shifting down of the Pd-$4d$ states compared to the Ni-$3d$ states or Pt-$5d$ states. The experimentally observed development in the γ values is qualitatively consistent with the trends in the calculated DOS at the Fermi level $N(E_F)$. We have also partitioned the total DOS into different contributions and the change of total DOS at E_F can be mainly ascribed to the variations of $N(E_F)^{U}_{f5/2}$.

Since the width of the covalence gap (>1 eV) exceeds the exchange splitting of elemental Co and Ni, any possible magnetism should arise from $5f$ electrons only. Applying the LDA Stoner theory, we have obtained the Stoner product $I \times N(E_F)$=0.6, 1.3, 2.0, 11.5, and 3.1 for U_2Co_2In, U_2Ni_2In, U_2Rh_2In, U_2Pd_2In, and U_2Pt_2In, respectively. Therefore the observed nonmagnetic ground state of U_2Co_2In and magnetic ground state of U_2Ni_2In and U_2Pd_2In are qualitatively consistent with our calculations. The nonmagnetic heavy fermion behavior of U_2Rh_2In and U_2Pt_2In cannot be described by our LDA calculations, which lead to a Stoner instability.

By specific-heat, magnetization, electrical resistivity, and neutron-diffraction measurements on a single crystal we have confirmed that UNiGe orders antiferromagnetically below 50.5 K into an incommensurate phase with $\mathbf{q}=(0,1/2,-1/2)\pm(0,\delta,\delta)$, $\delta\sim0.15$. δ decreases continuously with decreasing temperature to ~0.123 at 41.5 K, where the incommensurate phase vanishes in a first-order phase transition and a commensurate antiferromagnetic structure with $\mathbf{q}=(0,1/2,1/2)$ sets in and remains stable down to the lowest temperatures. If a magnetic field sufficient to induce a metalmagnetic transition (1–5 T) is applied along the c axis, both antiferromagnetic phases are transformed to an uncompensated AF phase with $q=(0,1/3,1/3)$ yielding a nonzero magnetization $M\approx1/3\times M_S$. The latter structure is destroyed and a complete alignment of U moments is achieved in fields above 10 T. The strikingly different B-T diagrams observed for a magnetic field applied along different crystallographic directions reflect strongly anisotropic exchange interactions.

I. INTRODUCTION

UNiGe belongs to the isostructural group of the UTX compounds (T=transition metal, $X=p$ metal), which crystallize in the orthorhombic TiNiSi-type structure. The nearest-neighbor uranium atoms in this structure form zigzag chains along the a axis. The coordination of U atoms is intimately connected with the anisotropy of bonding of $5f$ orbitals, which has serious consequences for the symmetry of the $5f$-electron magnetism.[1] Specifically, in UNiGe and other isostructural UTX compounds, the easy-plane magnetocrystalline anisotropy with the hard-magnetization direction along the a axis is observed as a rule.[1,2] This is manifest in the low-temperature magnetization, which is small and linearly dependent on the magnetic field up to 35 T applied along the a axis. For the other two field directions (along b and c) almost saturated magnetization M_S due to aligned U moments of 1.45 μ_B is attained above metalmagnetic transitions.[2] Note that the magnetization curves at 4.2 K display two metalmagnetic transitions at 17 and 25 T in the field applied along b (and at 3 and 10 T in $B\|c$). In both field geometries, the magnetization observed above the first transition amounts to approximately $1/3\times M_s^2$.

For some time, UNiGe was believed to order magnetically around 42 K,[2–7] although some indications of another transition around 50 K could be seen in the specific-heat data of Kawamata *et al.*.[7] Moreover, controversial conclusions about the magnetic structure at low temperatures could be found in the literature.[6,8] This unsatisfactory situation motivated us to perform an extensive study of a well-defined single crystal of UNiGe, which was governed by a Czochralski technique in a tri-arc furnace at the University of Amsterdam. Besides measurements of bulk properties (magnetization, electrical resistivity, and specific heat) over wide temperature and external magnetic-field intervals, we have performed extensive neutron-diffraction experiments. Results and experimental details of bulk measurements were published elsewhere,[2,9] along with preliminary neutron data indicating the existence of the incommensurate antiferromagnetic phase (IAFP) below 50 K[11]. In this paper we concentrate on both the temperature and magnetic-field stability of the IAFP in the complex magnetic phase diagram of UNiGe.

II. RESULTS AND DISCUSSION

The specific heat of UNiGe exhibits a sharp peak at 41.5 K and a weaker maximum around 50 K (see Fig. 1). The first-order magnetic phase transition at 41.5 K is also clearly reflected in the magnetization and resistivity.[2,9] Closer inspection of magnetization and electrical resistivity results, however, also reveals around 50 K slight (but well noticeable

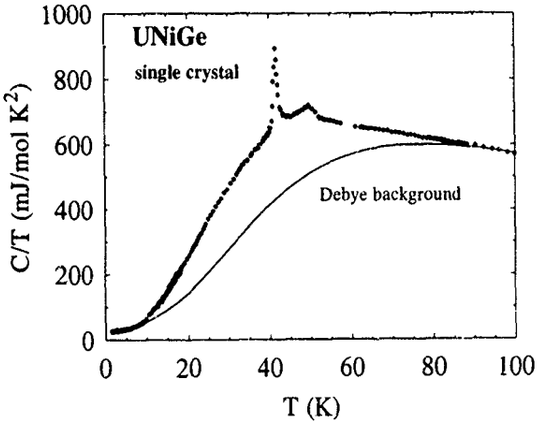

FIG. 1. Temperature dependence of the specific heat of UNiGe

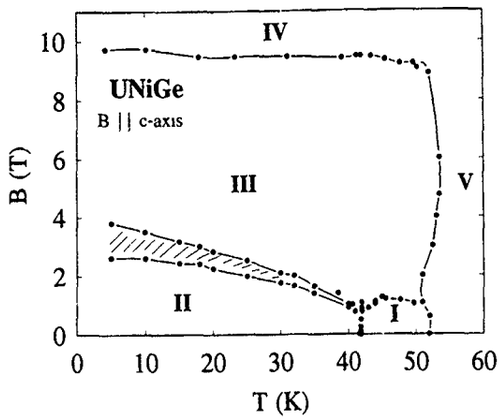

FIG. 2 Magnetic phase diagram of UNiGe in B parallel to the c axis, as determined from magnetization and neutron-diffraction measurements. (I) incommensurate antiferromagnetic phase, $\mathbf{q}=(0,1/2,-1/2)\pm(0,\delta,\delta)$, (II) commensurate antiferromagnetic phase, $\mathbf{q}=(0,1/2,1/2)$, (III) uncompensated antiferromagnetic phase, $\mathbf{q}=\pm(0,1/3,1/3)$, (IV) phase with "ferromagnetically" aligned U moments, and (V) paramagnetic phase.

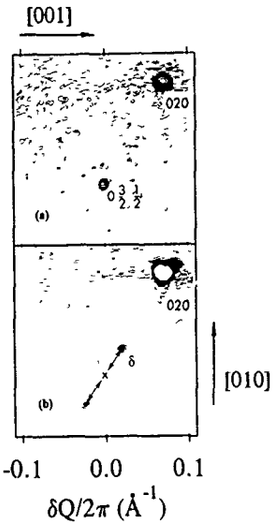

FIG. 3. Magnetic reflections in the vicinity of the 0, 3/2, −1.2 at (a) 20 K and (b) 46 K

in $\partial M/\partial T$ and $\partial\rho/\partial T$) anomalies, which corroborate the conclusion about the magnetic origin of this phase transition.

In order to obtain better knowledge of magnetic phases and transitions in UNiGe we performed neutron-diffraction experiments on the same single crystal at BENSC (on E2 and E4) and LANSCE (on SCD). The obtained magnetic phase diagram shown in Fig. 2 contains essential information from studies in magnetic fields applied along the c axis.

A. Zero magnetic field, $T\leqslant 41.5$ K

All observed magnetic reflections can be indexed as $h,k/2,1/2$ (with $k,1$ odd), suggesting the AF structure with $\mathbf{q}=(0,1/2,1/2)$ in agreement with Ref. 6. The U moments are locked in the b-c plane. The temperature dependence of the intensities of the magnetic reflections indicates that the U moment decreases slowly with increasing temperature.[11] At 40 K, the ordered U moments retain about 90% of the low-temperature value. The magnetic intensities then decrease abruptly at the 41.5 K first-order phase transition, where the low-temperature phase vanishes.

B. Zero magnetic field, $T\geqslant 41.5$ K

A crucial point of our research has been to indicate an IAFP, which propagates within the b-c plane. For this purpose experiments on the flat cone diffractometer E2 in Berlin and the single-crystal diffractometer SCD with an area detector at Los Alamos were indispensable. Both types of experiments provided compatible results confirming the existence of an IAFP with $\mathbf{q}=(0,1/2,-1/2)\pm(0,\delta,\delta)$. For illustration, we display in Fig. 3 typical patterns recorded on SCD in Los Alamos at 20 and 46 K, in which the difference between the respective magnetic states is manifest. Whereas at 20 K the 0, 3/2, −1/2 is characteristic for the commensurate AF phase stable below 41.5 K, this reflection is absent at 46 K and instead two satellites shifted by $\pm(0,0.141,0.141)$ indicate the presence of the IAFP. After identifying this phase, its stability and temperature evolution of δ were studied on E4 in Berlin. The results are displayed in Fig. 4 The IAFP emerges just above 41.5 K. The characteristic reflections 0, $k/2\pm\delta$, $-1/2\pm\delta$ reach a maximum intensity already around 43 K and then diminish continuously with increasing temperature. The reflections are at the limit of detectability at 50 K, but some residual intensity can be seen in the background up to approximately 53 K. The parameter δ varies from ~0.123 at 41.5 to 0.15 at 50 K. The transition at 41.5 K is apparently of the first-order type in contrast to the second-order transition around 50.5 K.

C. $B\leqslant 6$ T, $E\|c$, $T\leqslant 41.5$ K

The first metalmagnetic transition exhibits a large hysteresis.[11] The critical fields and the hysteresis (marked by the hatched region in Fig. 2) decrease with increasing temperature. When sweeping the field upwards, the $0,k/2,1/2$ reflections disappear rapidly around the transition. On the

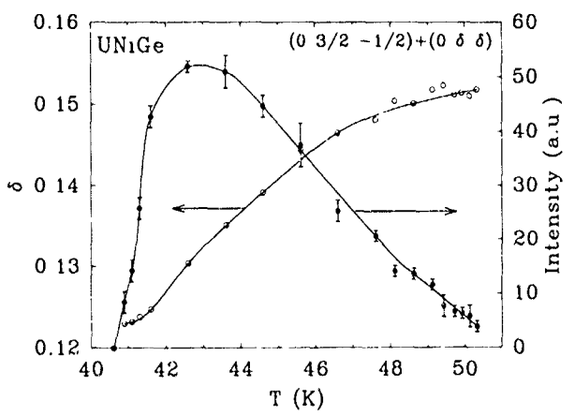

FIG 4 Temperature dependence the integral intensity and the parameter δ of the $(0,1/2,-3/2)\pm(0,\delta,\delta)$ reflection

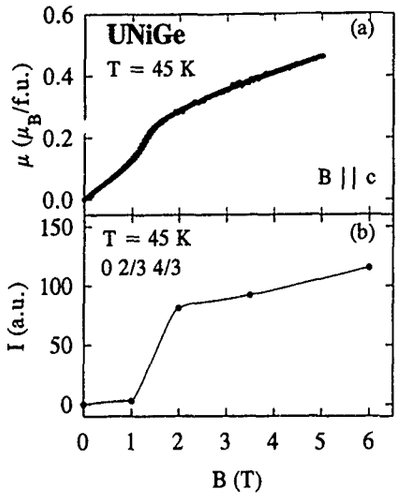

FIG. 5. Field scans of (a) magnetization and (b) the 0 2/3 4/3 reflection at 45 K.

other hand, $h,k/3,1/3$-type reflections and magnetic contribution to nuclear reflections emerge (following the magnetization dependence closely).[11] The metalmagnetic state connected with the uncompensated AF structure therefore has $\mathbf{q}=(0,1/3,1/3)$. This leads to the collinear arrangement of the U magnetic moments oriented along the c axis with the $++-$ stacking simultaneously along the b and c axis, which gives rise to the magnetization $M=1/3\times M_s$ in agreement with the above-mentioned result from magnetization measurements.

D. $B\leq 6$ T, $B\|c$, $T\geq 41.5$ K

The IAFP is stable in magnetic fields up to about 1 T, where it starts to transform gradually to phase III. This field correlates well with that of the metalmagnetic transition shown in Fig. 5(a). The $0,k/3,1/3$ reflections representing the phase III persist up to ~51 K, where a first-order transition (in contrast to the second-order transition in zero field) to the high-temperature paramagnetic phase takes place as shown in Fig. 5(b).

When the magnetic field is applied along the b axis a two-step metalmagnetic process appears. However, the critical fields of the metalmagnetic transitions are considerably higher, indicating pronounced anisotropy of the exchange interactions.

To analyze magnetic phases in U intermetallics, models considering the relation of U coordination and the type of anisotropy can be employed. The experimental findings in UNiGe corroborate the empirical rules[1] relating the symmetry of the bonding of the $5f$ orbitals in a particular structure to the type of magnetocrystalline anisotropy. The strong bonding axis (a axis in UNiGe and structure-related UTX compounds) determines the hard-magnetization direction whereas the magnetic moments are locked perpendicular to the hard direction (in the b-c plane in UNiGe). The exchange interaction along the strong bonding axis (plane) is usually strong and ferromagnetic, whereas the considerably weaker interaction(s) in the perpendicular direction(s) mediate the coupling between the ferromagnetic chains (planes). These interactions are frequently frustrated and a sequence of incommensurate and commensurate phases can be observed[12] when temperature is decreased.

Magnetic susceptibility and electronic specific heat of Anderson lattice with finite *f*-band width

Sunil Panwar and Ishwar Singh
Department of Physics, University of Roorkee, Roorkee 247667, India

We study an extension of the periodic Anderson model by considering finite f-band width. A variational method recently developed, has been used to study the temperature dependence of the average valence of magnetic susceptibility χ_s and electronic specific heat C_v for different values of the f-band width. As f-band width increases, the low-temperature peak in χ_s and C_v becomes more broad and shifts towards the high-temperature region.

I. INTRODUCTION

A class of certain lanthanide and actinide intermetallic compounds, now known as heavy fermions, show a variety of anomalous electronic and magnetic properties.[1-4] At high temperatures, there is a Curie–Weiss-like magnetic susceptibility χ_s. χ_s can be fitted to $(T-\theta)^{-1}$ where $\theta<0$ and there are large effective moments ($>\mu_B$). However, at low temperatures, χ_s shows T^2 dependence and tends to a constant value which for heavy-fermion systems is greatly enhanced over the value expected for a normal metal. The data on the electronic specific heat C_v also show interesting features. In general C_v varies linearly with temperature at very low temperature, $C_v=\gamma T$, which is the behavior expected for a Fermi liquid. In the recent past, the periodic Anderson model (PAM)[5] has been widely accepted as a model for understanding the basic electronic and magnetic properties of mixed valence and heavy fermion materials. Since there is an overlap of 5-f orbitals (thereby giving rise to a finite f-band width) in actinide materials,[6] we consider an extension of the PAM by considering finite f-band width. Recently, an extension to the Anderson model in which direct f-f hopping is included has been studied by several authors.[7-9] This model has been studied by several authors using the variational method.[10-14] Recently, we developed a variational method[15-20] to study the ground state and thermodynamic properties of PAM. We use this variational method here to study the PAM including finite f-band width. In Sec. II we give the basic formulation for the magnetic susceptibility and electronic specific heat. In Sec. III we discuss our results.

II. BASIC FORMULATION

The orbitally nondegenerate periodic Anderson model including finite band width of f electrons is described by the Hamiltonian

$$H=\sum_{k\sigma}\epsilon_k c^{+}_{k\sigma}c_{k\sigma}+\sum_{ij\sigma}T_{ij}b^{+}_{i\sigma}b_{j\sigma}-\sum_{ik\sigma}V_{ik}(c^{+}_{k\sigma}b_{i\sigma}+\text{h.c.})+\frac{U}{2}\sum_{j\sigma}n^{f}_{j\sigma}n^{f}_{j-\sigma}, \tag{1}$$

where

$$T_{ij}=\frac{1}{N}\sum_{k}E_k e^{ik(R_i-R_j)}. \tag{2}$$

Here, E_k is the f-band energy and other symbols have their usual meanings.

For simplicity, we assume that the form of the f band is the same as that of the conduction band. The f band is represented by the expression

$$E_k=\epsilon_f+A\left(\epsilon_k-\frac{W}{2}\right), \tag{3}$$

where A is a positive constant less than unity. Here W and AW are the band widths of conduction band and f band, respectively. For $A=0$, $E=\epsilon_f$ is the position of the f level.

In the k space, the Anderson–Hamiltonian may be written as

$$H=\sum_{k\sigma}\epsilon_k c^{+}_{k\sigma}c_{k\sigma}+\sum_{k\sigma}\left[\epsilon_f+A\left(\epsilon_k-\frac{W}{2}\right)\right]b^{+}_{k\sigma}b_{k\sigma}-\sum_{k\sigma}v_k(c^{+}_{k\sigma}b_{k\sigma}+\text{h.c.})+\frac{U}{2}\sum_{j\sigma}n^{f}_{j\sigma}n^{f}_{j-\sigma}. \tag{4}$$

Here we are considering strongly interacting (i.e., $U\to\infty$) case. In this case the probability of f^2 configuration is very small. The variational wave function which projects the f^2 configuration out, may be written as (Panwar and Singh[15])

$$|\psi\rangle=\prod_{k\sigma}[1+A_{k\sigma}(1-n^{f}_{-\sigma})b^{+}_{k\sigma}c_{k\sigma}]|F\rangle \tag{5}$$

when $|F\rangle=\Pi_{k\le k_{F,\sigma}}c^{+}_{k\sigma}|0\rangle$ is the Fermi sea of conduction electrons and $A_{k\sigma}$ the variational parameters. It can be seen that the resultant states are in the form of two quasiparticle bands; the lower (−) and upper (+) of quasiparticle spectra are given by

$$E^{\pm}_{k\sigma}=\frac{1}{2}\left\{\left[(1+AP_f)\epsilon_k+\epsilon_f P_f-\frac{AWP_f}{2}\right]\pm\sqrt{\left((1-AP_f)\epsilon_k-\epsilon_f P_f+\frac{AWP_f}{2}\right)^2+4V_k^2P_f^2}\right\}. \tag{6}$$

The A_k's are given by

 0021-8979/94/76(10)/6220/3/$6.00 © 1994 American Institute of Physics

$$A_k^{\pm}=\frac{1}{2V_kP_f^2}\left\{\left[\epsilon_k(1-AP_f)-\epsilon_fP_f+\frac{AWP_f}{2}\right]\right.$$
$$\left.\pm\sqrt{\left[\epsilon_k(1-AP_f)-\epsilon_fP_f+\frac{AWP_f}{2}\right]^2+4V_k^2P_f^2}\right\}, \tag{7}$$

where

$$P_f=(1-n^f_{-\sigma}).$$

At finite temperature, the number of conduction electrons and f electrons are given by (taking the total number of electrons such that the Fermi level lies in the lower band)

$$n^c_{k\sigma}=\left[\frac{f^-_{k\sigma}}{1+(A^-_{k\sigma})^2P_f^2}+\frac{f^+_{k\sigma}}{1+(A^+_{k\sigma})^2P_f^2}\right]$$
$$n^f_{k\sigma}=\left[\frac{(A^-_{k\sigma})^2P_f^3f^-_{kr}}{1+(A^-_{k\sigma})^2P_f^2}+\frac{(A^+_{k\sigma})^2P_f^3f^+_{kr}}{1+(A^+_{k\sigma})^2P_f^2}\right]. \tag{8}$$

Here Fermi functions $f^-_{k\sigma}$ and $f^+_{k\sigma}$ are given by

$$f^{\pm}_{k\sigma}=\frac{1}{\exp[\beta(E^{\pm}_{k\sigma}-\mu)]+1} \tag{9}$$

where μ is the chemical potential and $\beta=1/k_BT$.

A. Magnetic susceptibility

In the presence of a static magnetic field B, the f level is $E_f-g\sigma u_BB$; $E_f=\epsilon_f+A(\epsilon_k-W/2)$. The static magnetic susceptibility for the lower branch of quasiparticle spectra is given by

$$\chi_s=gu_B\sigma\frac{\partial}{\partial B}[n^f_{\sigma}-n^f_{-\sigma}]\Big|_{B\to 0}. \tag{10}$$

Putting n^f_{σ}'s from Eq. (8) one gets, after some algebra, the expression of susceptibility [in units of $(g\mu_B)^2$] at finite temperature[16] in the paramagnetic region.

B. Electronic specific heat

At finite temperature, the ground state energy is given by

$$\langle E\rangle=\sum_{k\sigma}[(E^-_{k\sigma}-\mu)f^-_{k\sigma}+(E^+_{k\sigma}-\mu)f^+_{k\sigma}]. \tag{11}$$

The electronic specific heat C_v is obtained by differentiating energy $\langle E\rangle$ with respect to temperature T. The total electronic specific heat gets the contribution from both the lower as well as the upper quasiparticle bands. It is given by

$$C_v=\frac{\partial\langle E\rangle}{\partial T}=\frac{\partial}{\partial T}\sum_{k\sigma}[(E^-_{k\sigma}-\mu)f^-_{k\sigma}+(E^+_{k\sigma}-\mu)f^+_{k\sigma}]. \tag{12}$$

III. RESULTS AND DISCUSSIONS

In these calculations, we have considered a tight-binding conduction band which is centered around zero energy with conduction band width $W=2.0$ eV. The total number of electrons per site (n^C+n^f) has been taken to be 1.5. The f-band width is $AW=2$ A. V is fixed on 0.25 eV. Figures 1(a) and 1(b) show the variation of average valence n^f and magnetic susceptibility χ_s^0 with parameter A, respectively, at $T=0$ K. In Fig. 1(a) curve I shows variation for the f-level position $\epsilon_f=-0.4$ and curve II for $\epsilon_f=0.0$. Here we find a smooth variation of n^f with A. We have also seen that for a constant value of A, n_f increases slowly with increasing temperature.

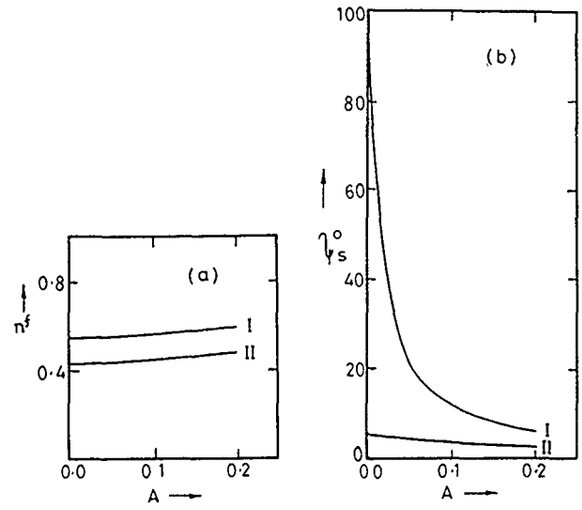

FIG. 1. (a) Variation of average valence n^f with A at $T=0$ K with tight-binding conduction band for different effective positions of f level. Curve I for $\epsilon_f=-0.4$, curve II for $\epsilon_f=0.0$ V is fixed on 0.25. (b) Variation of magnetic susceptibility χ_s^0 [in units of $(g\mu_B)^2$] with A at $T=0$ K with tight-binding conduction band for different effective positions of f level Curve I for $\epsilon_f=0.0$, curve II for $\epsilon_f=0.2$. V are fixed on 0 25.

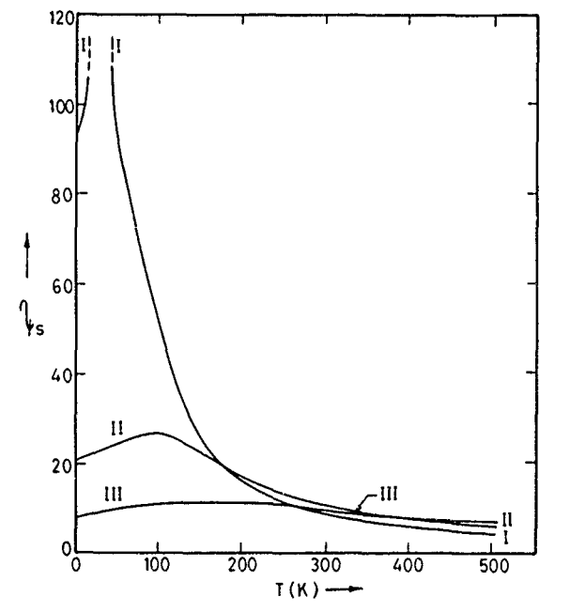

FIG. 2. Magnetic susceptibility χ_s [in units of $(g\mu_B)^2$] as a function of temperature for different A with tight-binding conduction band $V=0$ 25 and $\epsilon_f=0.0$ Curve I for $A=0$ 0, curve II for $A=0$ 05, and curve III for $A=0$ 15 Dashed part of curve I shows the divergence of χ_s in the temperature range 10–50 K

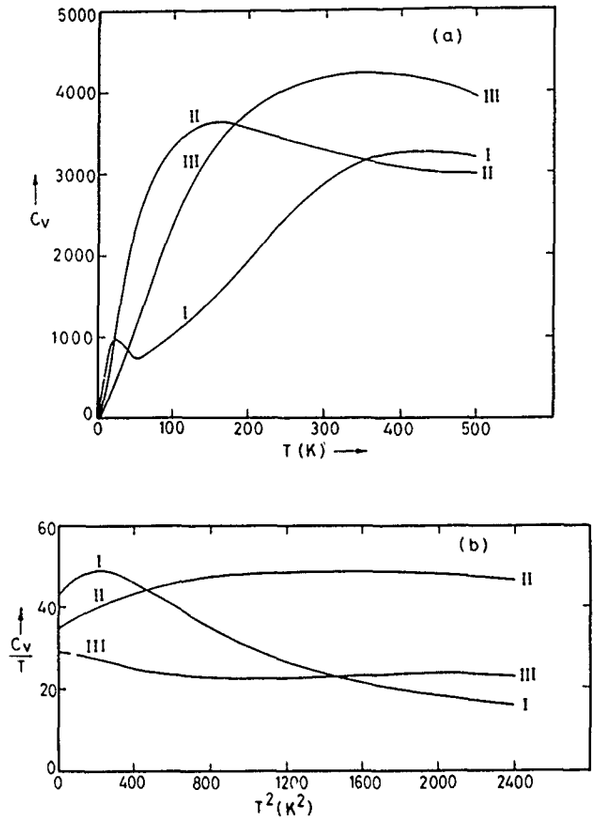

FIG. 3. (a) Variation of specific heat C_v with temperature with tight-binding conduction band for different values of A. Curve I is for $A=0.0$, curve II for $A=0.05$, and curve III for $A=0.15$. ϵ_f are fixed on -0.4. (b) Variation of specific heat coefficient C_v/T with temperature with tight-binding conduction band for different values of A. Curve I is for $A=0.0$, curve II for $A=0.05$, and curve III for $A=0.15$. ϵ_f are fixed on -0.4.

While in Fig. 1(b), curve I shows variation for $\epsilon_f=0.0$ and curve II for $\epsilon_f=0.2$. χ_s^0 increases rapidly as A is lowered.

We have shown results of magnetic susceptibility $\chi_s(T)$ in Fig. 2 for different A. ϵ_f is fixed on 0.0. Curve I stands for $A=0.0$, curve II for $A=0.05$, and curve III for $A=0.15$. The behavior of $\chi_s(T)$ is interesting. At low temperature $\chi_s(T)$ rises up to a maximum. This low-T peak in χ_s gets sharpened as A reduces from 0.15 to 0.10 and finally diverges at $A=0.0$. Also as the f level goes down, χ_s increases and we have a sharper peak at low temperature. This susceptibility behavior is characteristic of many mixed-valence compounds like $CeSn_3$, $CePd_3$, and of many Ce and U-heavy fermion systems like $CeAl_3$ and UPt_3.[21,22] As A increases, the f-band width increases and as a result the density of f states reduces and thereby reduces the Pauli susceptibility term.

Figures 3(a) and 3(b) show the variation of specific heat C_v and specific heat coefficient C_v/T, respectively, with temperature for different values of parameter A. ϵ_f is fixed on -0.4. Curve I shows variation for $A=0.0$, curve II for $A=0.05$, and curve III for $A=0.15$. Here $C_v(T)$ increases linearly at low temperature, and has a maxima near $T_{max}=25$ K at $A=0.0$. As A increases, the maximum is less pronounced and much broader and shifts towards higher temperature region. Also as A increases, the maxima in C_v/T at low temperature becomes wider and is less pronounced and in some cases disappears. We have a more sharp peak in C_v or C_v/T at low temperature as the f level goes down for a constant value of A. This behavior of specific heat curves has been the main characteristic of many mixed valence and heavy fermion materials like $NpSn_3$.[23]

From the above results of $\chi_s(T)$ and $C_v(T)$, one can conclude that by increasing the f-band width, we are making the "Fermi-liquid" nature of f electrons to be more pronounced.

Electrical resistivity and thermoelectric power of heavy fermions and mixed-valence systems

Sunil Panwar and Ishwar Singh
Department of Physics, University of Roorkee, Roorkee 247667, India

Representing the heavy fermions and mixed-valence systems by the periodic Anderson model, we have used the variational method to study the temperature dependence of electronic transport properties of these systems. The electrical resistivity $\rho(T)$ and thermoelectric power $Q(T)$ calculated show the features experimentally observed in these materials. In the low-temperature region $\rho(T)$ and $Q(T)$ increase rapidly. Toward high-temperature region, $Q(T)$ changes sign.

I. INTRODUCTION

The experimental results of electrical resistivity $\rho(T)$ of many heavy fermion systems (e.g., $CeAl_3$, $CeCu_2Si_2$, $CeCu_6$, UBe_{13}) at low temperatures show anomalous behavior.[1-5] $\rho(T)$ increases with increasing temperature in the very low-temperature region (known as the Fermi-liquid region or coherence region), reaching a maximum and then decreasing slowly like $\ln T$ (known as the Kondo region or independent-impurity region). The negative temperature coefficient (NTC) of the resistivity in the high-temperature regime is usually interpreted as a manifestation of the Kondo effect in a concentrated system.[1,2] The thermoelectric power $Q(T)$ also exhibits characteristic anomalies when compared to the thermoelectric power of usual metals. $Q(T)$ is very large in the case of these materials. It shows a maximum at a relatively low temperature T^*. In some heavy fermion systems like UPt_3,[6] $Q(T)$ changes sign at temperatures $T>T^*$. In the recent past it has been suggested that the low-temperature coherent Fermi-liquid phase may very well be represented by the periodic Anderson model (PAM) where one considers the coherent hybridization between conduction states and the f states on all N sites.[7-11]

Recently we developed a variational method to study the ground-state and thermodynamic properties of PAM.[11-15] We use this variational method here to study electrical resistivity and thermoelectric power of heavy fermion (HF) and mixed-valence (MV) systems within PAM. The details of the variational method may be found in Ref. 11. In the recent past, the characteristic anomalies in $\rho(T)$ and $Q(T)$ have been described by the frequency dependent relaxation time resulting from quasiparticle-quasiparticle scattering. In Ref. 16, the frequency dependence of the self-energy contains this information. We have not taken into account such lifetime effects in our variational approach. In this work, we suggest that the scattering mechanism is impurity scattering with a frequency independent mean free path and we have taken into account only the energy dependence of different factors like density of states appearing in the expression of $\rho(T)$ and $Q(T)$. We have used the Mott's formula for the electrical conductivity which takes the explicit energy dependence of the mean free path. Below we give the basic formulation for electrical resistivity and thermoelectric power. In Sec. III we discuss our results.

II. BASIC FORMULATION

The orbitally nondegenerate periodic Anderson model is described by the Hamiltonian

$$H=\sum_{k\sigma}\epsilon_k c^+_{k\sigma}c_{k\sigma}+\epsilon_f\sum_{\iota\sigma}b^+_{\iota\sigma}b_{\iota\sigma}-\sum_{k\sigma}V_k(c^+_{k\sigma}b_{k\sigma}+\text{h.c.})+\frac{U}{2}\sum_{j\sigma}n^f_{j\sigma}n^f_{j-\sigma}, \tag{1}$$

where symbols have their usual meanings.

A. Weak interaction case

In the weak-interaction case, where Coulomb interaction U is small and all the three configurations f^0, f^1, and f^2 are energetically possible, the variational wave function has been taken as in k space

$$|\Psi_0\rangle=\prod_{k\sigma}(1+A_{k\sigma}b^+_{k\sigma}c_{k\sigma})|F\rangle, \tag{2}$$

with $|F\rangle$ as the conduction-electron state and A_k the variational parameters. It can be easily seen that the resultant states are in the form of two quasiparticle bands; the lower branch of quasiparticle spectra is given by

$$E^-_k=1/2\left[\left(\epsilon_k+\epsilon_f+\frac{Un^f}{2}\right)-\sqrt{\left(\epsilon_k-\epsilon_f-\frac{Un^f}{2}\right)^2+4V_k^2}\right]. \tag{3}$$

B. Strong interaction case

In the high interaction case, where U is very large and the probability of f^2 configuration is very small, the variational wave function which projects the f^2 configuration out may be written as

$$|\Psi\rangle=\prod_{k\sigma}[1+A_{k\sigma}(1-n^f_{-\sigma})b^+_{k\sigma}c_{k\sigma}]|F\rangle. \tag{4}$$

For this case, the corresponding expression of E^-_k is

$$E^-_k=\tfrac{1}{2}[(\epsilon_k+\epsilon_f P_f)-\sqrt{(\epsilon_k-\epsilon_f P_f)^2+4V_k^2P_f^2}]. \tag{5}$$

C. Electrical resistivity

We are not interested here in the absolute value of resistivity and thermoelectric power but only in the variation of resistivity and thermoelectric power with temperature. In the

 0021-8979/94/76(10)/6223/3/$6.00 © 1994 American Institute of Physics

low-temperature regime, we assume the resistivity is produced by the impurities in the system. Then we use the electrical conductivity formula given by Mott[17]

$$\sigma(T)=\int\left(-\frac{\partial f_k^-}{\partial E_k^-}\right)\tilde{\sigma}(E_k^-)dE_k^-, \tag{6}$$

where $\tilde{\sigma}(E_k^-)$ can be written as

$$\tilde{\sigma}(E_k^-)=\sigma_0[N^c(E_k^-)]^2, \tag{7}$$

$$\sigma_0=\frac{2\pi e^2\hbar^3}{m^2}|D_E|^2_{\text{av}}. \tag{8}$$

The symbols in σ_0 are given in Ref. 17. σ_0 has been taken as a constant in our calculations. f_k^- is the Fermi function for the lower branch of the quasiparticle spectrum and $N^c(E_k^-)$ is the density of (lower part of) perturbed conduction states.

D. Thermoelectric power

The thermoelectric power $Q(T)$ may be written in terms of $\tilde{\sigma}(E_k^-)$ [17] in the following way

$$Q(T)=Q_0\frac{\int dE_k^-(-\partial f/\partial E_k^-)(E_k^--\mu)\tilde{\sigma}(E_k^-)}{\int dE_k^-(-\partial f/\partial E_k^-)\tilde{\sigma}(E_k^-)}, \tag{9}$$

where

$$Q_0=\frac{1}{e}. \tag{10}$$

III. RESULTS AND DISCUSSIONS

In these calculations we have considered a tight-binding conduction band which is centered around zero energy with a conduction-band width $W=2.0$ eV. The total number of elec-

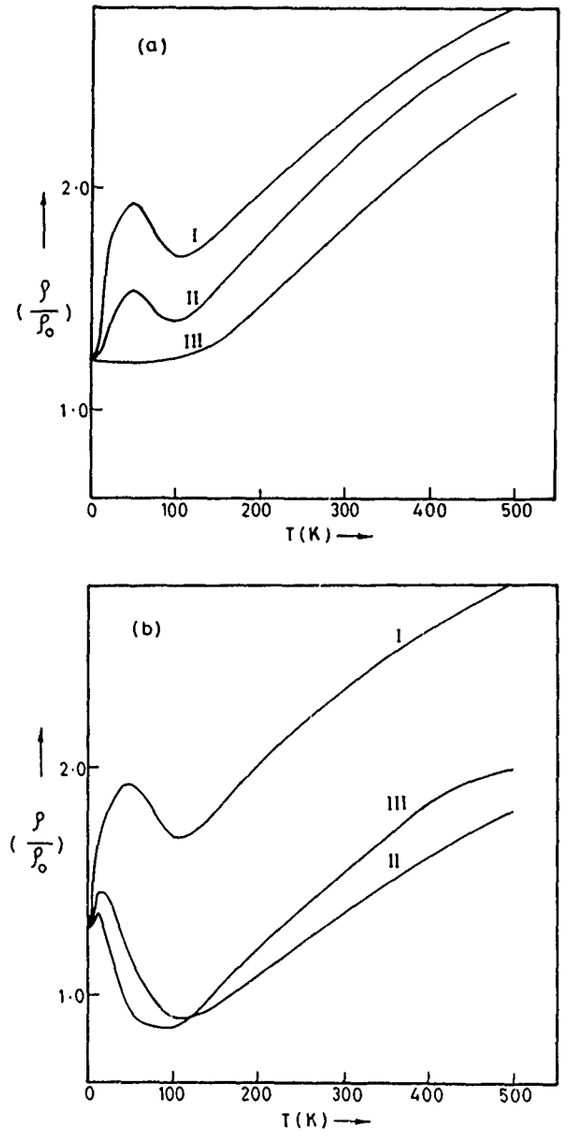

FIG. 1. Electrical resistivity ρ as a function of temperature for the tight-binding conduction-band case (a) $V=0.25$, $U=\infty$, curve I for $\epsilon_f=-0.6$, curve II for $\epsilon_f=-0.4$, and curve III for $\epsilon_f=-0.2$. (b) $V=0.25$, $\epsilon_f=-0.6$, curve I for $U=\infty$, curve II for $U=1.0$, and curve III for $U=0.5$

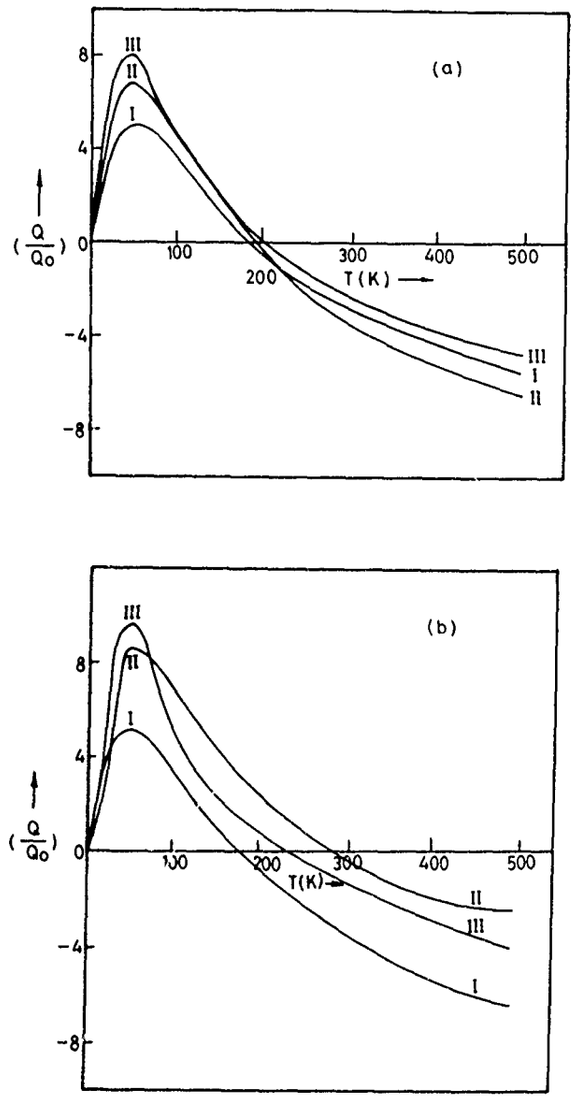

FIG. 2. Variation of thermoelectric power Q with temperature for tight-binding conduction-band case (a) $V=0.25$, $U=\infty$, curve I for $\epsilon_f=-0.6$, curve II for $\epsilon_f=-0.4$, and curve III for $\epsilon_f=-0.2$. (b) $V=0.25$, $\epsilon_f=-0.6$, curve I for $U=\infty$, curve II for $U=1.0$, and curve III for $U=0.5$

trons per site (n^c+n^f) has been taken to be 1.5. We have calculated here the temperature dependence of $\rho(T)$ for different effecti'' positions of f level ϵ_f and with finite as well as infinite U. ₃ results are shown in Fig. 1. Fig. 1(a) shows $\rho(T)$ for $\epsilon_f=-0.6$, -0.4, and -0.2 eV. We obtain the typical behavior in $\rho(T)$ with a rapid increase $\sim T^2$ at low temperatures, a maximum near $T_{max}=50$ K, and a NTC for higher temperatures. As f level ϵ_f shifts downward with respect to Fermi energy ϵ_F, $\rho(T)$ increases more sharply in the low-T regime; as a result, the peak in $\rho(T)$ becomes even sharper with a larger NTC. Figure 1(b) shows $\rho(T)$ for different interactions: $U=0.5$, 1.0, and ∞. Here when U is increased the resistivity increases and he peak at low temperature gets sharpened. These resistivity results are in qualitative agreement with experimental results for $YbAgCu_4$ (HF compound) and $CePd_3$ (MV compound).[16] It may be noted here that we have not considered the phonon contribution to resistivity, which is appreciable toward the high temperatures.

Corresponding results for the temperature dependence of the thermoelectric power $Q(T)$ are shown in Fig. 2. We observe the extremum in $Q(T)$ approximately at the same temperature T_{max}, where the resistivity has its maximum and this extremum in $Q(T)$ is also present when $\rho(T)$ does not have the maxima as in $\epsilon_f=-0.2$, in complete agreement with the experimental findings. We obtain a change of the sign of $Q(T)$ for relatively high temperatures. Our $Q(T)$ results match qualitatively with the experimental result of Visser *et al.*[6] for the HF compound UPt_3.

Our main conclusions are (1) Both types of resistivity behaviors (viz., with or without maxima at low T) can be obtained within the same treatment by changing slightly only one parameter like ϵ_f. (2) The relevant mechanism responsible for the temperature dependence of $\rho(T)$ and $Q(T)$ is the special type of dispersion curve of these systems, because of which they have a very high quasiparticle density of states. We have considered here the orbitally nondegenerate Anderson Hamiltonian. It explains much valence fluctuation and heavy fermion physics, at least qualitatively.

Understanding the great range of magnetic ordering behavior in correlated *f*-electron systems

Q. G. Sheng and B. R. Cooper
Department of Physics, West Virginia University, Morgantown, West Virginia 26506-6315

The magnetic ordering behavior of correlated f-electron systems varies widely. With regard to the value of the ordered moments, there are systems of saturated moment (e.g., CeSb), of moment somewhat reduced from the saturated value (e.g., UTe), of very small moment (e.g., UPt_3) and of no moment at all (e.g., $CeCu_2Si_2$). We show that such wide diversity in magnetic ordering is a manifestation of the competition between (1) hybridization and exchange interaction and (2) localization and itinerancy. By analyzing these effects, we develop a theory which organizes the diverse magnetic behavior into a unified picture describable through one model Hamiltonian. An important feature of this analysis is that we recognize and treat the effect of band-f Coulomb exchange simultaneously with that of band-f hybridization. Rather than adopting the standard analysis using the "Kondo resonance"–"Kondo compensation" concept, the development of this theory offers a new approach to treat the correlated f-electron state. The present theory naturally leads to a nonmagnetic singlet "Kondo state" which is one of the possible states, along with other magnetic states which the system could be in, when the conditions determining the state of the system favor that choice. The f orbital motions and spin-orbital coupling are given full consideration in the theory.

I. INTRODUCTION

For correlated f-electron systems, one interesting and not yet fully understood fact is that their magnetic ordering behavior has wide diversity. On one hand, there are "Kondo lattice" materials, in which the localized ordered moments are very small or vanishing; on the other hand, there are materials having strong magnetic ordering with almost saturated moments. Between the two extremes, there are a variety of materials with ordered magnetic moments ranging from very small to very large, while their magnetic structures also have rich complexities.[1] Can such diverse f magnetism be understood on the basis of one unified picture?

There are a variety of approaches to treat the correlated f-electron systems. For most of these approaches, the foundation of the theoretical framework is the concept of "Kondo resonance"–"Kondo compensation," and there are a large number of publications based on this line of thought.[2] In this work, we propose an alternative approach to treat the correlated f-electron systems, which has nothing to do with the concept of Kondo resonance–Kondo compensation. This theory covers the diverse f magnetism, and it naturally leads to the nonmagnetic singlet "Kondo state" as one of the possible states, along with other magnetic states, which the system could be in, depending on what the conditions favor. It shows how the diversity in f magnetism rests on the fundamental aspects of the f-electron systems, including the roles of hybridization versus exchange interaction, localization versus itinerancy, and the f orbital motion.

We describe the theory in three steps: (1) for a single atom, considering only the spins of electrons; (2) also for a single atom, including the f orbital motion; (3) forming a crystal using atoms described by (1) and (2).

II. STEP 1

Consider a single isolated atom which has two orbitals: an f orbital $|f\rangle$ and a ligand orbital $|l\rangle$. Assume the following Hamiltonian for this atom:

$$H_{\text{atom}}=\epsilon_l\sum_\sigma l_\sigma^\dagger l_\sigma+\epsilon_f\sum_\sigma f_\sigma^\dagger f_\sigma+U f_\uparrow^\dagger f_\uparrow f_\downarrow^\dagger f_\downarrow$$

$$+V\sum_\sigma (l_\sigma^\dagger f_\sigma+h.c.)-J\sum_{\sigma\sigma'} f_\sigma^\dagger f_{\sigma'} l_{\sigma'}^\dagger l_\sigma, \quad (1)$$

where ϵ_f and ϵ_l are the energies of $|f\rangle$ and $|l\rangle$, respectively; $f_\sigma^\dagger$ and $l_\sigma^\dagger$ create an electron with spin σ in $|f\rangle$ and $|l\rangle$, respectively; U is the f-f Coulomb repulsion; V is the hybridization between the two orbitals; and J is the exchange Coulomb interaction between f and ligand electrons. Suppose $\epsilon_l>\epsilon_f$. Hamiltonian (1) is the Anderson Hamiltonian plus a J interaction. The inclusion of J leads to significant magnetic consequences, which have been shown by first-principle calculations for several materials,[3] and will be further analyzed later.

Consider the case that the atom has two electrons. Neglect double occupancy of $|f\rangle$ by assuming $U\to\infty$. When $V=0$ and $J=0$, the system has a fourfold degenerate ground state, which, having one electron in $|f\rangle$ and the other in $|l\rangle$, has an energy $E_0=\epsilon_l+\epsilon_f$. The fourfold degenerate states can be grouped into a spin singlet $|\Phi_{S=0}\rangle$ and a spin triplet $|\Phi_{S=1}\rangle$:

$$|\Phi_{S=0}\rangle=\frac{1}{\sqrt{2}}(f_\uparrow^\dagger l_\downarrow^\dagger-f_\downarrow^\dagger l_\uparrow^\dagger)|0\rangle, \quad (2a)$$

$$|\Phi_{S=1}^{M=+1}\rangle=f_\uparrow^\dagger l_\uparrow^\dagger|0\rangle;$$

$$|\Phi_{S=1}^{M=0}\rangle=\frac{1}{\sqrt{2}}(f_\uparrow^\dagger l_\downarrow^\dagger+f_\downarrow^\dagger l_\uparrow^\dagger)|0\rangle; \quad (2b)$$

 0021-8979/94/76(10)/6226/3/$6.00 © 1994 American Institute of Physics

$$|\Phi_{S=1}^{M=-1}\rangle = f_{\uparrow}^{\dagger} l_{\downarrow}^{\dagger}|0\rangle.$$

The system has a singlet excited state, which, having two electrons in $|l\rangle$, has an energy $E_{ex}=2\epsilon_l$:

$$|\Phi_{ex}\rangle = l_{\uparrow}^{\dagger} l_{\downarrow}^{\dagger}|0\rangle. \tag{3}$$

When V is turned on but J is kept to zero, the system has the following changes: (i) The singlet $|\Phi_{S=0}\rangle$ mixes slightly with $|\Phi_{ex}\rangle$, lowers its energy by $\Delta E \simeq 2V^2/(\epsilon_l - \epsilon_f)$, and becomes the actual ground state. (ii) The triplet $|\Phi_{S=1}^{M=0,\pm 1}\rangle$ does not mix with $|\Phi_{S=0}\rangle$ or $|\Phi_{ex}\rangle$; its energy remains unchanged and becomes a low-lying excited state. (iii) $|\Phi_{ex}\rangle$ mixes slightly with $|\Phi_{S=0}\rangle$, and raises its energy by $\Delta E \simeq 2V^2/(\epsilon_l - \epsilon_f)$.

The above picture contains the key elements of the Kondo problem: at low temperatures ($T \ll \Delta E$), the system is bound in the nonmagnetic singlet state; as the temperature rises, the triplet state becomes populated and the system develops magnetic moments; at high temperatures ($T \gg \Delta E$), the singlet and triplet states are equally populated, and the f and ligand electrons can be seen as effectively decoupled. The foregoing treatments and discussions involving V were given by Fulde[4] and readers can find the details therein.

On the other hand, when J is turned on but V is kept to zero, the splitting of the ground state is reversed. The exchange energy is $+J$ for the singlet $|\Phi_{S=0}\rangle$ and $-J$ for the triplet $|\Phi_{S=1}\rangle$. Thus the ground state splits by $\Delta E = 2J$, and since $J>0$, the triplet instead of the singlet is the ground state. Therefore J tends to destroy the Kondo state driven by V and maintains magnetic moments for the system.

Ultimately, whether the system is in the nonmagnetic Kondo state or a magnetic state depends on whether V or J prevails. This opens the door for understanding the "Kondo-like" f phenomena and the non-Kondo magnetic f phenomena by a single model Hamiltonian.

III. STEP 2

We now do the same kind of analysis as in step 1, but with the f orbital motion included. We show that the features in step 1 are not fortuitous because of the neglect of the f orbital motion; instead, they are intrinsic to the f-electron systems. The atomic Hamiltonian is

$$H_{atom} = \epsilon_l \sum_{\sigma} l_{\sigma}^{\dagger} l_{\sigma} + \epsilon_f \sum_{m\sigma} f_{m\sigma}^{\dagger} f_{m\sigma} + \sum_{m\sigma} (V_m l_{\sigma}^{\dagger} f_{m\sigma} + \text{h.c.})$$

$$- J \sum_{m\sigma\sigma'} f_{m\sigma}^{\dagger} f_{m\sigma'} l_{\sigma'}^{\dagger} l_{\sigma}, \tag{4}$$

where m indicates the orbital state of $|f\rangle$. We have dropped U from Eq. (4) by excluding double occupancy of $|f\rangle$ from our discussion. Considering that in a lattice the orbital motion of the ligand states are largely quenched by the crystal field, we assume $|l\rangle$ is an s wave. Then J is m independent but V_m is not. We also include spin-orbit coupling in the following discussion by restricting the f electron to the $j=5/2$ states $|f_\mu\rangle$.

When $J=0$ and $V=0$, the ground state $|j,\nu\rangle$ ($E_0 = \epsilon_l + \epsilon_f$) is 12-fold degenerate, in which the total angular momentum j of the system can be $j=5/2 \pm 1/2$; and the excited state $|\Phi_{ex}\rangle$ ($E_{ex}=2\epsilon_l$) is the same as in Eq. (3).

When V is turned on but J kept zero, the resulting 13×13 Hamiltonian matrix has the following form:

$$\begin{pmatrix} E_{ex} & \tilde{V}_1 & \tilde{V}_2 & \tilde{V}_3 & \cdots & \tilde{V}_{12} \\ \tilde{V}_1^* & E_0 & 0 & 0 & \cdots & 0 \\ \tilde{V}_2^* & 0 & E_0 & 0 & \cdots & 0 \\ \tilde{V}_3^* & 0 & 0 & E_0 & \cdots & 0 \\ \vdots & \vdots & \vdots & \vdots & \ddots & \vdots \\ \tilde{V}_{12}^* & 0 & 0 & 0 & \cdots & E_0 \end{pmatrix}, \tag{5}$$

where $\tilde{V}_m$ is V_m multiplied by some coefficient. The elements of matrix (5) are all zero except those on the first row, first column, and the diagonal. This leads to the following eigenequation:

$$[(E_0-\lambda)(E_{ex}-\lambda) - 6\tilde{V}^2](E_0-\lambda)^{11} = 0, \tag{6}$$

where

$$\tilde{V}^2 \equiv \frac{1}{7} \sum_{m=-3}^{3} |V_m|^2. \tag{7}$$

As a result, the system has: (i) an 11-fold state $|\Phi_1\rangle$, which is purely $|j\nu\rangle$, and has an energy E_0; (ii) a singlet $|\Phi_0\rangle$, which is $|j\nu\rangle$ dominant but mixes slightly with $|\Phi_{ex}\rangle$, and has an energy $E_0 - \Delta E$; (iii) a singlet which is $|\Phi_{ex}\rangle$ dominant but mixes slightly with $|j\nu\rangle$, and has an energy $E_{ex} + \Delta E$, which we simply denote as $|\Phi_{ex}\rangle$. These are similar to the spin-only case: the 12-fold degenerate ground state splits into an actual ground-state singlet $|\Phi_0\rangle$ and a low-lying excited state multiplet $|\Phi_1\rangle$, and $|\Phi_0\rangle$ is the only one of these states which mixes with $|\Phi_{ex}\rangle$ through V, while $|\Phi_1\rangle$ is not affected by V. $\Delta E \simeq 6\tilde{V}^2/(\epsilon_l - \epsilon_f)$ and the singlet $|\Phi_0\rangle$ is

$$|\Phi_0\rangle \simeq \left[1 + \frac{6\tilde{V}^2}{(\epsilon_l - \epsilon_f)^2}\right]^{-1/2} \times \left(\sum_{\nu=-3}^{3} \frac{V_\nu^*}{\sqrt{7}\tilde{V}} |3,\nu\rangle + \frac{\sqrt{6}\tilde{V}}{\epsilon_l - \epsilon_f} l_{\uparrow}^{\dagger} l_{\downarrow}^{\dagger} |0\rangle \right). \tag{8}$$

By applying the condition that $V_{-m} = (-1)^{3+m} V_m^*$, one can verify that $\langle\Phi_0|\mathbf{j}|\Phi_0\rangle = 0$. Thus in $|\Phi_0\rangle$, an f $j=5/2$ moment and a ligand $s=1/2$ spin result in a nonmagnetic singlet, the Kondo state. $|\Phi_1\rangle$ is magnetic since $\langle\Phi_1|\mathbf{j}|\Phi_1\rangle \neq 0$. We conclude that the forming of the Kondo state can be regarded as a consequence of the local correlations. In contrast, in the theory of Kondo compensation it is not clear how an f $j=5/2$ moment can be fully "compensated" by conduction electrons without the hardly reasonable consequence of consuming five conduction $s=1/2$ spins.

We now turn on J. One can verify that the J interaction does not change the $|\Phi_0\rangle$ and $|\Phi_1\rangle$ states resulting from the V interaction, but simply shifts these states by different amounts. As a result, the 11-fold degenerate $|\Phi_1\rangle$ splits: Some levels move toward $|\Phi_0\rangle$, and some do not. If J is large enough, the lowest level from $|\Phi_1\rangle$ can cross over the V-induced gap ΔE and become the actual ground state, oth-

erwise, $|\Phi_0\rangle$ remains the actual ground state. Also similar to the spin-only case, whether the nonmagnetic singlet or the magnetic multiplet is the ground state depends on whether V or J prevails.

So far, we have seen that the key elements of step 1 remain when f orbital motion is included. A new aspect also emerges with the inclusion of f orbital motion. Unlike the spin-only case, $|\Phi_0\rangle$ and $|\Phi_1\rangle$ are not eigenstates of the total moment $\hat{j}_z$. This causes the system to respond to a magnetic field (external or internal) with complicated magnetic configurations. Thus a crystal formed by such atoms, if being magnetic, can have complicated magnetic structures. In contrast, the spin-only model can only have simple magnetic structures.

IV. STEP 3

We now construct a crystal using atoms described by steps 1 and 2. We call the interactions within an atom, which are represented by atomic Hamiltonians (1) and (4) and lead to atomic states $|\Phi_0\rangle$, $|\Phi_1\rangle$, and $|\Phi_{ex}\rangle$, local correlations. We call the overlaps between electronic wave functions from different atoms, together with the interactions between electrons from different atoms, nonlocal correlations. The nonlocal correlations, by driving the system toward itinerancy, tend to suppress the local effects, while the local correlations tend to preserve the local effects, and to suppress the itinerancy.

We maintain that, for a large number of materials, the suppression of the local effects by the nonlocal correlations is small. In other words, the atomic states $|\Phi_0\rangle$, $|\Phi_1\rangle$, and $|\Phi_{ex}\rangle$ resulting from the local correlations will be sustained to a large extent, while being dressed by the onset of nonlocal correlations. Based on this premise, we take $|\Phi_0\rangle$, $|\Phi_1\rangle$, and $|\Phi_{ex}\rangle$ as the starting states, and adiabatically turn on the nonlocal correlations. The result is the self-banding of these atomic states, which leads to density spectra $|\Psi_0(\mathbf{k})\rangle$, $|\Psi_1(\mathbf{k})\rangle$, and $|\Psi_{ex}(\mathbf{k})\rangle$, which are associated with $|\Phi_0\rangle$, $|\Phi_1\rangle$, and $|\Phi_{ex}\rangle$, respectively.

Such spectra are of two-electron representation, since $|\Phi_0\rangle$, $|\Phi_1\rangle$, and $|\Phi_{ex}\rangle$ are two-electron states. The effects of local correlations are completely built into the two-electron wave function, thus completely represented by the two-electron spectra. If we choose single-electron states as bases to form a spectrum, the local correlation effects cannot be represented in the spectrum so directly and completely.

$|\Psi_{ex}(\mathbf{k})\rangle$ forms a wide band, since $|\Phi_{ex}\rangle$ is a product of two $|l\rangle$s, which are spatially extended. $|\Psi_0(\mathbf{k})\rangle$ forms a narrow band, since $|\Phi_0\rangle$ is a product of one $|f\rangle$ and one $|l\rangle$, and $|f\rangle$ is spatially very small. $|\Psi_1(\mathbf{k})\rangle$ also forms a narrow band. We neglect the mixing between $|\Psi_0(\mathbf{k})\rangle$, $|\Psi_1(\mathbf{k})\rangle$, and $|\Psi_{ex}(\mathbf{k})\rangle$, since it will not change our discussion. We can also see that the Fermi level is always in the vicinity of narrow peaks from $|\Psi_0(\mathbf{k})\rangle$ and $|\Psi_1(\mathbf{k})\rangle$ by simple counting of the electron occupation.

We now have a two-component spectrum near the Fermi level: a nonmagnetic $|\Psi_0(\mathbf{k})\rangle$ component and a magnetic $|\Psi_1(\mathbf{k})\rangle$ component. The local V and J interactions determine which component is lower, and how much it is lower; the nonlocal correlations determine how wide they are, and the local and nonlocal correlations together determine how much they overlap. This opens a wide range of possibilities depending on by what proportion the two components are occupied, and such wide possibilities lead to a wide range of magnetic behaviors. Three such possibilities are: (a) $|\Psi_0(\mathbf{k})\rangle$ is occupied but $|\Psi_1(\mathbf{k})\rangle$ is empty, which leads to a nonmagnetic Kondo state; (b) $|\Psi_0(\mathbf{k})\rangle$ and $|\Psi_1(\mathbf{k})\rangle$ both are partially occupied, which leads to reduced moments; (c) $|\Psi_1(\mathbf{k})\rangle$ is occupied but $|\Psi_0(\mathbf{k})\rangle$ is empty, which leads to strong magnetism.

The above possibilities correspond to the case when the f population is close to 1. If we include the wide band $|\Psi_{ex}(\mathbf{k})\rangle$ into our discussion, it also opens the possibilities of reduced f population: the more $|\Psi_{ex}(\mathbf{k})\rangle$ is populated, the less the f population the system has.

From the description above, we see that this theory opens the door to understanding diverse f magnetism by addressing the fundamental aspects of the correlated f-electron systems, such as hybridization versus exchange interaction, localization versus itinerancy, and Kondo state versus magnetized state. As for the Kondo state, it comes from a new approach which is completely different, fundamentally, than the Kondo resonance–Kondo compensation theory. In this theory, the alternative possibility of the Kondo state and the magnetic states appears naturally as a consequence of local correlations.

More work is needed to see if the approach proposed here can be developed into a comprehensive theory of correlated f-electron systems. (We also point out that the part of the theory described in step 3 is only a preliminary illustration, and a more elaborate analysis will be published elsewhere.) To reach this goal, more aspects need to be addressed, such as: the spatial and time distribution of electrons in $|\Psi_0(\mathbf{k})\rangle$ and $|\Psi_1(\mathbf{k})\rangle$, magnetic excitations due to electronic scattering between $|\Psi_0(\mathbf{k})\rangle$ and $|\Psi_1(\mathbf{k})\rangle$, and effective mass and susceptibility of electrons in $|\Psi_0(\mathbf{k})\rangle$ or $|\Psi_1(\mathbf{k})\rangle$.

The complex magnetic behavior of holmium is a well-established experimental fact and has been studied by a variety of experimental techniques, including magnetization, x-ray diffraction, thermal expansion, and heat capacity. Our recent studies have focused on using neutron diffraction to study the temperature and field dependence of the helimagnetic structure. The pitch of the helix is described by τ, the spiral wave vector. τ usually varies smoothly with temperature but tends to lock in at various values that are commensurate with the lattice when a field is applied. These lock-ins provide clues to the nature of the different magnetic phases and, up to now, all the lock-ins have corresponded to features of the magnetic phase diagram obtained from magnetization measurements. However, recent experiments have revealed a previously unobserved lock-in at τ=2/9 rlu in a 1.4 T b-axis field. It shares the same general features of other lock-ins except that it does not correspond to any feature of the magnetic phase diagram.

Neutron diffraction has been particularly useful in determination of the magnetic structure and the nature of the ordering of magnetic substances. Holmium is one of the materials that has been frequently studied in this way.[1-4] For our part, we have used neutron diffraction to study holmium and its intricate magnetic phase diagram,[5-9] and used the results to supplement the information yielded by the various other experimental techniques.[10-19] One phenomenon which has been extensively investigated,[6-9] using neutron diffraction, is the lock-in behavior of the spiral wave vector τ.

We have found lock-ins in holmium for magnetic fields applied in different directions: specifically at τ=1/4 and 1/5 rlu (reciprocal lattice units) in a 3 T c-axis field.[5-7] τ=1/6 rlu is the "original" lock-in which occurs in zero field below the Curie temperature (T_c=20 K).[1] More recently, we have observed lock-ins at τ=1/4 and 5/18 for b-axis fields of 1.4 and 3 T.[8,9] In this paper we report our most recent studies, which have revealed a previously unobserved lock-in at τ=2/9 rlu which occurs at 75 K (in a 1.4 T b-axis magnetic field). The discovery of this lock-in is of particular interest for two reasons. First of all, τ=2/9 is part of a series of commensurate values arising from a simple spin-slip model.[2,20,21] Second, while all of the previously observed lock-ins correspond to features of the magnetic phase diagram seen in magnetization measurements,[13] this is not the case for the τ=2/9 lock-in. Given the previous correspondence between lock-ins and phase transitions, this raises the question of why this lock-in was not observed in magnetization measurements.

Measurements were made on the N5 triple-axis spectrometer at the Chalk River Laboratories of AECL-Research in Chalk River, Ontario. The scattering experiments were done elastically at an incident neutron energy of 8.23 THz, corresponding to a wavelength of 0.155 nm. The holmium sample was a high-purity single crystal roughly 2×1×1 cm, provided by Pechan and Stassis[3] and used in our previous neutron studies. The sample was mounted in the M2 cryostat,[22] which provided a horizontal field with less than a 2% variation in the field over the sample volume. The cryostat allows a range of temperatures from 4.2 K to room temperature, fields up to 3 T, and 350° access for the neutron beam. The sample was mounted so that we could observe the (h01) reflections. A platinum resistance thermometer was used to control the temperature of the sample and a carbon glass thermometer used to read the temperature. The thermometers were mounted in the copper base to which the sample mount was also connected. The temperatures were high enough, and the field was low enough, that magnetoresistance effects on the thermometers were negligible.

Holmium in its antiferromagnetic state (between 20 and 132 K in zero applied magnetic field) has a helimagnetic structure with the moments in the basal planes ferromagnetically aligned, but with the direction of alignment in the plane changing in angle as one moves from plane to plane along the c axis. The pitch of the helix is given by the spiral wave vector τ, which represents the periodicity in reciprocal space (for example, if the helix has a period of four lattice constants, then τ=1/4 rlu). The effect of the magnetic structure on the neutron-diffraction pattern is to produce magnetic satellite peaks offset by τ from the nuclear peaks in reciprocal space, for instance at (10$\pm\tau$). Since the magnetic cross section and the nuclear cross section are comparable under our experimental conditions, the primary peak and its satellites are roughly of the same, relatively large, intensity. We measured τ by scanning in the c^* direction, through both the satellite and the corresponding nuclear peak, carefully measuring their positions (determined using a Gaussian fit), and then obtaining the difference. In zero field τ decreases smoothly, from a value of 5/18 (0.2778) rlu at the Néel temperature (T_N=132 K), to 1/6 rlu at the Curie temperature. However, in the presence of an applied magnetic field, we have found that τ becomes locked in, causing the τ versus temperature curve to flatten out at certain values of τ that are commensurate with the lattice. As a locked-in region is entered in a temperature sweep, there is also a distinct anomaly

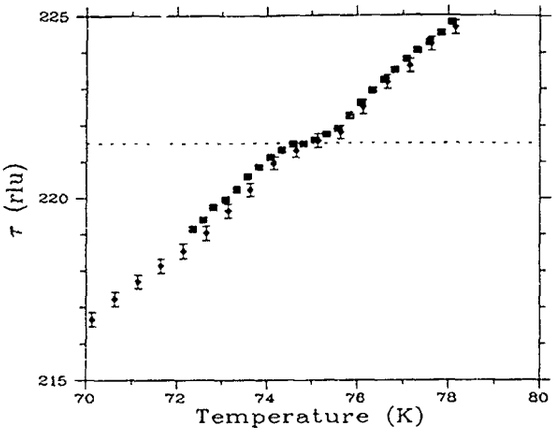

FIG 1. τ vs temperature in a 1.4 T b-axis field showing the 2/9 lock-in highlighted by the dashed line. Initial coarse runs are shown by ◆, and the finer temperature runs shown by ■

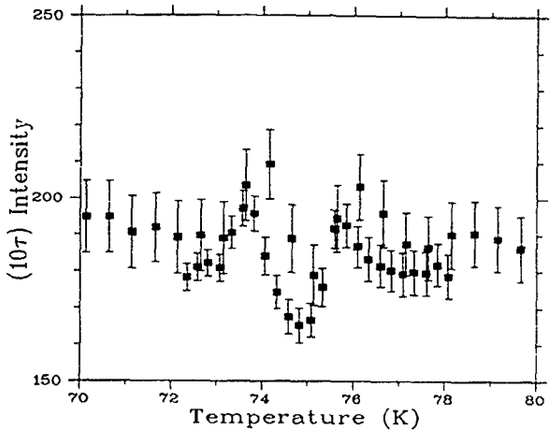

FIG. 2. (10τ) intensity vs temperature for the same runs as in Fig. 1 Notice the sharp anomaly in the lock-in region which has been present for all lock-ins observed so far.

in the intensity of the magnetic satellite. The occurrence of this anomaly is not understood, but it is very useful for identifying the lock-ins. The absolute error in τ is estimated to be ± 0.0010 rlu and relative error between the scans better than ± 0.0001 rlu. The absolute error in τ arises from uncertainty in the lattice parameters which are needed to measure distances in reciprocal space. Unfortunately, data for the thermal expansion of holmium in the presence of a 1.4 T field are not available and, given the large magnetostriction of holmium, it is unlikely that the use of zero-field thermal-expansion data in this region would give the lattice parameters to sufficient accuracy. The relative error arises from the counting statistics and least-squares-fitting procedure.

In Fig. 1 we show a plot of τ versus temperature for a 1.4 T b-axis field. This plot clearly shows the lock-in at which τ is 0.2215 ± 0.0010 rlu, corresponding to $\tau = 2/9$ rlu, at a temperature of 75 K. Despite the fairly modest field value, the lock-in is prominent and has a width of roughly 1.5 K for the flattened region, very similar to the widths of the lock-ins at much higher field values. Figure 1 also shows the reproducibility from run to run. There are two runs shown: one at a coarse temperature step of 0.5 K and another finer run at 0.25 K between the scans. The two plots are almost identical. A lock-in at 2/9 rlu is not altogether unexpected since it is one of the commensurate values that arises out of a simple spin-slip analysis. Although the spin-slip model was devised as a description of low-temperature phenomena (below 70 K), and is based on the detection of low-temperature phenomena (below 70 K), and is based on the detection of 5τ and 7τ peaks,[2,20] there may be some basis for its use in high-field situations where extra stabilizing effects may be present. The associated intensity anomaly is shown in Fig. 2. It is often useful to use the peaks in intensity to characterize the width of the lock-in, since they are sharply defined compared to the edges of the lock-in region on the τ vs T plot. If we examine this region of the magnetic phase diagram, obtained from magnetization measurements,[13] we find that this point falls below the closest coexistence curve by 0.4 T. In addition, if one follows this coexistence curve to zero field, one finds that this curve is associated with $\tau = 1/5$ and not 2/9 rlu. It thus appears that a branch of the phase diagram has been missed in the magnetization measurements. On looking at the magnetization measurements of Willis *et al.*,[13] it is seen that some of the magnetization anomalies are quite subtle and it is, perhaps, not too surprising that one might have been missed.

As well as the previously undiscovered 2/9 lock-in, we have also observed lock-ins at 1/4 and 5/18 rlu for the 1.4 T b-axis field. We have previously reported the 5/18 lock-in and compared it to the 5/18 lock-in for a 3 T b-axis field.[23] In that paper we mentioned that the width of the 5/18 lock-in appeared to vary as the square of the field, but this is not the case for the 1/4 lock-in. In Fig. 3 we show the 1/4 lock-in for a 1.4 T b-axis field, drawn to the same scale as Fig. 1 of our previous work.[9] Using the intensity anomaly to characterize the widths, we obtain a ratio of widths, (2.2 K/0.8 K)=2.8 compared with (3 T/1.4 T)^2=4.6, so our simple generalization does not apply here. This may have to do with the twisting of the phase diagram that occurs in this region compared

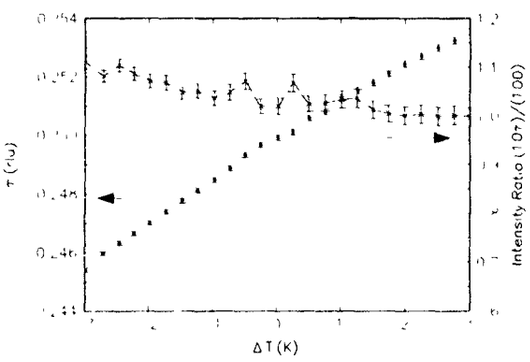

FIG. 3. τ vs the difference in temperature (ΔT) away from 99.6 K, in a 1.4 T b-axis field is shown by ● The 1/4 lock-in is much less prominent than in a 3 T field, and probably would have been overlooked if not for the intensity anomaly The ratio of the (10τ) intensity to that of the (100) nuclear peak is shown by ×.

to the higher temperature region and also the c-axis phase diagram. We also note that in the 1.4 T b-axis field the width of the 1/4 lock-in is less than half that of the 2/9 lock-in and is much less prominent.

There is also some question of how the 2/9 lock-in would manifest itself at higher fields. Due to the high magnetization under such conditions, and the size of our sample, we have experienced difficulties in the past with bending of the sample mount by the forces and/or torques on the sample. These problems occurred in the region from 80 to 95 K in which there were two distinct phases present.[9] Assuming that there is another 2/9 coexistence curve on the phase diagram, we would hope to be able to observe some sort of anomalous behavior in this region for $\tau=2/9$ rlu. This is not the case, and it appears as though some other interaction is dominating in this region. Clearly this region is deserving of further study at higher field values.

We gratefully acknowledge the financial support of the Natural Sciences and Engineering Research Council of Canada and the Canadian Institute for Neutron Scattering. We also thank AECL-Research, Chalk River, for the use of their excellent facilities and it is a pleasure to thank the staff of the Neutron and Condensed Matter Science Branch, especially Larry MacEwan, Peter Moss, Mel Potter, and Don Tennant. We are indebted to M. J. Pechan and C. Stassis for the loan of the sample.

Die-upset Nd-Fe-Co-B magnets from blends of dissimilar ribbons

C. D. Fuerst and E. G. Brewer
Physics Department, GM Research and Development Center, 30500 Mound Road, Warren, Michigan 48090-9055

We prepared die-upset Nd-Fe-Co-B magnets from melt-spun ribbon powders which were a series of blends of two ribbon alloys. One alloy was always ternary Nd-Fe-B (no cobalt), and in the other cobalt replaced up to half of the iron. Differential scanning calorimeter measurements revealed that during hot working, the cobalt diffused across ribbon boundaries, effectively redistributing the transition metal concentration throughout the magnet. Instead of anomalies indicating the Curie temperatures of the two original ribbon compositions, we found a single transition consistent with the average cobalt concentration in the magnet. However, the transition was broader than expected, suggesting that the homogenization was incomplete. These results are new evidence of massive diffusion occurring between ribbons, changing the microstructure and facilitating the deformation of the otherwise rigid 2-14-1 magnet.

I. INTRODUCTION

Hot deformation, or die upsetting, was first presented as a viable process for greatly enhancing (>60%) the remanence of magnets produced from melt-spun Nd-Fe-B ribbons, by Lee *et al.* in the early 1980s.[1,2] Mishra and Lee[3] have described the microstructure of die-upset magnets as platelet-shaped grains (50–100 nm thick and 200–600 nm in diameter) where the short dimension corresponds to the c axis of the tetragonal $Nd_2Fe_{14}B$ crystalline[4] phase. The deformation process not only encourages anisotropic grain growth, but also causes the alignment of the grains with the c axis along the press direction (perpendicular to the flow of material). Optimizing alignment while maintaining sufficient coercivity has resulted in extremely high-energy products, nearly 50 MGOe, in melt-spun 2-14-1 magnets.[5,6]

The success of die upsetting depends on a fine-grained microstructure in the starting material. Suitable grain sizes can be easily obtained by melt spinning at moderate quench conditions.[5,7] It has also been demonstrated that mechanically alloyed[8] and hydrogen, decomposition, desorption, and recombination (HDDR)[9,10] materials can be used as precursors for die-upset magnets. During die upsetting there is a burst of grain growth at high temperatures (1000–1100 K), creating a coarser-grained structure within a relatively short period of time (~1 min). Material is diffusing between regions as smaller grains vanish and are replaced by the new larger platelet-shaped grains. The diffusion momentarily softens the matrix, permitting the deformation which in turn leads to the crystallographic alignment of the microstructure. Once the new microstructure stabilizes, the matrix becomes essentially rigid and further die upsetting is impossible.

In this paper, we have used differential scanning calorimeter (DSC) measurements of the Curie temperature (T_C) to characterize the extent of iron and cobalt diffusion within the die-upset magnet. These measurements are sensitive to the specific heat of the material which experiences an abrupt change in slope at T_C. This effect is very similar to that observed in thermal expansion measurements near T_C.[11–16]

II. EXPERIMENTAL DETAILS

We used our standard sample preparation techniques which have been extensively described elsewhere.[5,17] The melt-spun ribbons were crushed to less than 60 mesh and sieved to remove fine particles (less than 270 mesh). The composition of the ribbons was ~14 at. % neodymium, 6 at. % boron, and the remainder transition metal $TM=(Fe_{1-x}Co_x)$, where $0 \leq x \leq 0.5$.

Ribbon blends were prepared by mixing cobalt-free ($x_0=0$) ribbons with cobalt-containing ribbons ($x_1>0$). The average cobalt concentration (x_{avg}) depended on the weight ratios ($1-w$ and w) of the ribbons and can be approximated as $x_{avg} \cong (1-w)x_0 + wx_1$ or $x_{avg} \cong wx_1$ since $x_0=0$. At the extremes, $w=0$ and $w=1$, the powders consisted of a single composition with a cobalt concentration of x_0 and x_1, respectively.

The blends of ribbon powders were hot pressed to produce fully dense precursors (about 16 g). Subsequent die upsetting reduced sample heights by just over 50%. Magnetic properties were measured with a hysteresis graph after premagnetizing in a pulsed magnetic field (100 KOe). The remanences (B_r) for magnets with moderate cobalt levels ($x_{avg} \leq 0.2$) were in the range 12–12.5 kG; the coercivities (H_{ci}) were slightly more variable, 7–10 kOe. At higher cobalt concentrations ($0.2 < x_{avg} \leq 0.25$) the remanences tended to be lower, $B_r \sim 11$ kG with no commensurate change in coercivity. In general, the reduced energy products, $(BH)_{max}/(B_r/2)^2$, were in the range 0.9–0.95. Above $x_{avg} \sim 0.3$, the coercivities dropped off considerably.

A high-speed diamond saw was used to cut small (2 $\times 3 \times 3$ mm^3) samples weighing about 135 mg for the differential scanning calorimeter (DSC) measurements. We used a Perkin–Elmer model System-7 DSC with a temperature scan rate of 25 K per minute and a 25 ml per minute flow of argon

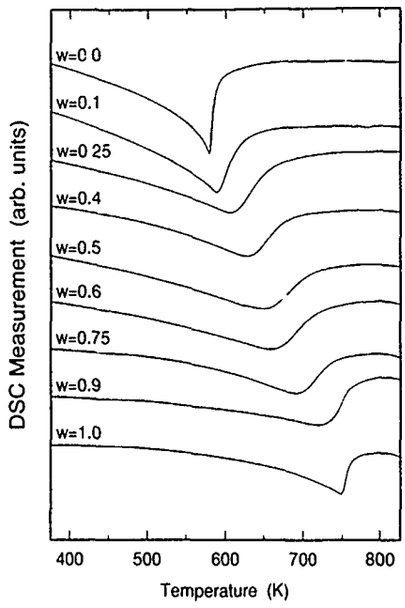

FIG. 1. DSC measurements of nine die-upset magnets produced by combining different weight fractions, $1-w$ and w, of two ribbon alloys, $x_0=0$ and $x_1=0.2$. For clarity, the measurements have been displaced vertically with the single-alloy magnets at the top ($w=0$) and bottom ($w=1$). The exothermic heat flow is upward.

gas. The DSC data have been adjusted to level the overall slope and were plotted in the figures with the exothermic direction of heat flow upward.

III. RESULTS AND DISCUSSION

The DSC measurements labeled $w=0$ and $w=1$ in Fig. 1 are characteristic of magnets from single-ribbon alloys. There is a relatively sharp minimum in each curve corresponding to T_c. Both transitions occurred at temperatures appropriate for their respective cobalt content, $T_c=588$ K for the $x_0=0$ cobalt-free alloy ($w=0$) and $T_c=757$ K for the $x_1=0.2$ cobalt-containing alloy ($w=1$).[18,19] However, when die-upset magnets were made from mixtures of these two ribbon alloys ($0<w<1$), there was no evidence of either of these transitions in the DSC measurements. Instead, the measurements revealed a single minimum or transition centered on the T_c expected for an alloy with a cobalt level equal to x_{avg}. Clearly the diffusion of iron and cobalt within the matrix is sufficient to create a material with nearly uniform cobalt distribution. This requires more than intergranular diffusion; rather, material transport is necessary over distances encompassing two or more ribbon particles.

It is also clear from Fig. 1 that the homogenization of the composition was incomplete, because rather than sharp transitions similar to the end points ($w=0$ and $w=1$), the blends produced broadened transitions, suggesting that small variations in cobalt concentrations between regions persisted. The greatest broadening occurred in the range $0.4\leq w\leq 0.8$, just where one would expect the greatest statistical variation in the average composition. The variation can be reduced by grinding the ribbon powders, which increases the number of

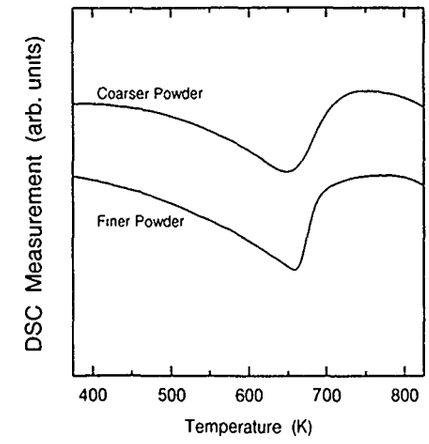

FIG. 2. DSC measurements on two die-upset magnets, both produced from a blend of equal weight fractions ($w=0.5$) of two ribbon alloys, one cobalt-free ($x_0=0$) and the other cobalt containing ($x_1=0.2$). The upper curve was typical for magnets made from as-crushed coarse powder, less than 60 mesh (<250 μm) and greater than 270 mesh (>53 μm). The lower curve was obtained from a magnet made from powder ground to finer than 325 mesh (<45 μm). The exothermic heat flow is upward.

particles within a given volume. The result can be seen in Fig. 2, which shows DSC measurements from two magnets with identical overall compositions, one produced from our standard (coarse) powder and the other with powder ground to less than 270 mesh (fine powder). The fine powder produced a sharper transition, consistent with less statistical variation and more uniform cobalt distribution.

Figure 3 shows DSC measurements for a series of magnets containing half cobalt-free ribbons and half cobalt-

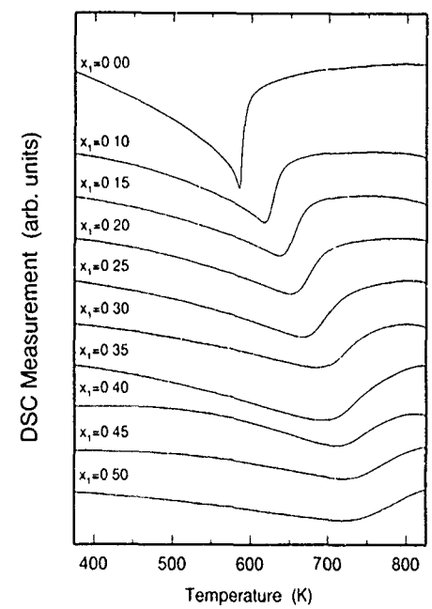

FIG. 3. DSC measurements of ten die-upset magnets, nine of which were produced by combining equal weight fractions ($w=0.5$) of cobalt-free ribbon alloys ($x_0=0$) and cobalt-containing ribbon alloys ($x_1>0$). The tenth magnet (top) contained no cobalt ($x_0=x_1=0$). The exothermic heat flow is upward.

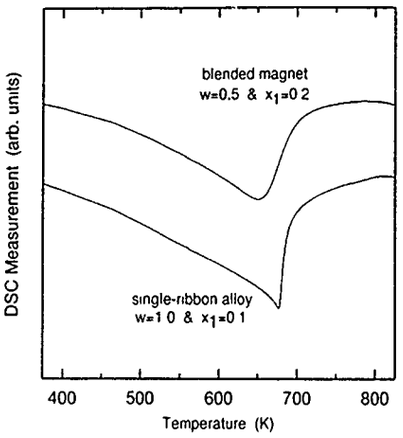

FIG 4. DSC measurements of two die-upset magnets, each with the same average cobalt content, $x_{avg}=0.1$. The first magnet (bottom) was prepared from a single ribbon alloy ($w=1$) containing cobalt, $x_1=0.1$. The second magnet (top) was prepared from a blend ($w=0.5$) of cobalt-free ribbons ($x_0=0$) and cobalt-containing ribbons ($x_1=0.2$). The exothermic heat flow is upward.

containing ribbons ($x_1>0$). The curve labeled $x_1=0$, corresponding to the single-ribbon alloy with no cobalt, is provided for comparison. In each case, the minimum corresponds to the anticipated T_c for a 2-14-1 alloy with a cobalt concentration of x_{avg}. The broadening increases monotonically with increasing x_1 until the transition is almost unrecognizable for the highest x_1 values. Even broader transitions might be possible at higher cobalt levels (up to $x_{avg}=0.5$), but the coercivities of die-upset magnets become very poor for $x_{avg}>0.3$.

We have also compared the DSC measurements of similarly prepared magnets with the same average cobalt concentration (see Fig. 4). Here both magnets have $x_{avg}=0.1$, but one was prepared from powders of a single-ribbon alloy ($w=1$ and $x_1=0.1$) and the other from blended ribbons ($w=0.5$ and $x_1=0.2$). The apparent Curie temperatures were both near 675 K, but the minimum was broader for the blended r agnet.

IV. SUMMARY

We have shown that DSC measurements can be used to characterize the relative distribution of iron and cobalt within die-upset 2-14-1 magnets. When compared to single-ribbon alloy magnets, the anomaly associated with T_c was considerably broader for magnets produced from blends of cobalt-free ribbons and cobalt-containing ribbons. When blending two ribbon powders, the broadest transitions were seen with nearly equal weight fractions. Since the broadening is controlled by regional variations in composition, the effect can be maximized by using coarse powers and selecting powders with large compositional differences, $x_1 \gg x_0$. Despite the broadening, the transition temperatures indicate that massive diffusion across ribbon boundaries has significantly homogenized the composition of the magnet. A more controlled study of particle size could reveal more precisely the diffusion distances involved.

ACKNOWLEDGMENTS

The authors have benefited greatly from discussing with J. F. Herbst, J. W. Herchenroeder, and R. K. Mishra. We are very grateful to C. B. Murphy for preparing the melt-spun ribbons and to P. Johnson for his assistance with our magnetic measurements.

Evidence for reversal by nucleation in RE-Fe-B die-upset magnets

L. Henderson Lewis, Y. Zhu, and D. O. Welch
Department of Applied Science, Brookhaven National Laboratory, Upton, New York 11973

Electron microscopy and initial magnetization studies at elevated temperatures were performed on two die-upset rare-earth magnets with bulk compositions $Nd_{13.75}Fe_{80.25}B_6$ and $Pr_{13.75}Fe_{80.25}B_6$. In both compositions the intergranular phase is amorphous and occurs primarily on those surfaces parallel to the tetragonal 2-14-1 phase c axis. The intergranular phase is enriched in iron relative to the bulk grain, with an average width of 8–12 Å in the Nd-based magnet and 15–20 Å in the Pr-based magnet. The initial magnetization curves and the dependence of the coercivity upon maximum magnetizing field both increase linearly with a common slope and then saturate, consistent with nucleation-dominated behavior. These results suggest that the dominant reversal mechanism in these magnets is nucleation of reversed domains in the iron-rich intergranular region of reduced anisotropy.

I. INTRODUCTION

Not only are magnets based on the $RE_2Fe_{14}B$ tetragonal intermetallic compounds more economical to manufacture than other rare-earth-based magnetic compounds, but they possess impressive energy products which significantly exceed those of prior-existing magnets.[1] However, a major drawback of this class of magnets is their high-temperature coefficient of coercivity, which causes the coercivity to fall steadily to unacceptably low values for temperatures much above 400 K. One method to compensate for this behavior is to increase the coercivity of the magnet[2] so that it more closely approaches its theoretical maximum value, the anisotropy field ($2K_1/M_S$), which is around 90 kOe for $Nd_2Fe_{14}B$ at room temperature.[3] Such directed engineering would be greatly facilitated by the identification of the dominant mechanism of magnetization reversal in these magnets. It is generally agreed upon in the literature that sintered 2-14-1 magnets attain their coercivity by the nucleation of reversed domains.[4] In constrast, the limiting mechanism which controls magnetic reversal in the $RE_2Fe_{14}B$ die-upset magnets produced by melt-quench methods remains an open question. Some researchers believe that strong pinning of domain walls by a nonmagnetic intergranular phase determines the coercivity in these magnets.[5,6] However, other studies comparing sintered and melt-spun magnets have concluded that the nucleation mechanism is dominant in both die-upset and sintered magnets, and recent data obtained from magnetic viscosity measurements[10] performed on melt-quenched magnets support this claim.

In order to identify definitively and understand the reversal mechanism operative in the 2-14-1-based die-upset magnets, it is necessary to investigate simultaneously the microstructural and the magnetic properties.[11] We present here some microstructural, microcompositional, and initial magnetization evidence which suggests that the dominant reversal mechanism in these magnets is the nucleation of reversed domains.

II. EXPERIMENTAL PROCEDURES

Both high-resolution analytical transmission electron microscopy (TEM) and magnetic measurements were performed on two (2-14-1)-based die-upset rare-earth magnets, with bulk compositions $Nd_{13.75}Fe_{80.25}B_6$ and $Pr_{13.75}Fe_{80.25}B_6$, obtained from the General Motors Research and Development Center. The magnets were manufactured by standard hot-deformation processing:[12] overquenched melt-spun ribbons were hot pressed at 750 °C and then further deformed at 800 °C to produce oriented die-upset magnets. Additional processing details are contained in Refs. 13 and 14.

The analytical electron microscopy was performed on the intergranular phases and the boundaries of deformed grains using both a VG Instruments HB-501 and a JEOL 2000FX transmission electron microscope. The samples were thinned with mechanical dimpling followed by argon-ion milling at room temperature. Over 30 unique grain-boundary regions were examined in the Pr-based sample while 10 were examined in the Nd-based sample.

The initial magnetization curves and the dependence of the coercivity upon maximum magnetizing field at elevated temperatures were investigated in the range 350 K$\leqslant T\leqslant$425 K in applied fields up to 20 kG using a superconducting quantum interference device (SQUID) magnetometer manufactured by Quantum Design. Each sample was machined down to the approximate dimensions 1.3 mm×1.3 mm×2.0 mm and was subsequently sealed in a quartz capillary tube of 2 mm (i.d.)×3 mm (o.d.) to avoid the possibility of oxidation during measurement. Prior to each minor loop measurement the magnets were thermally demagnetized by heating to 30° above their nominal 2-14-1 Curie temperatures and then cooled in zero field to the measuring temperature. The resultant hysteresis loops were corrected for demagnetization using the equation[15]

$$H_{\text{demag}}=4\pi M_s\times(2/\pi)\times\arcsin(1/1+q), \tag{1}$$

where q is the dimensional ratio. H_{demag} was corrected further a constant multiplicative factor of 0.815, obtained from a measurement of low coercivity nickel.

III. RESULTS

The microstructures of both the Nd-based and the Pr-based die-upset magnets are very similar. As described in previous publications[16–18] the materials are highly anisotropic, consisting mostly of platelet-shaped grains of the 2-14-1 phase stacked parallel to their c axes and separated

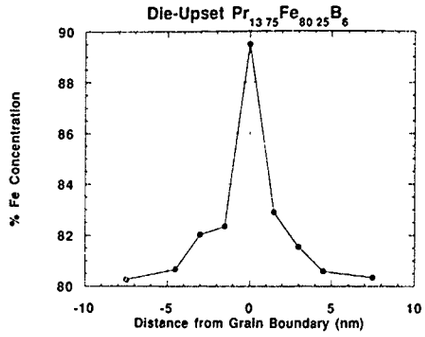

FIG. 1. Iron concentration for $Pr_{13.75}Fe_{80.25}B_6$ as a function of distance from grain boundary.

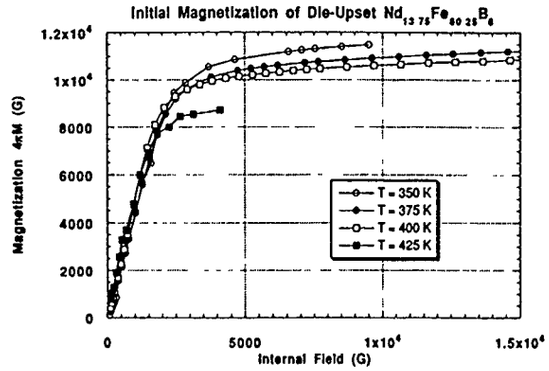

FIG. 3. Initial magnetization curves for die-upset $Pr_{13.75}Fe_{80.25}B_6$ at various temperatures.

from one another by a thin intergranular phase. The average dimensions of the deformed grains are 600 nm±150 nm in length by 150 nm±75 nm in width. A certain fraction of the grains are larger and equiaxed; these contain a speckling of precipitates in the grain interior which was not found in the more deformed grains. Mishra[18] estimated this fraction of larger grains to be around 15%. During our studies it was found that the intergranular phase is amorphous and its presence is dependent upon the nature of the grain boundary in question: there appears to be no intergranular phase in (001) twist boundaries parallel to the tetragonal basal plane. The average width of the intergranular phase is 8–12 Å in the Nd-based magnet and 15–20 Å in the Pr-based magnet. The high-resolution analytical electron microscope studies reported here show that, for both the Nd-based and the Pr-based compositions, the intergranular phase is enriched in iron relative to the bulk grain composition. Figure 1 illustrates the iron concentration profile in Pr-Fe-B upon traveling from one grain to another across the intergranular phase; it is to be noted that the iron concentration in the bulk grain is near 80%. Figure 2 gives a histogram of the relative ratio of iron to praseodymium in the grain-boundary region versus that in the grain interior for a sampling of 30 grain boundaries. The trends for iron in the Nd-based sample were found to be very similar to those shown here for the Pr-based sample.

The magnetic data are illustrated in Figs. 3 and 4 for Pr-Fe-B. The results for Nd-Fe-B look very similar. Figure 3 shows the initial magnetization curves at various temperatures. The initial curves of both samples show a steep temperature-independent rise in the magnetization, followed by an approach to saturation that is temperature dependent. Figure 4 illustrates the development of the coercivity in Pr-Fe-B with maximum applied field. As was the case with the initial magnetization curves, the coercivities initially develop rapidly and level out to a constant, temperature-dependent value.

IV. DISCUSSION

Structurally, nucleation may be controlled by small numbers of relatively large defects whereas pinning requires a regular distribution of defects, such as fine precipitates, to be present in the material.[19,20] For efficient pinning it is desired that the magnetic properties of the two phases constituting the material be very different.[11] The microstructure of these magnets more closely matches that of a material characterized by nucleation reversal because the deformed grains, which comprise ~85% of the sample, are largely free of precipitates.

The high-resolution microcompositional analyses reported here clearly show an enrichment of iron in the grain-boundary region relative to the grain itself, for a sampling of

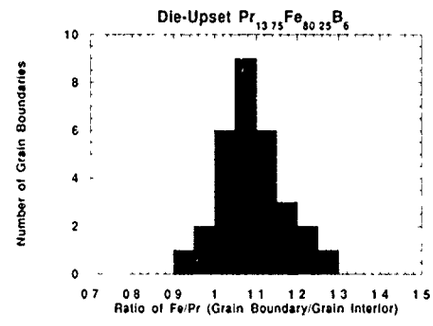

FIG 2. Histogram depicting Fe/Pr ratio for the grain-boundary phase vs the grain interior.

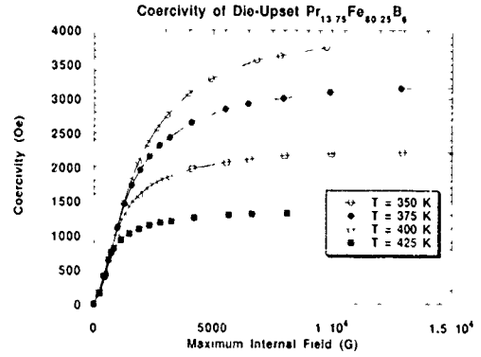

FIG. 4. Coercivity vs maximum applied field for die-upset $Pr_{13.75}Fe_{80.25}B_6$

30 grain boundaries. Additionally, this grain-boundary phase is not found to evenly wet all surfaces of the 2-14-1 main phase particles, but rather is found mainly on those boundaries parallel to the c axis. These results differ considerably from those of Mishra,[18] obtained by lower-resolution methods, who reported a grain-boundary phase with a composition close to the eutectic phase $Nd_{70}Fe_{30}$ (or $Pr_{70}Fe_{30}$) and which coats each grain uniformly. We do not doubt that a phase with a composition close to $Nd_{70}Fe_{30}$ does exist in these materials, especially since the excess rare-earth present in these magnets must be present somewhere in the microstructure. However, the exact distribution within the microstructure of rare-earth-rich and iron-rich grain boundaries, as well as intragranular phases, remains to be determined.

The presence of excess iron in the grain-boundary phase has several important consequences with regards to intergrain interactions. One result is that the grains are most probably exchange coupled as well as magnetostatically coupled. The micromagnetic origins of the coercivity in fine-grained material strongly depend upon the type of coupling between the grains. Recent numeric micromagnetic calculations[21] of nucleation fields of 2D magnetic structures demonstrate that if grains have direct exchange interactions, the entire sample can easily demagnetize after reversal of one grain.

The presence of a ferrous intergranular phase, which may well be magnetic, also allows for the existence of lower-anisotropy sites for reverse magnetization nucleation while at the same time it may reduce the probability of domain wall pinning at the intergranular phase. As is stated by Livingston,[19] pinning is a necessary requirement, even in nucleation-controlled magnets, to avoid catastrophic reversal originating at low-coercivity regions. In these magnets a likely place for pinning to occur is at the larger RE-rich nonmagnetic pockets found along some of the grain boundaries and at grain-boundary triple points.

Our magnetic data strongly suggest that the coercivity of these magnets develops by the nucleation of reverse domains. A distinguishing characteristic between nucleation-dominated and pinning-dominated materials is the behavior of the initial susceptibility. A low initial susceptibility of a thermally demagnetized magnet implies that no free domain wall displacement occurs, because the walls are pinned within the crystallites. This results in only very small changes of magnetization for fields less than a critical unpinning field. Magnets that exhibit a high initial susceptibility have domain walls that move easily, implying that no domain-wall pinning occurs within the crystallites.[9,22] The initial magnetizations of the Pr-based magnets, Fig. 3, show a high initial susceptibility which is independent of temperature.

Another distinguishing characteristic between nucleation-controlled and pinning-controlled magnets is the development of the coercivity with applied field. Hadjipanayis and Kim[22] state that for nucleation-dominated magnets the coercivity H_c increases linearly with magnetizing field and then saturates, whereas in those magnets characterized by pinning the coercivity is almost negligible up to a critical field and then it suddenly increases to saturation. Figure 4 clearly shows that these 2-14-1 die-upset magnets behave in the former manner at elevated temperatures. The common slope of the H_c vs H_a curve implies that these nucleation sites are structural features, but are thermally sensitive.

V. CONCLUSIONS

Evidence is presented which strongly suggests that the development of coercivity at elevated temperatures in die-upset $RE_2Fe_{14}B$ magnets is probably dominated by the nucleation of reversed domains. It is likely that these reversed domains nucleate at reduced-anisotropy sites residing within the iron-rich grain-boundary phase, observed using high-resolution analytical TEM. However, the origin of the temperature dependence of the coercivity, which was attributed by Pinkerton and Fuerst[5,6] to strong pinning, still remains to be clarified.

The above conclusions suggest methods to improve the temperature coefficient of coercivity in die-upset $RE_2Fe_{14}B$ magnets. An ideal microstructure for a nucleation-type magnet consists of grains of a magnetically hard phase that are exchange isolated from one another.[11] Therefore, segregation of nonmagnetic atoms to the grain-boundary phase via metallurgical manipulation would produce higher-coercivity magnets. In fact, preliminary work along those lines has been done by Fuerst and Brewer[23] in which an increase of coercivity was observed in die-upset Nd-Fe-B magnets upon introduction of noble-metal elements to the melt-spun ribbons.

Microstructure and magnetic properties of mechanically alloyed anisotropic Nd-Fe-B

J. Wecker, H. Cerva, C. Kuhrt, K. Schnitzke, and L. Schultz[a)]
Siemens AG, Research Laboratories, Erlangen and Munich, Germany

Mechanically alloyed Nd-Fe-B powders with additions of Dy, Co, and Ga were hot compacted to magnetically isotropic materials and then deformed by die upsetting to obtain anisotropic magnets. Magnets can be processed either with a medium coercivity H_{ci} of 7.8 kA/cm but with a high-energy product $(BH)_{max}$ of 330 kJ/m^3 or with a coercivity of 21.2 kA/cm and a lower $(BH)_{max}$ of 192 kJ/m^3. Plane-view transmission electron microscopy (TEM) pictures show nearly equiaxed $Nd_2Fe_{14}B$ grains. In cross section, the grains display the typical platelet form known from MQ 3-type magnets with a length of about 300 nm and a height of 100 nm. Characteristic for mechanically alloyed materials are up to 500 nm large globular NdO_x particles distributed regularly throughout the microstructure which inhibit the anisotropic grain growth. In addition 5–20 nm small NdO_x precipitates are found within some $Nd_2Fe_{14}B$ grains. X-ray diffraction studies also indicate that the degree of texturing after die upsetting is smaller for mechanically alloyed than for melt-spun materials. High-resolution TEM experiments did not show any grain boundary phase usually found in melt-spun materials; however, this needs to be confirmed.

I. INTRODUCTION

The small grain sizes of rapidly quenched or mechanically alloyed Nd-Fe-B prohibit the preparation of anisotropic magnets by an alignment of the respective powders in an external magnetic field. Anisotropy can be induced by hot compaction of the ribbons or powders to fully dense isotropic magnets followed by hot deformation.[1,2] From transmission electron microscopy (TEM) analysis of melt-spun Magnequench (MQ)-type magnets it was concluded that the alignment proceeds by a combination of grain boundary sliding and grain boundary migration.[3] For mechanically alloyed materials a detailed investigation of the microstructure and its correlation to the magnetic properties remained to be done. First preliminary experiments already showed the presence of Nd oxides in both the isotropic and the die-upset samples.[4]

II. EXPERIMENTAL

Mechanically alloyed Nd-Fe-B powders were prepared by high-energy ball milling in a planetary ball mill or in an attritor with typical batch sizes of 30 or 300 g (milling time 48 h). For comparison we also prepared rapidly quenched ribbons by conventional melt spinning. The compositions of the different samples are given below. The as-milled powders or the as-quenched ribbons were hot compacted to cylindrical magnets (diameter $d=10$ mm, height $h=10$ mm) followed by a die-upset process. For both processes the temperatures were between 720 and 750 °C for mechanically alloyed powders and at 690 °C for the melt-spun ribbons with a deformation ratio h_0/h of 4 (h_0 and h being the heights of the magnets before and after deformation). Magnetic measurements were done in a vibrating sample magnetometer after magnetizing the samples in a field of 50 kA/cm. For TEM analysis, the cylinders were sliced parallel and perpendicular to the press direction. The samples were ground and ion milled and were examined in a transmission electron microscope (JEOL 2000 FX). Chemical microanalysis was done by energy dispersive x-ray analysis (EDX).

III. RESULTS

A. Magnetic properties

As for sintered or melt-spun Nd-Fe-B, the properties of mechanically alloyed magnets can be tailored to the desired needs by a proper choice of alloying additions. Figure 1 shows the demagnetization curve of a magnet with a remanence J_r of 1.32 T and thus with a high-energy product $(BH)_{max}$ of 333 kJ/m^3. Because of the low rare-earth content, the coercivity H_{ci} is rather low. H_{ci} can be increased by nearly a factor of 3 by the partial substitution of Nd by Dy via an increase of the anisotropy field. However, because of

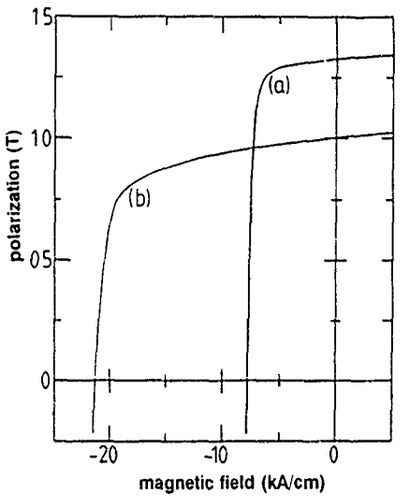

FIG. 1. Demagnetization curves of two anisotropic mechanically alloyed magnets with compositions of $Nd_{15.5}Fe_{72}Co_6Ga_{0.5}B_6$ (curve a) and of $Nd_{14}Dy_3Fe_{68}Co_{7.5}Ga_{0.75}B_{6.75}$ (curve b).

$Nd_{14}Fe_{71.4}Co_8Ga_{0.6}B_6$[a]	7.1	1.36	4.3	350

[a]Melt-spun material.

the antiferromagnetic coupling of the Dy to the transition metal sublattice the remanence decreases (Fig. 1). The simultaneous addition of Co improves the temperature dependence of the magnetic properties and guarantees a coercivity of 9.0 kA/cm even at 150 °C necessary, e.g., for the substitution of Sm-Co magnets in electromotors.

For mechanically alloyed Nd-Fe-B, the texturing of fully dense magnets by die upsetting is only possible above a rare-earth concentration of 14 at %. Below this critical value hardly any anisotropy develops and J_r remains low (Table I). Above, one obtains energy products greater than 300 kJ/m^3 and H_{ci} increases with the Nd content in the same way as for MQ magnets.[5] The ratio, $R=J^{\parallel}/J^{\perp}$, of the remanences measured parallel and perpendicular to the press direction is a measure of the degree of texturing and shows values above 4. For higher Nd concentrations $(BH)_{max}$ decreases probably because of nonmagnetic impurity phases. The magnet prepared for comparison from melt-spun ribbons with a Nd concentration of 14 at % but with a slightly different concentration of the remaining elements had a $(BH)_{max}$ of 350 kJ/m^3 (Table I).

B. Microstructure

Cross-sectional TEM images which were taken parallel to the press direction show the typical platelet form of the $Nd_2Fe_{14}B$ (Φ) grains known from MQ-type magnets[3] with a length and a height of about 300 and 100 nm, respectively (Fig. 2). The flat surfaces of the grains are normal to the press direction and to the c axis of the tetragonal unit cell. In plane view, the grains are nearly equiaxed. Characteristic for mechanically alloyed magnets are up to 500 nm large Nd-oxide particles distributed regularly throughout the microstructure which were already observed previously.[4] EDX analysis proves that the main metallic constituents of these oxides are Nd and Dy. The particles show a sponge-like contrast and their diffraction patterns can be assigned to cubic NdO and Nd_2O_3. A characteristic feature is the fact that in their vicinity the growth of the Φ grains to flat platelets is inhibited as can be seen in Fig. 3 where the oxide particle in the center is marked by an arrow. Besides these intergrain oxides we also frequently observe 5–20 nm small precipitates within $Nd_2Fe_{14}B$ (see arrows in Fig. 2) which by EDX analysis are identified as oxides. Such intragrain oxides were also observed in sintered magnets and are probably hexagonal Nd_2O_3.[6] We have not observed the metallic intergranular phase found in MQ-3 magnets[3] (Fig. 4). Instead the grain boundary appears to be free of a minority phase and the lattice planes of neighboring Φ grains directly meet at the grain boundary.

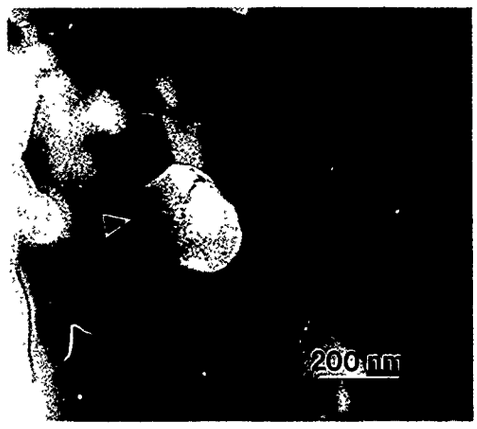

FIG. 3 Cross-section bright-field TEM image of die-upset $Nd_{14}Dy_3Fe_{62}Co_{14}Ga_{0.75}B_{6.25}$. The large oxide grain marked by the arrow inhibits the growth of $Nd_2Fe_{14}B$ to the typical platelet shape seen in Fig. 1.

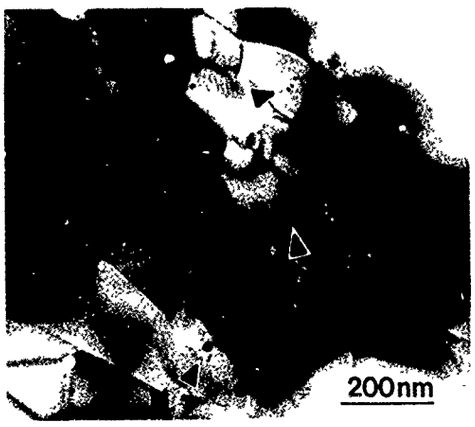

FIG 2 Cross-section bright-field TEM image of die-upset $Nd_{15.5}Dy_{2.5}Fe_{65}Co_{10}Ga_{0.75}B_{6.25}$ The arrows mark oxide inclusions in $Nd_2Fe_{14}B$ grains

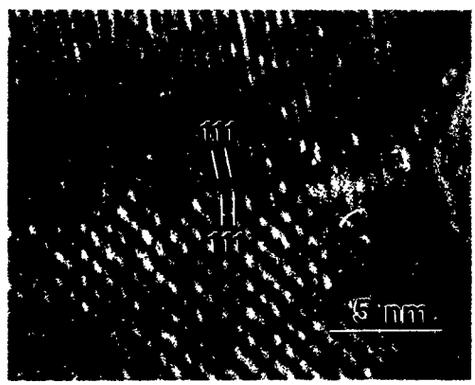

FIG 4. High-resolution image showing the grain boundary between $Nd_2Fe_{14}B$ grains in die-upset $Nd_{15.5}Dy_{2.5}Fe_{65}Co_{10}Ga_{0.75}B_{6.25}$

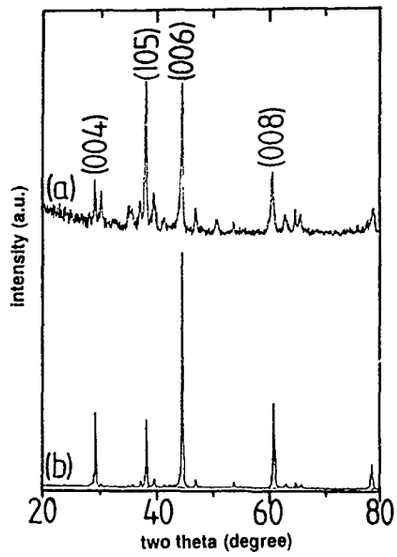

FIG. 5. X-ray diffraction pattern of die-upset mechanically alloyed Nd-Fe-B (curve a) compared to melt-spun materials (curve b).

The texturing during die upsetting becomes also evident in x-ray diffraction patterns taken in $\Theta/2\Theta$ geometry which show prominent (001) peaks (Fig. 5) indicative of an alignment of the c direction normal to the surface of the magnet. Compared to the MQ-type magnet, however, the intensity of the (105) line is higher [Fig. 5(b)], hinting to a smaller degree of orientation in the mechanically alloyed material.

IV. DISCUSSION

Mechanical alloying like conventional sintering is a powder metallurgical technique to prepare high performance permanent magnets. Therefore, the presence of oxides in the microstructure is not unexpected. Indeed, by chemical analysis we detect an oxygen content of up to 0.5 wt % in the final magnet which is comparable to sintered magnets. The oxygen contamination is introduced to about 0.2 wt % with the starting powders and the rest coming from the uptake during processing. Since the oxygen forms rare-earth oxides, the amount of the Nd-rich intergranular phase which is supposed to be necessary for texturing via the anisotropic grain growth[3] should be reduced. This explains why we do not observe a crystallographic alignment for too low Nd concentrations (<14 at %), i.e., when the Nd surplus is almost completely reacted to Nd oxides in contrast to the samples prepared from melt-spun ribbons which have an oxygen content below 0.1 wt %. $Nd_2Fe_{14}B$ has no plasticity at the temperatures used for die upsetting but shows brittle fracture[7] and therefore, the grain boundary phase indeed also should be present in our materials but obviously to a smaller amount. The observation of no grain boundary phase in the TEM experiments does not unambiguously prove that there is no Nd-rich phase at all because of only too few analyses we did. Also, the micrograph may have been taken from a part of the grain boundary which is not decorated by the Nd-rich phase. However, grain boundary phases were previously detected in the isotropic compacted magnets.[4]

The bimodal size distribution of oxide particles, i.e., large intergrain oxides and small particles within the $Nd_2Fe_{14}B$ were also observed in high-strength NiAl-based alloys and seem to be characteristic of mechanically alloyed materials.[8] So far, it is not clear to what extent the lack of texturing in the vicinity of large oxide particles (cf. Fig 3) is a direct consequence of their presence which prevents grain growth. Or if it results from the local absence of the Nd-rich phase which accelerates diffusional mass transport because it is liquid at the deformation temperatures. But both factors do reduce the remanence and thus the energy product as can be seen by comparing the mechanically alloyed and the melt-spun samples (Table I). Since the occurrence of oxides at least under practical conditions can never be prevented in powder metallurgy the energy product of mechanically alloyed magnets will always be somewhat lower than for respective MQ-type materials whereas the coercivities do not show any significant difference. For the latter magnets a $(BH)_{max}$ of 335 kJ/m^3 was obtained with an even lower Nd concentration of 13.7 at % and a comparable deformation ratio.[5] Some improvement of the texturing of mechanically alloyed magnets may be possible by trying to introduce a low melting grain boundary phase artificially. For example, small amounts of diffusion alloyed Zn additives were shown to increase not only the coercivity of die-upset MQ magnets but also the remanence.[9]

Preparation and transmission electron microscope investigation of sintered $Nd_{15.4}Fe_{75.7}B_{6.7}Cu_{1.3}Nb_{0.9}$ magnets

Johannes Bernardi and Josef Fidler
Institute of Applied and Technical Physics, T. U. Vienna, Wiedner Hauptstrasse 8-10, A-1040 Vienna, Austria

Sintered magnets were prepared from jet-milled and hydrogen-decrepitated jet-milled Nd-Fe-B:(Cu,Nb) powder. The HD process started after heating the cast material up to 200 °C. A single-step annealing treatment at 525 °C improved the magnetic properties of all samples. Magnets prepared from the jet-milled powder required a short time sintering (<60 min) to obtain optimum coercivity but had poor density. Magnets prepared from the HD powder showed a higher remanence and energy density product but a slightly smaller coercivity than the magnets prepared from the jet-milled powder. The sintered and annealed magnets contain a multiphase microstructure. Nb was found as small precipitates within the hard magnetic grains and as intergranular boride phase. The addition of Cu lowers the melting point of the liquid phase during sintering and leads to the formation of an orthorhombic NdCu phase that is partly replacing the Nd-rich intergranular phases. The intergranular δ-phase $Nd_6Fe_{13}Cu$ was found regularly in the annealed samples. Nd_2Fe_{17} was not detected in the investigated samples.

I. INTRODUCTION

The magnetic properties of $Nd_2Fe_{14}B$ magnets can be improved by the substitution of expensive Dy and Co and/or by the addition of two types of dopant elements that influence the microstructure in a similar way.[1] Type I dopants ($M1$=Al, Cu, Zn, Ga, Ge, Sn) form binary $M1$-Nd or ternary $M1$-Fe-Nd compounds, while type II dopants ($M2$=Ti, V, Nb, Mo, W) form $M2$-B or $M2$-Fe-B borides. In a previous investigation we showed that the addition of Ga and Nb leads to good magnetic properties.[2] Small amounts of Cu improved the workability of hot worked magnets[3] and led to the formation of new intergranular phases like NdCu.[4] The purpose of this work was to study the microstructure and the magnetic properties of a Dy and Co-free magnet containing a type I (Cu) and a type II (Nb) dopant.

II. EXPERIMENT

The alloy with the nominal composition $Nd_{15.4}Fe_{75.7}B_{6.7}Cu_{1.3}Nb_{0.9}$ was supplied by Treibacher Chemische Werke. Magnets were prepared by the powder-metallurgical sintering process from jet-milled powder (A) and from hydrogen decrepitated (HD) and jet-milled powder (B). The average diameter of powder A was 2.9 and 1.75 μm of powder B, respectively (determined by FSSS). An initial temperature of 200 °C was necessary to start the HD process at +1 bar H_2 pressure. Green compacts were pressed at 200 MPa transverse to the direction of the aligning field of 1.25 T. Sintering was done at temperatures from 1040 to 1120 °C for different times followed by a single-step annealing treatment. The magnetic properties were determined with a hysteresigraph at room temperature. The microstructure of the magnets was investigated by means of analytical transmission electron microscopy in a JEOL 200CX microscope fitted with two energy dispersive x-ray detectors, a high take-off angle Si detector and a low take-off angle Ge detector for light element analysis. Electron transparent samples were produced by grinding and following ion-beam thinning.

III. RESULTS

A. Magnetic properties

The magnets produced from powder A were sintered between 1080 and 1120 °C. The density of the samples and the remanence increased with increasing sintering temperature while the coercivity increased for the samples sintered for short times (40–60 min) at lower temperatures. A single-step annealing treatment at 525 °C improved the magnetic properties. The magnet with the highest coercive field was sintered at 1080 °C for 40 min and annealed at 525 °C. That sample showed a coercive field of 910 kA/m and a remanence of 1.14 T, but had a poor density (<7 g/cm^3).

The magnets produced from the HD powder B were sintered between 1040 and 1090 °C. Good magnetic properties were achieved after a single-step annealing treatment at 525 °C (Fig. 1). At comparable sintering temperatures the HD magnets showed a higher remanence and energy product but a slightly reduced coercivity than the magnets produced from powder A.

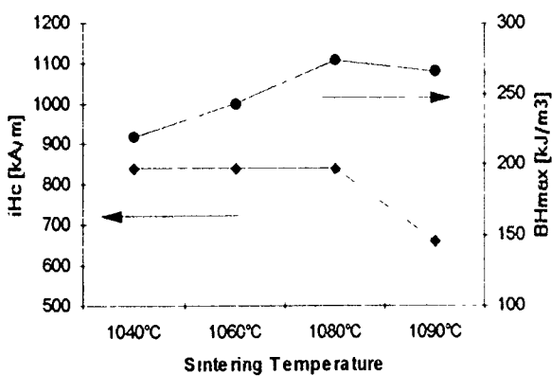

FIG. 1. Magnetic properties of the sintered and annealed $Nd_{15.4}Fe_{75.7}B_{6.7}Cu_{1.3}Nb_{0.9}$ magnets produced from the HD powder. All samples were sintered for 1 h and annealed at 525 °C.

TABLE I. Phases found in the sintered and annealed $Nd_{15.4}Fe_{75.7}B_{6.7}Cu_{1.3}Nb_{0.9}$ magnet.

Phase	Composition	Structure
ϕ	$Nd_2Fe_{14}B$ with Cu substitutions	Tetragonal
$p\phi$	Nb containing precipitates within ϕ	Hexagonal NbFeB
η	Intergranular $Nd_{1+\epsilon}Fe_4B_4$	Tetragonal
iB	Intergranular NbFeB	Hexagonal NbFeB
$n1$	Intergranular Nd rich (+Fe)	fcc
$n2$	Intergranular Nd rich	hcp
cu	Intergranular NdCu	Orthorhombic
δ	$Nd_6Fe_{13}Cu$	Tetragonal
no	Nd_2O_3 impurities	Rhombohedral

B. Microstructure of the magnets

A magnet from set A, sintered at 1080 °C for 40 min and annealed at 525 °C, was chosen for the transmission electron microscope (TEM) investigation. The phases detected in that magnet are summarized in Table I. The magnet contained a multiphase microstructure consisting of the hard magnetic phase (ϕ), two types of boride phases (η and iB), several Nd-rich intergranular phases, and the δ-phase $Nd_6Fe_{13}Cu$.

Like in the case of the Ga- and Nb-doped magnets,[2] the hard magnetic $Nd_2Fe_{14}B$ phase (ϕ) was found with a high amount of spherical NbFeB precipitates $p\phi$ with a diameter up to 50 nm as shown in Fig. 2. But some ϕ grains did not show any precipitates. Intergranular boride phases occurred as grains with a diameter up to several microns as hexagonal NbFeB (iB) and as tetragonal $Nd_{1+\epsilon}Fe_4B_4(\eta)$. Both intergranular boride phases usually contained a high density of crystal defects (Fig. 3). Nd-rich intergranular phases were found with fcc ($n1$) or hcp ($n2$) crystal structure. The fcc phase ($n1$) usually contained some Fe or oxygen as in Ref. 5. In addition an intergranular orthorhombic NdCu phase (cu) was partly replacing the Nd-rich phases (n1) and (n2). Figure 4 shows the NdCu phase besides a Nd-rich phase and a hard magnetic grain with the corresponding x-ray spectra. Nd_2O_3 was found as an impurity phase. The tetragonal

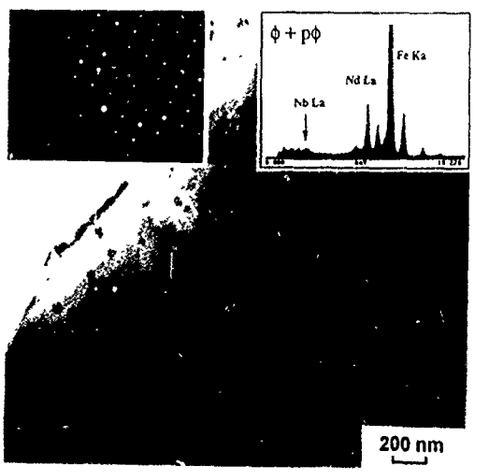

FIG 2. Micrograph of the hard magnetic phase ϕ containing a high amount of spherical NbFeB precipitates $p\varphi$

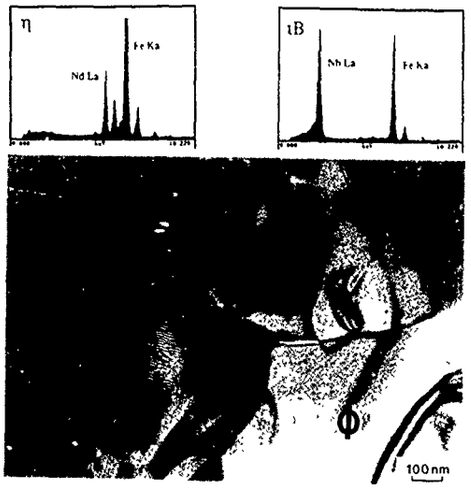

FIG. 3. Micrograph of the intergranular boride phases $Nd_{1+\epsilon}Fe_4B_4$ (η) and NbFeB (iB) with the corresponding x-ray spectra besides a hard magnetic grain ϕ.

δ-phase $Nd_6Fe_{13}Cu$ that is in equilibrium with Nd and NdCu in the ternary Nd-Fe-Cu phase diagram[6] was found quite regularly as a separate grain with a size up to several microns in the $Nd_{15.4}Fe_{75.7}B_{6.7}Cu_{1.3}Nb_{0.9}$ magnet (Fig. 5). Nd_2Fe_{17} was not detected in the investigated sample.

IV. DISCUSSION

Ternary Nd-Fe-B magnets have a poor temperature stability and bad corrosion resistance. To overcome these problems, Dy and Co are widely added to magnets. The addition of dopants helps to produce magnets with good magnetic properties without the expensive heavy rare-earth element Dy and without Co. From the ternary Nd-Fe-M1 phase diagrams it is clear that type I dopants like Cu, Al, or Ga lower the melting temperature of the liquid phase during sintering. On the other hand, the wettability of the liquid phase is different for Cu, Al, and Ga, respectively. Improved wettability of the liquid phase leads to a better decoupling of the hard

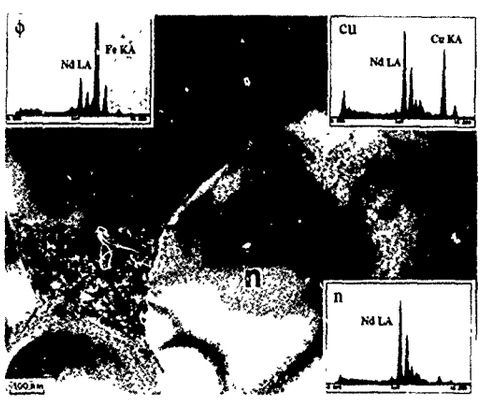

FIG 4. NdCu phase (cu) and a Nd-rich phase (n) besides a hard magnetic grain (ϕ) The NdCu phase is partly replacing the Nd-rich intergranular phases.

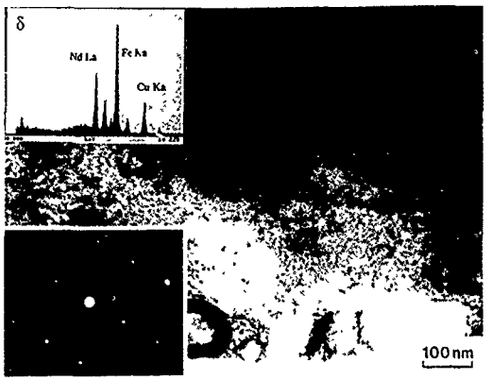

FIG. 5. Micrograph of a $Nd_6Fe_{13}Cu$ grain (δ phase) with the corresponding x-ray spectrum. This phase is found quite regularly in the $Nd_{15.4}Fe_{75.7}B_{6.7}Cu_{1.3}Nb_{0.9}$ magnet

magnetic grains[1] and therefore to an improved coercivity. In the case of Cu poor wettability leads to a lower density and lower coercivity of the magnets compared with Al- and Ga-doped magnets. In addition binary $M1$-Nd and ternary $M1$-Fe-Nd ($M1$=Cu, Al, Ga) occur, partly replacing the fcc and hcp Nd-rich intergranular phases that are mainly responsible for the bad corrosion resistance of Nd-Fe-B magnets. In the investigated $Nd_{15.4}Fe_{75.7}B_{6.7}Cu_{1.3}Nb_{0.9}$ magnet, the orthorhombic NdCu phase and the tetragonal δ-phase $Nd_6Fe_{13}Cu$ were found regularly, and the corrosion resistance was improved, compared with Nd-Fe-B sintered magnets. According to the ternary Nd-Fe-Cu phase diagram,[6] at the Nd-rich side Nd is in equilibrium with NdCu and with the δ phase. The Nd_2Fe_{17} phase, which is also in equilibrium with Nd and the δ phase, was not observed in this magnet. This could be due to a sufficiently high Cu concentration in the liquid phase during annealing which prefers the formation of the δ phase instead of the soft magnetic Nd_2Fe_{17} phase. Nb shows a low solubility at sintering temperature within the hard magnetic phase[7] and forms NbFeB precipitates within the $Nd_2Fe_{14}B$ phase as well as intergranular NbFeB grains that also help to decouple the hard magnetic grains.

Compared to ternary Nd-Fe-B magnets, where the HD process allows a lowering of the sintering temperature,[8] the sintering temperature of the HD-processed Cu- and Nb-doped powder could not be reduced to obtain high coercive fields. This explains why wettability is not improved by Cu addition. For a given sintering temperature the remanence and the energy density product of the HD magnets was larger than that of the magnets prepared by the standard jet-milling process. The main advantage of Nd-Fe-B:Cu magnets is the improved corrosion resistance compared with Nd-Fe-B magnets. Nb-addition suppresses the formation of α-Fe.

Fe-Nd-C-based ingot permanent magnets by solid-state transformation

M. Leonowicz, H. A. Davies,[a] and S. Wojciechowski
Department of Materials Science and Engineering, Warsaw University of Technology, Narbutta 85, 02-524 Warszawa, Poland

The effects of composition, annealing temperature, and annealing time on the magnetic properties and microstructure of $Fe_{66}M_2Nd_{20}C_{9.5}B_{0.5}$ (M=Ga,Nb,Cu,Al) ingot magnets are presented. It has been found that the magnitude of the hard magnetic properties, which evolve during the solid-state transformation $Fe_{17}Nd_2C_x$ to $Fe_{14}Nd_2C$, depends on the additive elements. These additions which decrease the melting temperature of the intergranular phase accelerate the transformation process and those which increase this temperature retard the transformation. Coercivities up to 880 kA/m combined with a remanence 0.58 T were produced in alloy ingots with Cu. The initial grain size was found to be crucial in producing good magnetic properties and coercivities as high as 980 kA/m were achieved for Fe-Nd-C-B alloy magnets hot pressed from microcrystalline melt spun ribbon. A modest increase of remanence (~0.7 T) was achieved by die-upset forging of ingot alloys.

I. INTRODUCTION

The principal routes for the production of RE-Fe-B permanent magnets are those based on liquid phase sintering,[1] or on melt spinning,[2] followed by resin bonding or hot working the crushed ribbon.[2] Both technologies are based on powder processing. However, there are two systems for which useful coercivities can be obtained in the cast state. Fe-Pr-B ingot magnets exhibit coercivities up to 1000 kA/m and partly columnar alloys show remanences of ~0.7 T.[3,4] The second system is based on the $Fe_{14}Nd_2C$ compound.[5–8] Its structure and intrinsic magnetic properties are broadly comparable with those of $Fe_{14}Nd_2B$.[5] The possibility of producing cast magnets is attractive due to the simplicity of the processing, low cost, and the ability to manufacture net shape products without the need for handling powders or ribbon. The Fe-Nd-C system is interesting also because the $Fe_{14}Nd_2C$ compound forms by a solid-state peritectoid reaction, which occurs below 900 °C.[6] Small addition (0.05%) of boron accelerates the nucleation rate of the $Fe_{14}Nd_2C$ phase, increases the transformation temperature (~1050 °C), and reduces the annealing time.[7]

In this study the possibility of achieving useful coercivities in the Fe-M-Nd-C-B (M=Cu,Ga,Nb,Al) ingot magnets, within a relatively short annealing time of a few hours was investigated and the temperature-microstructure relations were analyzed.

II. EXPERIMENTAL PROCEDURE

The $Fe_{66}M_2Nd_{20}C_{9.5}B_{0.5}$ (M=Ga,Nb,Cu,Al) alloys were made by induction melting the pure elements under an argon atmosphere. The ingot magnets were prepared by annealing the ingots in evacuated silica tubes. The $Fe_{68}Nd_{20}C_{9.5}B_{0.5}$ alloy was also prepared in ribbon form by melt spinning in an argon atmosphere and the crushed ribbon was subsequently hot pressed at 700 °C in argon. The magnetic properties were measured using an Oxford VSM with maximum applied field of 5 T. Phase identification was performed by x-ray diffraction. Microstructural observations were made using scanning electron and optical microscopy. The Curie temperature and the melting point of the grain boundary phase were evaluated in a Perkin–Elmer DSC-2 scanning calorimeter.

III. RESULTS AND DISCUSSION

The effects of annealing temperature on the magnetic properties of the $Fe_{68}Nd_{20}C_{9.5}B_{0.5}$ alloy are shown in Fig. 1. The alloy was annealed for a constant time of 5 h. The $Fe_{14}Nd_2C$ compound first appeared at 800 °C but due to only partial transformation at this temperature, the remanence (J_r) was relatively low. Both J_r and coercivity ($_JH_c$) achieved

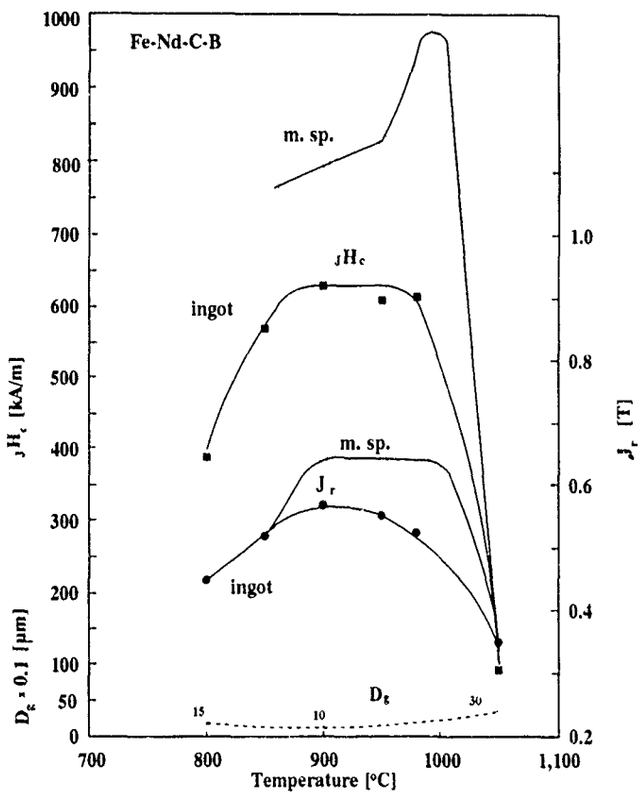

FIG. 1 Magnetic properties for $Fe_{68}Nd_{20}C_{9.5}B_{0.5}$ ingot and melt spun (m sp.) ribbon alloys annealed at different temperatures for 5 h. Mean grain size for the ingot alloy is also shown.

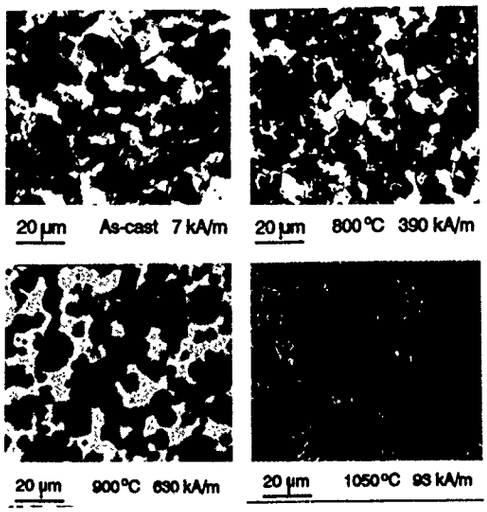

FIG 2. SEM micrographs for $Fe_{68}Nd_{20}C_{9.5}B_{0.5}$ ingots: as-cast ($_JH_c$=7 kA/m), and annealed for 5 h at 800 °C ($_JH_c$=380 kA/m), 900 °C ($_JH_c$=630 kA/m), and 1050 °C ($_JH_c$=93 kA/m). Backscattered electrons images

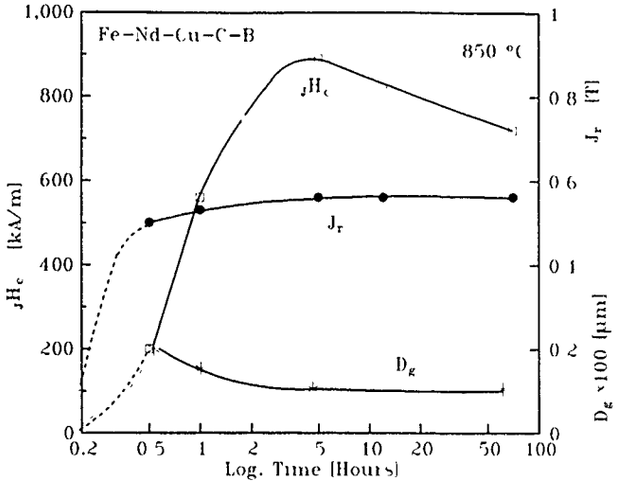

FIG 3. Magnetic properties and mean grain size for $Fe_{66}Cu_2Nd_{20}C_{9.5}B_{0.5}$ ingot magnets after annealing at 850 °C for different times.

maxima at 900 °C and the shape of the demagnetization curve for this sample indicated that the material consisted largely of the $Fe_{14}Nd_2C$ phase. Samples annealed at 1050 °C appeared to contain much soft magnetic phase and this temperature seemed to be close to the point of equilibrium coexistence of the $Fe_{14}Nd_2C$ and $Fe_{17}Nd_2C_x$ phases. The mean grain size (D_g) for the cast ingot alloy was inversely proportional to the amount of $Fe_{14}Nd_2C$ phase and showed a minimum of ~10 μm for the sample annealed at 900 °C. The coercivity of the magnets correlated closely with the grain size. Samples having a much smaller grain size (~50 μm) produced by hot pressing of rapidly solidified ribbon exhibited $_JH_c$ up to 300 kA/m higher than the ingot magnets of the same composition.

Fe-Nd-C-B alloys crystallized from the melt formed a fine dendritic microstructure. These elongated grains became equiaxed during annealing, firstly as $Fe_{17}Nd_2C_x$ (~15 μm), then reducing their size to ~10 μm, on decomposition to $Fe_{14}Nd_2C$. Long time annealing (70 h) at 850 °C did not result in coarsening of the microstructure. In contrast, the alloys annealed at 1050 °C were transformed by a small proportion only so that the final structure consisted of large grains (~30 μm) of mostly $Fe_{17}Nd_2C_x$ phase (Fig. 2).

The effect of annealing time on the magnetic properties was investigated for the $Fe_{66}Cu_2Nd_{20}C_{9.5}B_{0.5}$ alloy. The as-cast alloy was magnetically very soft but $_JH_c$ of 880 kA/m was developed after annealing for 5 h at 850 °C (Fig. 3). Significant coercivity appeared after a relatively short annealing time of 0.5 h. The reaction was completed after about 4 h annealing. For the longer annealing times at 850 °C a decrease of coercivity was observed though J_r was almost unchanged at a level of 0.58 T. X-ray diffraction analysis for this alloy showed patterns typical of the $Fe_{17}Nd_2C_x$ and $Fe_{14}Nd_2C$ structures for the as-cast and annealed (70 h at 850 °C) samples, respectively. The microstructure observations showed a decreasing grain size from ~20 μm for the specimen annealed for 0.5 h to ~10 μm for the fully transformed material.

Partial substitution for iron was made in a series of alloys $Fe_{66}M_2Nd_{20}C_{9.5}B_{0.5}$ with M=Ga,Nb,Cu,Al. These elements M were known to increase the coercivity of the Fe-Nd-B type magnets, mostly by changing the properties of the boundary phases.[9] The magnetic properties of substituted alloys are shown in Table I. The ternary and Cu-containing alloys exhibited high $_JH_c$ after very short annealing times, starting from 1 h, within the temperature range 850–1000 °C. Somewhat longer times were required for the Ga-containing alloy whereas the alloys with Nb and Al additions, even after long time annealing (five days), were only partially transformed and showed considerable proportions

	annealed	312	>727

of a soft magnetic phase. Results of the DSC analysis, presented in Table II, showed no change of the Curie temperature which suggested that no substantial amounts of the additives entered the $Fe_{14}Nd_2C$ phase. However, quite large differences in the melting points of the boundary phase were found. The multiphase grain boundaries melt in several stages which, due to the equipment limitations, we were able to measure only up to 727 °C. The lowest melting point was exhibited by the Cu-containing alloy which, on the DSC trace, showed a small primary melting peak at 523 °C and a large melting effect starting at 575 °C. This alloy had the best magnetic properties in the ingot state which moreover were developed within a short annealing time.

It has not been possible in the present study to establish whether the other alloys exhibit multistage melting because their incipient melting temperatures. The Al-containing alloy did not show a melting effect up to 727 °C. The two alloys having the highest melting temperatures of the intergranular phases, i.e., containing Nb and Al, did not transform completely to the $Fe_{14}Nd_2C$ phase even after a very long annealing time within the whole temperature range 800–1000 °C. Thus, it seems plausible that the properties of the intergranular liquid phase affects the kinetics of the peritectoid transformation, either acting as an aid to the process by increasing diffusivity across the phase boundary or retarding the diffusion and stabilizing the $Fe_{17}Nd_2C_x$ phase.

To increase J_r of the magnets attempts were made to produce anisotropic microstructures by hot deformation. Die-upset forging of cast alloys resulted in a modest increase of the remanence with a substantial decrease of the coercivity, as is shown in Fig. 4 for $Fe_{66}Ga_2Nd_{20}C_{9.5}B_{0.5}$ alloy. The reduced coercivity exhibited by the die-upset forged magnets we relate to squeezing out of the specimen the Nd-rich boundary phase which separates the hard magnetic grains. This appears to be more pronounced for the magnets containing additional elements which lower melting point of the boundary phase.[10]

IV. CONCLUSIONS

A coercive ingot material, with $_JH_c$ up to 880 kA/m, was fabricated by solid-state transformation during heat treatment

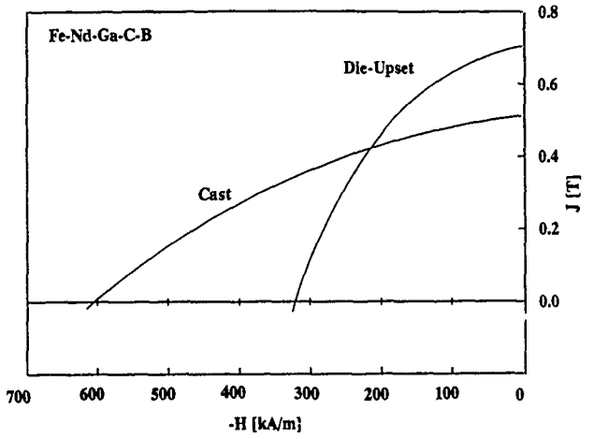

FIG. 4. Cast and die-upset forged $Fe_{66}Ga_2Nd_{20}C_{9.5}B_{0.5}$ alloys.

of Fe-Nd-C-B type ingot alloys. The useful annealing temperatures were in the range 800–1000 °C. Annealing times of a few hours was found to be sufficient to achieve complete transformation for $Fe_{68}Nd_{20}C_{9.5}B_{0.5}$ and for Cu, and Ga-added alloys. However, only small volume fractions of $Fe_{14}Nd_2C$ were obtained for Nb- and Al-containing alloys. The kinetics of the peritectoid transformation were found to be affected by the melting temperature of the intergranular phases. The elements which lower this temperature are considered to act as an aid to the process by increasing diffusivity across the phase boundary and the elements that increase melting point can inhibit the process and effectively stabilize the $Fe_{17}Nd_2C_x$ phase. The optimally annealed alloys had mean grain sizes of ~10 μm and their coercivity showed strong dependence on the initial microstructure before the heat treatment. Some increase of the remanence (~0.7 T) was achieved after die-upset forging of cast alloys.

Generation of highly uniform fields with permanent magnets (invited)

M. G. Abele
New York University School of Medicine, New York, New York 10016

A review of a design methodology of permanent magnets composed of magnetic materials with quasilinear demagnetization characteristics is presented. The paper focuses on the design of efficient permanent magnets for applications that require strong and highly uniform fields. The compensation of the field distortion caused by design constraints and fabrication tolerances is one of the aspects of magnet design discussed in this paper. A design procedure based on active filter structures that restore a required degree of field uniformity is reviewed.

I. INTRODUCTION

The evolution of the design of permanent magnets in recent years has been prompted by the development of high-energy product rare-earth magnetic materials. The characteristics of these alloys, and, in particular, their high intrinsic coercive force, have extended the use of permanent magnets to a number of applications. Compared to electromagnets, permanent magnets have the obvious advantage of requiring no external power supply and no maintenance cost. Their basic disadvantages are the high cost of the magnetic material, the technological problems of achieving any desired distribution of magnetization, and the difficult operations of preparing and assembling the magnetic blocks.

The most striking property of modern rare-earth materials is their quasilinear demagnetization characteristics. This property has led to the introduction of new design approaches that depart drastically from the traditional magnet designs where only approximate numerical solutions are possible due to the highly nonlinear characteristics of older magnetic alloys.[1] Exact mathematic solutions of the field generated by the new material have resulted in novel magnetic structures that differ from traditional magnetic circuits both in terms of geometry and field properties as well.[2–4]

At present, the most significant application of large permanent magnets is found in nuclear magnetic resonance imaging in medicine, where the size of a magnet is dictated by the dimensions of the human body and the field strength is selected on the basis of imaging requirements. Superconductive magnets still have the lion's share of the medical field and their technology is constantly improving in terms of size, self-shielding property, and reduction of maintenance of the cryogenic equipment. On the other hand, the advantages of permanent magnets justify the current efforts to reduce their cost, weight, and size. At present, the main application of permanent magnets is found in the low to medium field strength.[5] Two major challenges face the designer: generation of high fields of the order of the remanence within acceptable limits of size and weight, and reduction of the complexity of the problem of compensation of field distortions due to practical design constraints and magnetization tolerances.[6]

II. BASIC MAGNETIC STRUCTURES

The quasilinear demagnetization characteristics of modern magnetic materials is the basis of the development of a linear theory of the design of permanent magnets that relegates the nonlinear effects to a perturbation of basic linear solutions.[7–9]

The design of a magnet is the classical inverse problem where once the field is assigned within a region of interest, the designer must find the configuration of the magnetic structure capable of generating such a field. On one hand, the designer faces the problem of the indeterminacy of the solution of the inverse problem. On the other hand, the indeterminacy makes it possible to satisfy specific requirements by choosing the solution among several categories of magnetic structures, in order to satisfy specific design requirements.

Once a field distribution is specified within a given region, it is always possible to generate such a field with a magnetic structure that encloses the assigned region. As an example, consider the problem of generating a two-dimensional periodic field with a period $4z_0$ along the z coordinate of a prismatic cavity of rectangular cross section of dimensions $2x_1$, $2y_1$. The field is independent of the x coordinate and on the plane $y=0$ is oriented in a direction perpendicular to the plane, as indicated in the schematic of Fig. 1.

The scalar potential within the prismatic cavity is

$$\Phi = \frac{H_0}{k} \sinh ky \cos kz, \tag{1}$$

where $k=\pi/2z_0$ and H_0 is the amplitude of the field intensity on the $y=0$ plane. Equation (1) describes the field of an undulator.[10] A structure that generates the periodic field with-

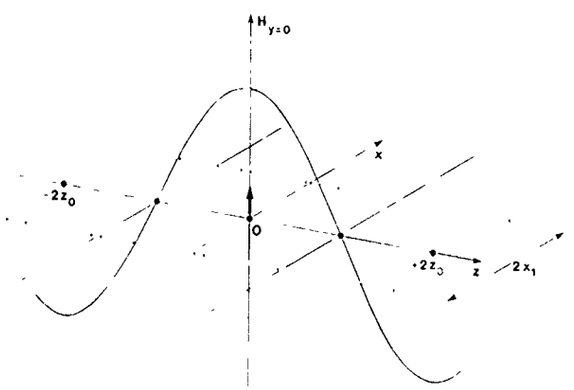

FIG 1. Periodic two-dimensional field.

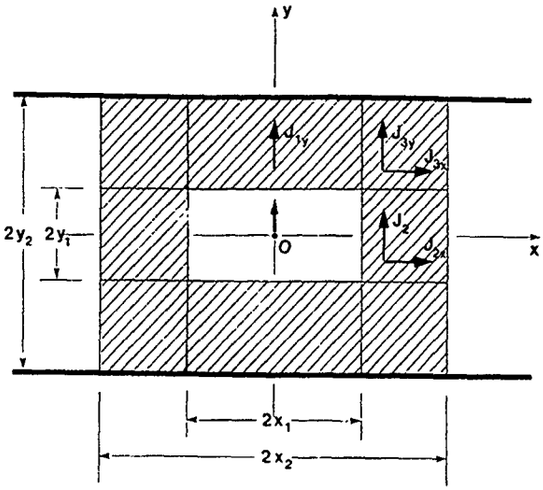

FIG. 2. Cross section of undulator.

out introducing harmonics is shown in Fig. 2, where the magnetic material is distributed between the cavity and an external rectangular boundary of dimensions $2x_2$, $2y_2$.

The two sides of the external boundary perpendicular to the y axis interface with a high magnetic permeability material that closes the flux of the magnetic induction. The flux does not cross the sides perpendicular to the x axis. These two sides are also equipotential and, as a consequence, they interface with external nonmagnetic media. In the first quadrant the components of the remanence of the magnetic material are

$$
\begin{aligned}
&J_{1x}=0, \quad J_{1y}=-\mu_0 H_0 \frac{\sinh ky_2}{\sinh k(y_2-y_1)}\cos kz, \\
&J_{2x}=-\frac{\mu_0 H_0}{k(x_2-x_1)}\sinh ky\,\cos kz, \quad J_{2y}=0, \\
&J_{3x}=-\frac{\mu_0 H_0}{k(x_2-x_1)}\frac{\sinh ky_1}{\sinh k(y_2-y_1)}\sinh k(y_2-y)\cos kz, \\
&J_{3y}=-\mu_0 H_0 \frac{\sinh ky_2}{\sinh k(y_2-y_1)}\frac{x_2-x}{x_2-x_1}\cos kz.
\end{aligned}
\tag{2}
$$

Equation (2) shows that both magnitude and orientation of the remanence are a function of position. In general, a nonuniform field requires a nonuniform distribution of magnetization in the magnetic structure; this could be very difficult, if not impossible, to implement in practice. Thus even if an exact solution is found, the design and fabrication of a magnetic structure would have to be an approximation of the theoretical model. An exception is found in the generation of a uniform field in which case the exact solution of the design problem yields structures of uniformly magnetized polyhedrons that can be fabricated from standard blocks of magnetic material.

The existence of a design solution with uniformly magnetized polyhedrons is based on a condition that relates the geometry of the polyhedrons that compose the magnetic structure and the uniform remanence $\mathbf{J}$ of each polyhedron.[7] A uniform field is found in each polyhedron if and only if at each point common to n interfaces between polyhedrons the remanences and the orientations of the interfaces satisfy the condition

$$
\sum_{h=1}^{n} \boldsymbol{\tau}_h \cdot \boldsymbol{\eta}_h \times (\mathbf{J}_{h-1}-\mathbf{J}_h)=0, \tag{3}
$$

where $\boldsymbol{\eta}_h$ is a unit vector perpendicular to the hth interface between polyhedrons of remanences $\mathbf{J}_{h-1}$, $\mathbf{J}_h$, oriented from the medium of remanence $\mathbf{J}_{h-1}$ to the medium of remanence $\mathbf{J}_h$, and $\boldsymbol{\tau}_h$ is a unit vector in the plane of the hth interface, perpendicular to the line common to the n interfaces and pointing away from the hth interface.

The magnetic structures that satisfy condition (3) can be classified in several categories characterized by different properties: yoked magnets where the flux of the induction generated by the magnet closes through an external yoke of high permeability material, yokeless magnets where the flux is confined within the same structure of the magnetic material without the need of an external yoke, and hybrid magnets combining both yoked and yokeless structures that optimize the magnet efficiency for a particular geometry and field intensity within the magnet cavity.

A fourth category includes magnets that take full advantage of linear demagnetization characteristics with small values of the magnetic susceptibility. In the ideal limit of zero susceptibility, the magnetic material is perfectly transparent to the field generated by other sources. Thus the field within the region of interest can be increased by superimposing the field generated by independent magnets. In the particular case of yokeless magnets, this is achieved by a multiplicity of magnets inserted one inside each other around the region of interest.

An example of yoked magnet is presented in Fig. 3(a), which shows a section of a two-dimensional magnet designed to generate a uniform field inside a prismatic cavity of rectangular cross section. The heavy line in the schematic of Fig. 3(a) represents the external yoke. A characteristic feature of such a magnet is the presence of the nonmagnetic regions between the blocks of magnetized material. The flux of the induction in these regions does not circulate within the cavity and is the equivalent of the fringe field in a traditional magnet.

Figure 3(b) shows an example of yokeless magnet that is characterized by a combination of an internal structure that interfaces with the cavity and an external structure designed to confine the field. The magnet of Fig. 3(b) is also designed around a prismatic cavity of rectangular cross section. In general the basic difference between yoked and yokeless structures is that a yokeless magnet requires a larger amount of magnetic material to perform the double function of generating and confining the field. An important property of a two-dimensional yokeless magnet is that its geometry is independent of the orientation of the field within the cavity.[7]

An example of hybrid magnet designed around the same cavity of Figs. 3(a) and 3(b) is shown in Fig. 3(c); it combines a yoked component of magnetic material with yokeless structures of triangular cross section where the magnetic induction is zero. As a consequence, the total flux of the mag-

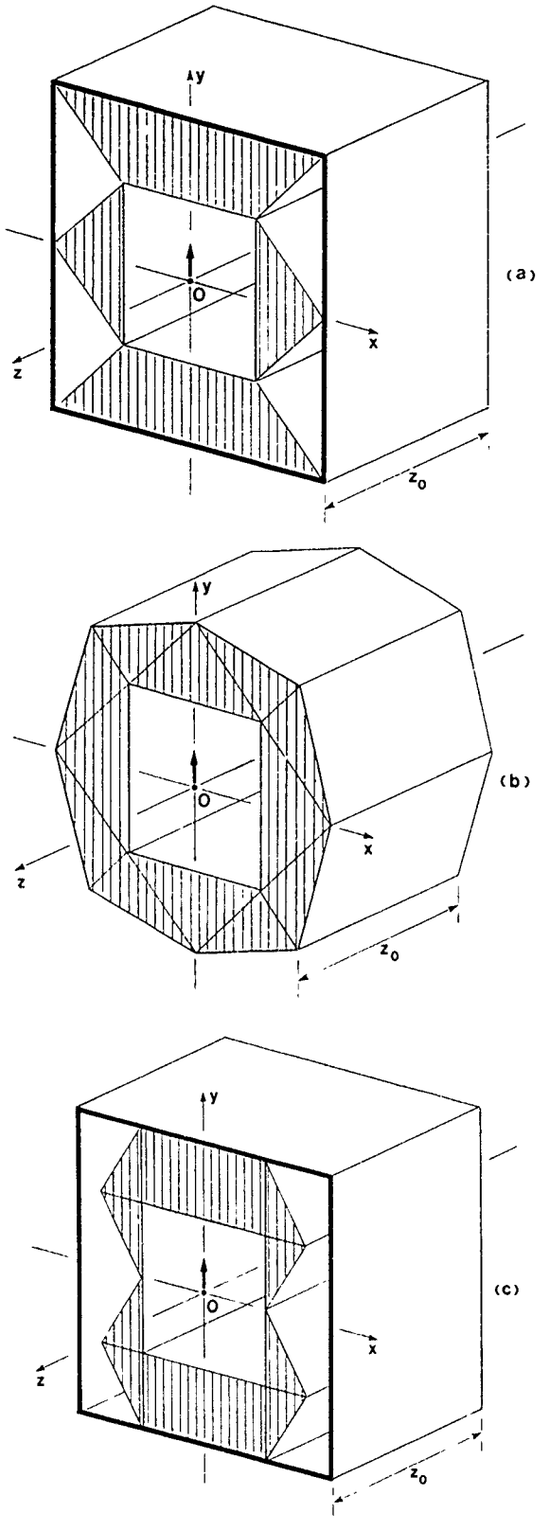

FIG. 3. Examples of two-dimensional magnets with the same internal prismatic cavity: (a) yoked, (b) yokeless, (c) hybrid.

netic induction flows through the cavity and closes through the yoke. In Fig. 3(c) the heavy line that represents the yoke can be closed without interfacing with the components of triangular cross section and no field is found in the region between these components and the yoke. One observes that Fig. 2 is another example of hybrid structure.

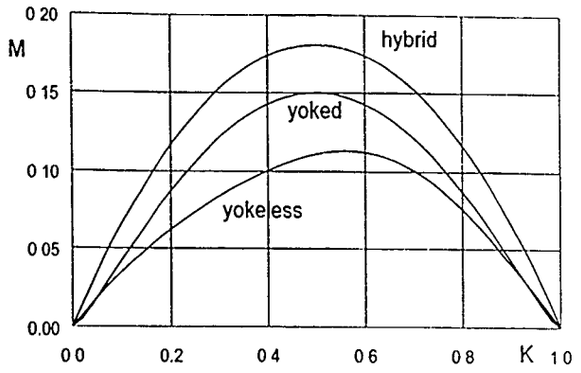

FIG. 4. Figure of merit of three magnets with the same cavity geometry.

If the same magnetic material is used in all the components of a magnetic structure designed to generate a uniform field intensity H_0 within the cavity, one can define the parameters

$$K=\mu_0\frac{H_0}{J_0},\quad M=K^2\frac{V_c}{V_m}, \tag{4}$$

where J_0 is the remanence and μ_0 is the magnetic permeability of a vacuum. M is the figure of merit of the magnet and V_c, V_m are the volumes of the cavity and of the magnetic material, respectively. Figure 4 shows the plotting of the figure of merit of the three magnetic structures of Fig. 3 versus K for the dimensions of the cavity cross section $2x_0=4y_0$. The hybrid structure exhibits the highest value of M, and the yokeless the lowest. M attains its maximum in the range $0.5<K<0.6$ for the three magnets, and it decreases to zero as the field within the cavity approaches the value of the remanence. This is due to the fact that as the field increases, the outside layer of magnetic material becomes less and less efficient in contributing to the field within the cavity.

By virtue of Eqs. (4) and Fig. 4, the volume of the magnetic material diverges at $K=1$, and, as a consequence, the structures of Fig. 3 cannot generate a field equal or larger than the remanence. The upper limit $K=1$ is removed by multilayer structures, like the schematic of Fig. 5 which shows a number m of concentric yokeless magnets around a regular polygonal cavity of n sides. If m is the number of layers, the values of K and M of the structure of Fig. 5 are

$$K=m\left(1-\cos\frac{\pi}{n}\right),\quad M=\frac{K^2}{\cos^{-2m}(\pi/n)-1}. \tag{5}$$

Even if a structure like Fig. 5 makes it possible to generate values $K>1$, the optimum design condition is achieved for large values of n and a large number of layers at $K\approx0.8$ and $M\approx0.16$. An example of multilayer structure is the two layer, two-dimensional magnet with a square cross-section cavity shown in Fig. 6 where the internal layer generates a field corresponding to $K=0.51$. The total value of K of this magnet is $K\approx0.79$ and its figure of merit is $M\approx0.13$.

The optimum design of a multilayered magnet is a structure of hybrid layers that combines materials with different remanences. Specifically, the figure of merit attains its maximum in multilayered structures where the highest value of

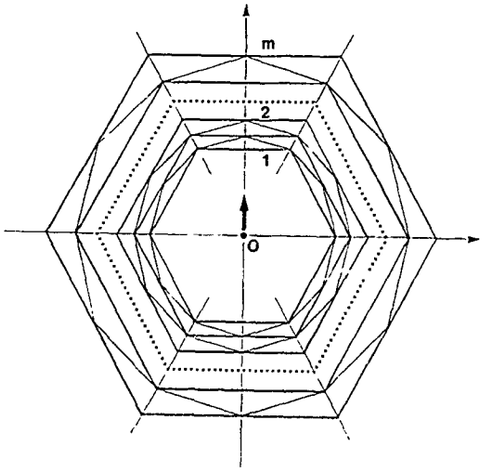

FIG. 5. Multilayer structures.

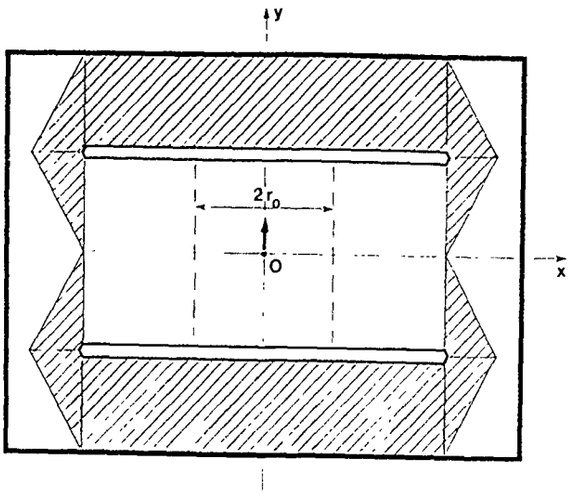

FIG 7. Insertion of high magnetic permeability plates

the remanence is used for the internal layer and the remanence of the other layers decrease with the distance of each layer from the cavity. The absolute maximum value of the figure of merit is 0.25 regardless of geometry and distribution of magnetization.[11]

III. OPEN MAGNETS

A magnet cavity has to be closed to achieve a perfectly uniform field. In practice a magnet must be open to access the region of interest. For instance, a magnet may be a section of length $2z_0$ of one of the structures illustrated in Fig. 3 open at both ends. The distortion of the field due to the opening reduces the region of the cavity where an acceptable degree of uniformity is found. In applications requiring a moderate field uniformity a simple solution is the choice of a sufficiently large dimension $2z_0$, of the order of several times the dimension of the region of interest. However, in applications like NMR imaging in medicine, where the uniformity has to be of the order or better than 10^{-5}, this approach would lead to extremely large values of $2z_0$. In this case, the compensation of the field distortion becomes the most critical problem that faces the designer in order to keep magnet dimensions and cost within practical limits.

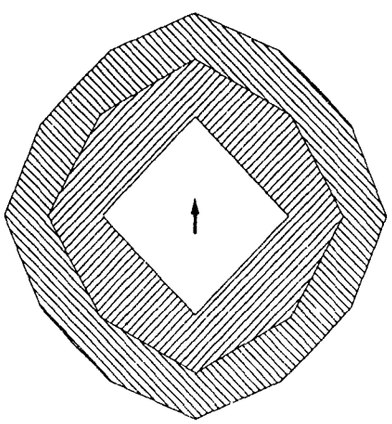

FIG. 6 Two-layer yokeless magnet

The field distortion results not only from the opening of the magnet cavity but also from the fabrication tolerances, and in particular from the magnetization tolerance of the magnetic materials. The magnitude of the remanence may vary by a few percent and the orientation of the remanence may vary by a few degrees. While the effects of the magnet opening may be corrected in the design phase, the compensation of fabrication and magnetization tolerances must be accomplished in the shimming of the assembled magnet. However, the same logic followed in the design phase can be applied to derive the shimming procedure from the field measurements in the assembled magnet.

Because of the quasilinearity of the magnetized material, the compensation of the field distortion in the design phase can be accomplished by designing a compensating structure to be added to the main structure of the magnet. A number of solutions can be adopted involving magnetic materials as well as ferromagnetic components.[7] The quantitative derivation of these solutions can be obtained by expressing the field distortion in terms of the spectrum of its spatial harmonics. Consider the type of magnets where the interface between cavity and magnetic material includes two parallel planes perpendicular to the magnetic field in the cavity. The region of the expansion in the spatial harmonics can be a cylinder of radius r_0 containing the region of interest, with its axis parallel to the field, and closed by two thin plates of high magnetic permeability material inserted at the two interfaces perpendicular to the field as indicated in the schematic of Fig. 7. The plates must be sufficiently thin in order not to affect the figure of merit of the magnet.

The two plates in Fig. 7 act as magnetic mirrors of the field inside the cavity and at the same time they are an effective filter of the high spatial frequency components of the field distortion generated by the magnetization tolerances.[12]

Within the region of the cylinder between the plates, the scalar potential of the field is

$$\Phi=\Phi_0\frac{y}{y_0}+\sum_{m,n} I_m\left(n\pi\frac{r}{y_0}\right)$$

$$\times(a_{m,n}\cos m\psi+b_{m,n}\sin m\psi)\sin\left(n\pi\frac{y}{y_0}\right), \tag{6}$$

where Φ_0 is a constant; r, ψ, y are the cylindrical coordinates, $a_{m,n}$, $b_{m,n}$ are the amplitudes of the harmonics, and I_m is the modified Bessel function

$$I_m\left(n\pi\frac{r}{y_0}\right)=i^{-m}J_m\left(in\pi\frac{r}{y_0}\right). \tag{7}$$

If H_0 is the uniform field intensity within the magnet cavity, the quantity

$$\frac{1}{y_0}\Phi_0+H_0 \tag{8}$$

represents the loss of the field intensity within the region of interest. Usually this loss can be tolerated and the compensation procedure can be confined to the correction of the nonuniformity expressed by the summation on the right-hand side of Eq. (6). As a consequence the amount of magnetic material necessary to perform the compensation reduces to only a fraction of the total material of the magnet.

IV. COMPENSATION OF FIELD DISTORTION

Once the distortion of the field is defined by its spectrum, the compensation can be performed by means of a filter structure located outside the cylindrical surface; this is designed to eliminate the dominant harmonics $a_{m,n}$, $b_{m,n}$ up to the point where the residue of the harmonics expansion is within an acceptable value. An essential part of the filter is a structure that allows the control of the potential of the surface of the two high permeability plates in Fig. 7 outside the cylindrical region selected for the expansion. This is accomplished in each plate by means of elements of magnetized material sandwiched between the main body of the plate and a number of magnetically insulated high permeability plates that interface with the cavity.[13] If the dimensions of the insulated plates are large compared to the thickness of the sandwiches, the scalar potential of each insulated plate relative to the main plate is a linear function of the amount of magnetic material magnetized in the direction perpendicular to the plate and is independent of the position of the material in the space between the insulated plate and the main plate. Consequently, the effect of each sandwich on the field within the cavity is controlled by the mechanical precision of fabrication of the plates and by the amount of material of each sandwich. This structure leads itself to a mechanical tuning of the filter both in the construction of the magnet as well as in its final shimming.

A schematic of filter structures inserted in each plate is shown in Fig. 8 where individual elements of the filter structure are arranged on a circular pattern. The distribution of potential of the elements of the filter is computed to generate harmonics equal in amplitude and opposite sign of the harmonics of order m of the spectrum of the field of the magnet. Thus the maximum value of m of the harmonics to be compensated determines the minimum number of the elements of the filter. The potential of each element determines the amount and magnetization of the material to be inserted in the element. Because of the linearity of the relationship between potential of each element of the filter and its filling, the compensation of the distortion is achieved by the addition of the amount of material required by each harmonic.

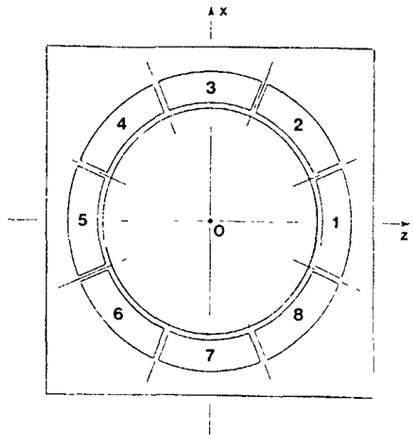

FIG. 8. Schematic of filter composed of eight elements inserted in each high permeability plate.

The elements of the filter on the plate of Fig. 8 alone are one part of the entire filter designed to compensate any harmonic of indices m,n. To generate a spectrum containing a specified number of n harmonics, the filter structure must contain also elements distributed in a number of additional rings on the main plates as well as in the region between the plates. Obviously the complete filter structure cannot interfere with the access to the region of interest. Therefore the filter elements distributed between the plates must occupy only a part of the full circle, as indicated in the schematic of Fig. 9, which shows filter elements located on the $y=0$ plane.

A typical spectrum of the harmonics of the field distortion is shown in Table I which corresponds to a rectangular

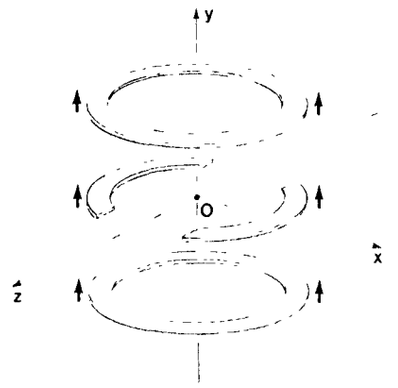

FIG. 9. Filter structure with elements distributed on the $y=0$ plane.

TABLE I. Typical spectrum of harmonics in a yoked magnet.

m	n	$a_{m,n}$	$n\pi a_{m,n} I_m(n\pi r/y_0)$
0	1	1.5×10^{-4}	1.3×10^{-3}
0	2	$\sim10^{-6}$	$\sim10^{-4}$
2	1	6.5×10^{-4}	1.8×10^{-3}
2	2	$\sim10^{-7}$	$\sim10^{-6}$
4	1	4.2×10^{-4}	1.0×10^{-4}
4	2	$\sim10^{-6}$	$\sim10^{-5}$

prismatic cavity open on opposite sides, with cavity dimensions $2z_0=2x_0=4y_0$. The values of the amplitude of the harmonics listed in Table I correspond to a yoked structure designed for $K=0.5$ with the two main plates inserted in the cavity. Because of symmetry, all amplitudes $b_{m,n}$ are zero and the spectrum reduces to the harmonics of even order m. If the required degree of uniformity is such that harmonics with values $a_{m,n}<10^{-6}$ can be disregarded, only harmonics of order $n=1$, with the exception of the harmonics ($m=0$, $n=2$), ($m=4$, $n=2$), constitute the spectrum that must be compensated. Thus in this particular case, the filter structure can be implemented following the schematic of Fig. 9. Table II lists the values of the three elements numbered in the schematic of the filter structure shown in Fig. 8 that cancel the harmonics ($m=0$, $n=1$), ($m=2$, $n=1$), ($m=4$, $n=1$). By symmetry, the potential of the other elements are

$$\delta\Phi_8=\delta\Phi_6=\delta\Phi_4=\delta\Phi_2,$$
$$\delta\Phi_5=\delta\Phi_1,\quad \delta\Phi_7=\delta\Phi_3. \tag{9}$$

The filter structure based on the control of the potential of the filter elements by means of magnetic material is the active equivalent of the passive pole pieces of traditional magnets whose geometry is designed to achieve the desired field configuration. The ability to control the amount of material inside each element of the filter structure extends the use of the filter to the correction of the effects of magnetic and fabrication tolerances. The final shimming of a magnet can be performed by extracting the harmonics from the measurement of the field in the fully assembled magnet and by correcting the potential of each element of the filter either by inserting additional magnetic material or by changing the orientation of the material inside each element.

V. CONCLUDING REMARKS

The new design approaches are already being adopted for the commercial development of permanent magnets and the application of permanent magnet technology to the field of medical imaging is expanding. In the low-field range, a remarkably compact 0.2 T ferrite magnet has been successfully development by Esaote Biomedica of Italy. In the medium field range, Sumitomo Special Metals of Japan, which has pioneered the use of permanent magnets in medical imaging, has recently developed a powerful 0.45 T Nd.Fe.B magnet designed for whole body imaging.

As new higher-energy product materials are being developed,[14] smaller and more efficient magnetic structures can be designed. With an expanding range of applications, the cost of these new materials is bound to decline steadily, and as the cost per unit energy decreases, more powerful magnets are becoming a viable solution in large scale applications requiring field energies of the order of 10^5 J/m^3 or larger.

Fabrication of multipolar magnetic field sources

H. A. Leupold and G. F. McLane
U. S. Army Research Laboratory, Fort Monmouth, New Jersey 07703

The emergence of high-energy-product permanent magnets has made possible the generation of extraordinarily high magnetic fields in the internal working spaces of relatively small structures. The widespread use of such structures has been hampered by the variety and complexity of their magnetic components and the concomitant difficulty and expense of manufacture. This paper describes approaches to fabrication and assembly that should significantly ease both fabricational and economic problems. Examples of these approaches are given for the production of cylindrical multipolar sources (magic rings, quadrupolar electron beam guides) and spherical dipolar sources (magic spheres).

I. INTRODUCTION

The high-energy-product permanent magnet materials afford shell-like structures that produce in their internal chambers fields that are much higher than those obtainable from the conventional structures that can be made of the older materials such as the alnicos. Unfortunately for many such structures the required distributions of the magnetization are complex and require components with many different magnetic orientations. This augments the difficulty and expense of the manufacture.

Two particularly useful configurations are the so-called magic rings (really cylindrical shells) and magic spheres.[1,2] In the cylinder, the magnetization is uniform in magnitude, has no z component, and varies in direction γ with the azimuthal angle as $\gamma=2\phi$ [see Fig. 1(a)]. If a circular section of such a cylinder is rotated about its polar axis, its locus forms a spherical shell or magic sphere like that shown in Fig. 1(b).

The cylinders and spheres produce in their internal chambers uniform fields of $H_c=B_r \ln(r_o/r_i)$ and $H_s=(4/3)B_r \ln(r_o/r_i)$, respectively. Here B_r, r_o, r_i are the magnetic remanence and outer and inner radius, respectively. These formulas show that fields of any magnitude are possible for either structure if the ratio r_o/r_i is made large enough. However, the field's logarithmic dependence on outer radius results in prohibitive bulks for fields much in excess of 20 kOe in the cylinder and about 27 kOe for the sphere. Within these limits, however, performance is quite impressive. A sphere of 8 cm diameter produces 20 kOe in a cavity of 2.5 cm diameter with a material of B_r equal to 12 kG.

II. ASSEMBLY OF A MAGIC RING

In practice the continuous magnetic structure of rings and spheres is approximated by an array of segments each of uniform magnetization within its boundaries which changes abruptly upon passage to a neighboring segment (Fig. 1). Therefore many different orientations are needed in the magic ring and, it would seem, many different operations to produce them. These operations can be reduced to one by the following considerations.

If a cylindrical tube is aligned and uniformly magnetized perpendicularly to its principal axis one notes that every possible orientation of the magnetization relative to the local radius is represented. Therefore, only a simple rearrangement of cylindrical segments is needed to form the desired magic ring [Fig. 2(a)].[3] Alternatively each segment can be rotated 180° about its local radius to obtain the same results [Fig. 2(b)]. Either procedure obviates the necessity of multiple magnetizations on many different cylindrical segments.

III. MULTIPOLAR RINGS

A similar procedure may be used to form rings and cylinders of higher order polarity. Of these probably the most useful is the quadrupole, which is extensively employed in the focusing of charged particle beams.[1] A typical arrangement is that of Fig. 3 which shows that the magnetic orientation goes as $\gamma=4\phi$. Because the orientation changes twice as fast with ϕ as in the dipolar structure, it follows that the orientation increment between adjacent segments of given size is twice as great while twice as many segments of a given orientation are needed. For example, the initial uniform magnetization of a cylinder yields only one radially oriented segment that points inward while for a quadrupole, two such are needed. This problem can be solved by the magnetization of two cylinders and then the procedure of Fig. 4 to form two slightly different segmented approximations to ideal quadrupolar cylinders.

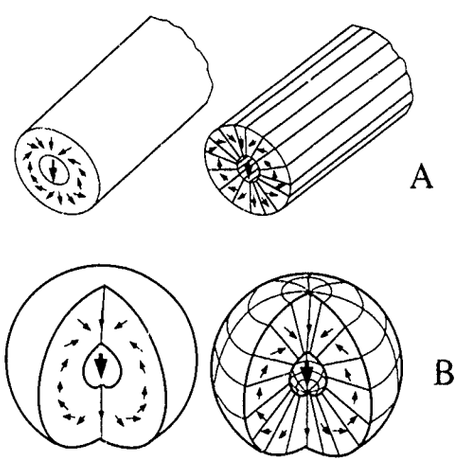

FIG 1 Permanent magnet structures with segmented approximations (A) magic ring, (B) magic sphere

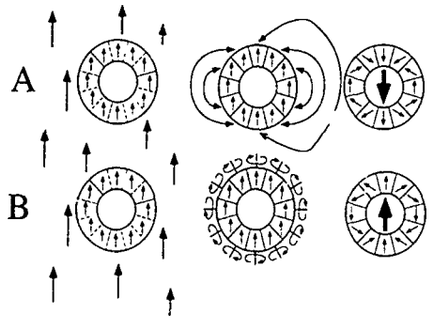

FIG. 2. Assembly of a magic ring by (A) rearrangement of segments after uniform magnetization, (B) rotation of segments about local axes after magnetization.

Alternatively a ring could be segmented before magnetization with every other piece elevated above the original stack, revolved $2\pi/n$ about the original axis and stacked as shown in Fig. 5. The stack would then be uniformly magnetized with the correct number of each type of required segment. After a π rotation of each segment about its local radius and an angular contraction of the gapped stack into a half cylinder with two identical semidisc layers, the said layers are appropriately joined at their equatorial planes as illustrated in Fig. 5.

Similar procedures are used to form multipolar rings of higher order. In general $n/2$ stack layers of m/n segments each are used, where n is the desired multipolar order and m is the total number of segments needed to attain the required structural fineness.

IV. MAGIC SPHERES

A magic sphere is made from magic ring slices that have been beveled to form the melon-slice shapes of Fig. 6. These are then assembled, tangerine-like, into the required magic sphere. Unfortunately this involves the possible, but inconvenient, step of machining a magnetized ring. Unfortunately the uniform magnetization of a spherical segment and its subsequent rotation about the local radius does not work with

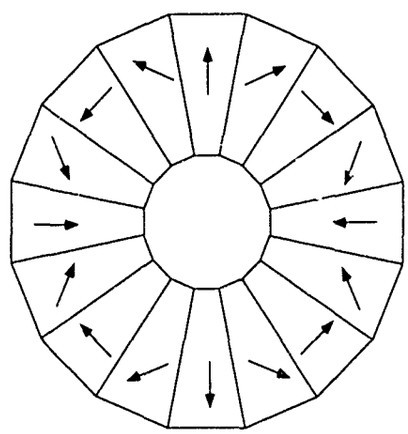

FIG 3 Cylindrical quadrupolar cross section

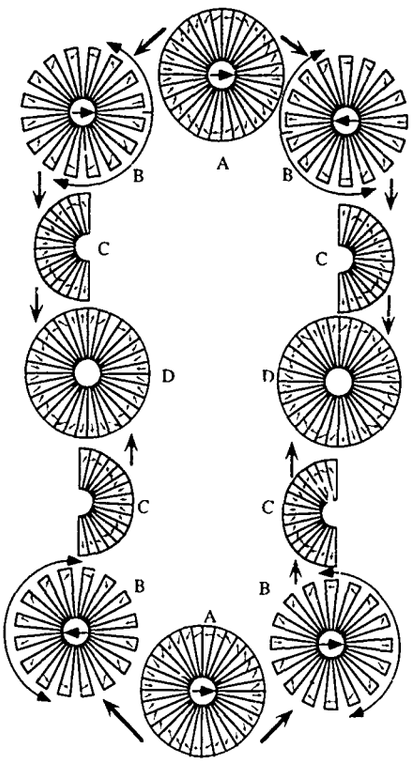

FIG 4 formation of two quadrupole sources from two dipole sources (A) Start with two dipolar structures. the sphere as with the ring. The lengths of the areas that subtend the width of a segment on the spherical surface depend on the polar angle. This results in a mismatch when the required rotation about the local radius leaves the shorter arc where the larger should be and vice versa. This difficulty can be avoided by a rotation of the segment prior to magnetization as in Fig. 7. After magnetization the segments are rotated back into their initial positions with the correct magnetic orientations.

V. SUMMARY

Multipolar cylinders and dipolar spheres can all be magnetically oriented in a single uniform magnetization. In the case of the sphere this can be done either before or after the necessary machining. The machining for the sphere can be minimized to a single bevelling operation on magic ring segments instead of the cutting of many compound angles on a multiplicity of different spherical segments.

Kinetic studies on solid-HDDR processes in Nd-Fe-B-type alloys

O. Gutfleisch, M. Verdier, and I. R. Harris
School of Metallurgy and Materials Science, University of Birmingham, Birmingham B15 2TT, United Kingdom

The kinetics of solid-HDDR (hydrogenation, disproportionation, desorption, recombination) processing of Nd-Fe-B-type alloys have been characterized by means of *in situ* electrical resistivity measurements and hydrogen absorption and desorption studies on nondecrepitated samples. The fundamental differences in reaction rate and mechanism between a $Nd_{16}Fe_{76}B_8$ as-cast and a homogenized stoichiometric $Nd_2Fe_{14}B$ alloy at $T=800$ °C and $p(H_2)=0.7$ bar are reported. The disproportionation and recombination rates were found to be significantly lower in the stoichiometric alloy, particularly in the case of the latter. The onset of the disproportionation and recombination reaction in $Nd_{16}Fe_{76}B_8$ in a temperature range of $T=780-880$ °C under hydrogen atmosphere was investigated and these reactions were found to depend critically on the pressure. Low-temperature recombination at $T=620$ °C was studied by the development of the Curie-point resistance anomaly of the $Nd_2Fe_{14}B$ matrix phase. It has been shown that the amount of reformed $Nd_2Fe_{14}B$ matrix phase during recombination can be monitored by this method.

I. INTRODUCTION

The hydrogenation, disproportionation, desorption, recombination (HDDR) process has been reported as a method of producing highly coercive Nd-Fe-B-based powder via a hydrogen-induced structural change; this powder can be used for the production of Nd-Fe-B-type hot pressed and bonded magnets (see, for example, Refs. 1 and 2). Heating under a hydrogen atmosphere results in the decrepitation of the ingot which is described as the HD process.[3] The disproportionation reaction occurs at elevated temperatures and results in the formation of an intimate mixture of α-Fe, Nd-hydride, and Fe_2B. On desorbing the hydrogen, the different constituents recombine to form the thermodynamically stable $Nd_2Fe_{14}B$ phase. The main microstructural feature of the HDDR process is the conversion of the coarse grained $Nd_2Fe_{14}B$ phase into a material with submicron grain size.

The kinetics of the disproportionation and recombination reactions, which depend on alloy composition, initial microstructure, temperature, and hydrogen pressure, can be monitored by means of *in situ* electrical resistivity measurements of the nondecrepitated material by introducing the hydrogen at elevated temperatures ($T\sim800$ °C).[4,5] This type of reaction can be referred to as solid-HDDR.[6] In this article it is reported how *in situ* electrical resistivity measurements during solid-HDDR processing can be employed to study the differences in kinetics and reaction mechanisms in Nd-Fe-B-type alloys with and without the presence of Nd-rich grain boundary material. Other factors such as hydrogen pressure and the absence of grain boundary melting are also examined.

II. EXPERIMENT

The *in situ* electrical resistivity measurement employed is based on the standard four-probe method and can be used up to 1000 °C under vacuum or hydrogen atmosphere. Detailed procedures have been given elsewhere.[5] Materials under investigation were as-cast $Nd_{16}Fe_{76}B_8$ and stoichiometric $Nd_2Fe_{14}B$ alloy which was homogenized at 1060 °C for 264 h under vacuum.[7] After homogenization, a small area fraction of ~2% free Fe dendrites was found to be present in the material. The microstructure of the $Nd_{16}Fe_{76}B_8$ alloy is typical of "Neomax"-type alloys with this composition,[8] whereas the stoichiometric alloy is virtually free of Nd-rich phase.

The overall HDDR kinetics of the two alloys were investigated at $T=800$ °C and $p(H_2)=0.7$ bar. The electrical resistivity and hydrogen absorption and desorption pressures were recorded in order to monitor the disproportionation and recombination reactions. In addition, a fully disproportionated $Nd_{16}Fe_{76}B_8$ alloy was heated from 700 to 1000 °C under various hydrogen pressures to provide further information about the contributions of the different constituents in the disproportionated mixture to the overall electrical resistivity. In order to investigate the onset of the disproportionation and recombination reactions of a $Nd_{16}Fe_{76}B_8$ alloy under hydrogen, the pressure was varied at different isotherms between $T=780$ and 880 °C. The resistivity of $Nd_2Fe_{14}BH_x$ or NdH~2, α-Fe, and Fe_2B as a function of hydrogen content was recorded. Rapid changes in resistivity were interpreted as the onset of the disproportionation or recombination reactions.[4,5] Controlled recombination at $T=620$ °C was achieved by monitoring the hydrogen desorption behavior and the development of the Curie-point resistance anomaly of the reformed $Nd_2Fe_{14}B$ matrix phase. At this temperature, the desorption of the hydrided Nd-rich grain boundary phase is avoided and hence melting of the grain boundary material is also avoided. The observed changes in resistivity will be derived entirely from transformations within the matrix phase. The disproportionated material was then cooled under hydrogen to room temperature and reheated to $T=620$ °C under vacuum to desorb for 2 h and cooled again, this cycle was repeated until the material was fully recombined.

III. RESULTS AND DISCUSSIONS

A. Comparison of HDDR kinetics between a Nd-rich and a stoichiometric alloy

A schematic diagram for a complete HDDR experiment monitored by measuring the electrical resistivity has been reported previously.[5] Resistivity, hydrogen absorption and

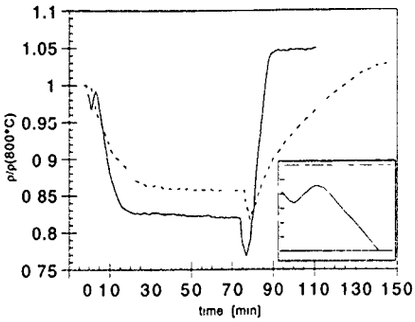

FIG. 1. Isothermal part of the electrical resistivity vs time monitoring the S-HDDR process at $T=800$ °C and $p(H_2)=0.7$ bar for an as-cast $Nd_{16}Fe_{76}B_8$ (solid line) and a stoichiometric $Nd_2Fe_{14}B$ alloy (dashed line); hydrogen introduction at $t=0$ min and vacuum at $t=75$ min. Inset shows the initial variations in more detail.

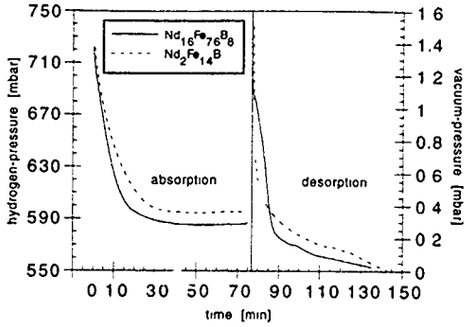

FIG. 2. Hydrogen absorption and desorption behavior during disproportionation and recombination of a $Nd_{16}Fe_{76}B_8$ as-cast (solid line) and a stoichiometric $Nd_2Fe_{14}B$ alloy (dashed line) at $T=800$ °C and $p(H_2)=0.7$ bar.

desorption pressures, and temperature are recorded. During heating and cooling the magnetic and phase transitions are delineated. The rapid decrease in resistivity after the introduction of hydrogen at elevated temperatures corresponds to the disproportionation process and can be attributed mainly to the formation of free iron. Another contribution arises from the formation of the Nd-hydride. On evacuating the system, the $NdH_{2\pm x}$ phase desorbs and the sudden decrease in resistivity can be attributed to the dissociation of Nd-hydride into Nd which subsequently recombines with the other constituents resulting in an increase in resistivity.

Figure 1 shows the isothermal part of the electrical resistivity versus time, which delineates the S-HDDR process at $T=800$ °C and $p(H_2)=0.7$ bar for the $Nd_{16}Fe_{76}B_8$ as-cast and the stoichiometric $Nd_2Fe_{14}B$ alloy. It can be seen that the disproportionation and recombination reaction rates are higher for the $Nd_{16}Fe_{76}B_8$ alloy. Shortly after the introduction of hydrogen a small maximum (see inset in Fig. 1) in the resistivity curve of the $Nd_{16}Fe_{76}B_8$ alloy can be observed, and this can be related to the rapid hydrogenation of the Nd-rich grain boundary resulting in the formation of $NdH_{2\pm x}$. Further studies, which will be published elsewhere, have shown that the hydrogenation of the grain boundary phase results in the solidification of this phase, which has its melting point at $T=650$ °C.[8] For the stoichiometric alloy no such maximum is observed, consistent with the absence of the Nd-rich grain boundary phase in this alloy. Microstructural characterization[6] has shown that the material is fully disproportionated when a constant, equilibrium resistivity is attained and the same applies for the recombination reaction. The resistivity data indicate that the $Nd_{16}Fe_{76}B_8$ alloy is fully disproportionated after 19 ± 2 min of exposure to hydrogen at $p(H_2)=0.7$ bar and fully recombined after 20 ± 2 min of desorption at $T=800$ °C. The corresponding times for the stoichiometric $Nd_2Fe_{14}B$ alloy are 29 ± 2 and 71 ± 2 min, respectively (for identical sample thicknesses of $t=0.8$ mm). Thus, both reactions are much slower for the stoichiometric alloy. These changes in resistivity correspond to the hydrogen absorption and desorption pressure behaviors shown in Fig. 2. The slightly smaller quantity of hydrogen absorbed in the stoichiometric $Nd_2Fe_{14}B$ alloy can be attributed to the absence of Nd-rich phase in this material.[10]

These studies could indicate that the N ...n grain boundary phase has a significant influence on the kinetics of the HDDR reactions. It was reported earlier[6] that the hydrogen diffuses either in the hydrided Nd-rich phase or at the interface between this phase and the matrix phase. It was shown[6] that the disproportionation reaction begins at the Nd-rich/$Nd_2Fe_{14}B$ boundaries and proceeds towards the center of the original grains. For the stoichiometric $Nd_2Fe_{14}B$ alloy no such fast transport paths exist, which could explain the lower reaction rates in this material. A reverse mechanism can be assumed for the desorption of hydrogen during the recombination reaction. However, it is interesting to note that, in particular, the latter process is much slower in the $Nd_2Fe_{14}B$ alloy, which could indicate that the Nd-rich grain boundary phase plays an additional role in the recombination process.

B. Onset of disproportionation and recombination in as-cast $Nd_{16}Fe_{76}B_8$

Figure 3 shows the electrical resistivity and the hydrogen desorption behavior of a disproportionated $NdH_{\sim2}$, α-Fe, Fe_2B mixture between $T=750$ and 1000 °C under an initial pressure of $p(H_2)=35$ mbar. The measurements revealed the Curie-point resistance anomaly of α-Fe at $T=770\pm5$ °C and

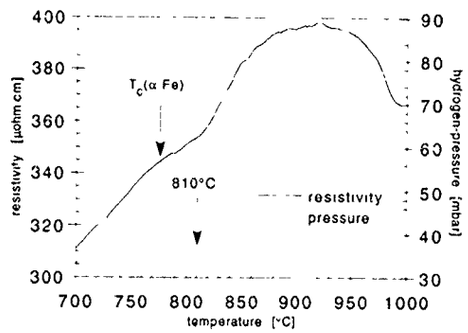

FIG. 3 Electrical resistivity and hydrogen desorption behavior between $T=750$ and 1000 °C under an initial pressure of $p(H_2)=35$ mbar of a disproportionated $NdH_{\sim2}$, α-Fe, Fe_2B mixture

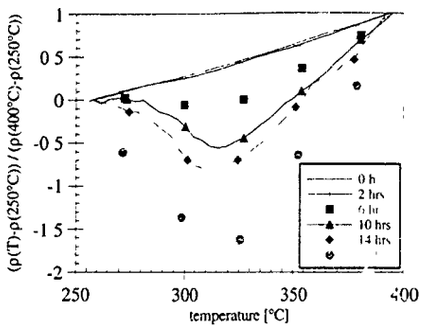

FIG. 4. Ratio of $[\rho(T)-\rho(250\,^{\circ}\mathrm{C})]/[\rho(400\,^{\circ}\mathrm{C})-\rho(250\,^{\circ}\mathrm{C})]$ vs temperature monitoring the development of the Curie point of an as-cast $Nd_{16}Fe_{76}B_8$ alloy for different stages of recombination at $T=620\,^{\circ}\mathrm{C}$.

a major desorption at $T=810\pm5\,^{\circ}\mathrm{C}$ causing another change in slope in the resistivity curve. This event can be interpreted as recombination under a hydrogen atmosphere. It was observed that, the higher the pressure, the higher the temperature for the desorption event. The pressure changes at higher temperatures can be attributed to the desorption of the Nd-rich grain boundary phase (to be published) and this corresponds with a fall in the resistivity.

Starting from a recombined material, the hydrogen pressure was increased step by step and the "equilibrium" resistivity was measured at different isotherms. It was found that, at $T=880\,^{\circ}\mathrm{C}$, for example, the 2-14-1-hydride shows a Sieverts'-type behavior before the sharp onset of the disproportionation reaction at $p(H_2)=0.46$ bar. These studies indicate that the start of the disproportionation and recombination reactions depend critically on the stability of NdH_2, which is determined by hydrogen pressure and processing temperature. A hysteresis effect[11] for the NdH_2 was found as the data for the onset of disproportionation and recombination were derived from absorption and desorption isotherms, respectively. These results are in agreement with work by Takeshita and Nakayama,[12] who reported, on the basis of x-ray diffraction measurements, that the disproportionated mixture will recombine above 1000 °C under a hydrogen pressure of 1 bar.

C. Low-temperature recombination in as-cast $Nd_{16}Fe_{76}B_8$

At conventional HDDR-processing temperatures (750–850 °C) it can be assumed that the Nd-rich grain boundary phase will remelt after the hydrogen is fully desorbed, whereas at $T=620\,^{\circ}\mathrm{C}$ the microstructural changes will occur in a solid-solid reaction as the Nd-rich grain boundary phase remains in the solid, hydrided state. Figure 4 shows the development of the Curie-point anomaly by evaluating the resistivity data during the heating stage of the cycling procedure described in part II. The ratio $[\rho(T)-\rho(250\,^{\circ}\mathrm{C})]/[\rho(400\,^{\circ}\mathrm{C})-\rho(250\,^{\circ}\mathrm{C})]$ is plotted over the temperature range of $T=250$–$400\,^{\circ}\mathrm{C}$. At $T=620\,^{\circ}\mathrm{C}$, the different stages during recombination can be monitored and the amount of reformed $Nd_2Fe_{14}B$ matrix phase can be estimated, because the observed changes are due entirely to transformations in the matrix phase. After 18 h at $T=620\,^{\circ}\mathrm{C}$, no further changes occur and therefore it can be assumed that the material is fully recombined. The pattern in the overall resistivity behavior is similar to that of a stoichiometric alloy at $T=800\,^{\circ}\mathrm{C}$. The development of the magnetic properties and the microstructural changes during the different stages of recombination will be reported elsewhere.[13]

IV. CONCLUSIONS

The fundamental differences in HDDR-reaction kinetics and mechanisms between a $Nd_{16}Fe_{76}B_8$ as-cast and a homogenized stoichiometric $Nd_2Fe_{14}B$ alloy at $T=800\,^{\circ}\mathrm{C}$ and $p(H_2)=0.7$ bar have been characterized by means of *in situ* electrical resistivity measurements and hydrogen sorption studies on nondecrepitated samples. The absence of the Nd-rich grain boundary phase in the stoichiometric alloy causes the disproportionation and recombination rates to be significantly lower. The Nd-rich phase not only acts as a transport path for the hydrogen, but effects in particular the desorption/recombination reaction. The onset of the disproportionation and recombination reactions under hydrogen atmosphere in a temperature range of $T=780$–$880\,^{\circ}\mathrm{C}$ depend critically on the hydrogen pressure. Desorption at $T=620\,^{\circ}\mathrm{C}$ revealed the different stages during re-formation of the $Nd_2Fe_{14}B$ matrix phase. At this temperature the recombination process is a solid-solid reaction.

Study of desorbed hydrogen-decrepitated anisotropic Nd-Fe-B powder using x-ray diffraction

G. P. Meisner
Physics Department, GM NAO Research and Development Center, Warren, Michigan 48090-9055

V. Panchanathan
GM Magnequench, Anderson, Indiana 46013

The intrinsic magnetic coercivity (H_{ci}) of Nd-Fe-B-based permanent magnet material is profoundly affected by hydrogen absorbed during the hydrogen decrepitation (HD) process for producing anisotropic powders from bulk anisotropic hot-deformed MAGNEQUENCH (MQ) magnets. Hydrogen (H) content and x-ray diffraction measurements clarify the effects of H and desorption temperature (T_d) on the intrinsic magnetic anisotropy (IMA) of the $Nd_2Fe_{14}B$-type phase and the nature of the intergranular phases, both of which are crucial for high H_{ci}. The Nd-rich intergranular phase disproportionates during HD, initially forming a microcrystalline Nd-hydride phase, possibly Nd_2H_5. For $T_d \leq 220$ °C, H remains in the $Nd_2Fe_{14}B$-type phase, severely degrading the IMA, which causes a low H_{ci}. For 220 °C$\leq T_d \leq$250 °C, enough H desorbs from the $Nd_2Fe_{14}B$-type phase and the IMA recovers its large prehydrided value, and the microstructure supports a high $H_{ci} \leq 10$ kOe in spite of the H disproportionated intergranular phase. Only for $T_d > 250$ °C is H_{ci} degraded by the microstructure, corresponding to further H desorption and the microcrystalline Nd-hydride phase becoming well-crystallized NdH_2. The NdH_2 phase decomposes with continued H desorption and at $T_d > 580$ °C recombines to re-form the Nd-rich intergranular phase of prehydrided MQ material. H is completely desorbed above 580 °C and $H_{ci} > 11$ kOe, nearly that of the prehydrided MQ magnets.

Anisotropic permanent magnet powder is of considerable importance in high performance bonded magnet production. The $Nd_2Fe_{14}B$-type phase[1,2] of Nd-Fe-B-based magnets has a very large intrinsic magnetic anisotropy[3] (IMA) that orients the magnetic moments uniaxially in the tetragonal lattice, and such magnets potentially have a very large bulk magnetic anisotropy. Melt-spun Nd-Fe-B ribbons are easily crushed into powder and used in bonded magnets directly but are nearly isotropic, consisting of randomly oriented crystallites.[4,5] Hot-pressing ribbons followed by hot-deformation results in substantial crystallite alignment[6,7] without degrading the high intrinsic magnetic coercivity (H_{ci}), yielding highly anisotropic permanent magnets. Fabrication of hot-deformed magnets with specific shapes and alignment directions while achieving grain alignment throughout, however, is difficult. Powders produced from hot-deformed Nd-Fe-B-based magnets remain anisotropic, and bonded magnets using such powder can be made highly anisotropic by aligning the powder grains in an applied magnetic field during the bonding process.[8–15]

Powders of Nd-Fe-B-based material can be mechanically ground,[8–11] a difficult process[15] that degrades H_{ci} of the smallest powder grains,[12] and the magnetic properties of the powder are not consistent from lot to lot.[16] An alternate method is hydrogen decrepitation (HD)[13–15] where hydrogen (H) absorbing interstitially in the $Nd_2Fe_{14}B$-type phase causes spontaneous pulverization. Incorporation of H into the $Nd_2Fe_{14}B$-type lattice, however, dramatically reduces the IMA[17] which in turn greatly degrades H_{ci}. Desorption of H after HD is therefore necessary to recover high performance magnetic properties. In previous work,[18] we studied H desorption and magnetic properties of HD hot-deformed Nd-Fe-B-based (MQ3) magnets. In this paper we present chemical analysis and x-ray diffraction measurements on HD MQ3 anisotropic powders as a function of desorption temperature (T_d).

The Nd-Fe-B-based material for this study was H-containing powder of HD[19] MQ3-E alloy.[20] Direct chemical analysis[21] yielded the H content in HD MQ3 powder as a function of T_d. These results along with the curve for H_{ci},[18] are shown in Fig. 1 where four T_d regions are quite apparent. X-ray diffraction spectra,[22] Fig. 2, correspond to the $Nd_2Fe_{14}B$-type major phase plus a few diffraction peaks from minor phases. For $T_d \leq 240$ °C, Figs. 2(a)–2(c), the peaks for the $Nd_2Fe_{14}B$-type phase are slightly broadened and shifted to lower angles. The shift is considerably less than for the fully hydrided state, Fig. 3(a), but quite evident from the position of the (301) peak. A small amount of H evidently remains in the $Nd_2Fe_{14}B$-type phase until $T_d \cong 240$ °C.

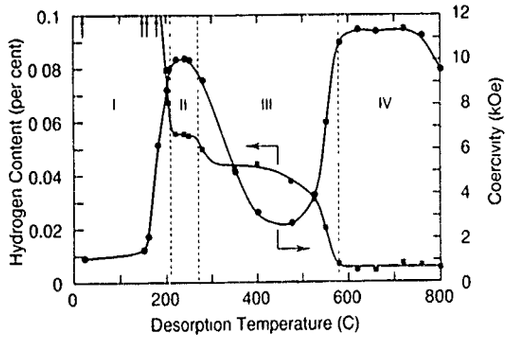

FIG. 1 Hydrogen content and magnetic coercivity H_{ci} vs desorption temperature T_d for HD MQ3 powder Vertical dashed lines delineate four regions of desorption temperature, vertical arrows indicate H contents greater than 0 1 wt %, and solid lines are guides for the eye

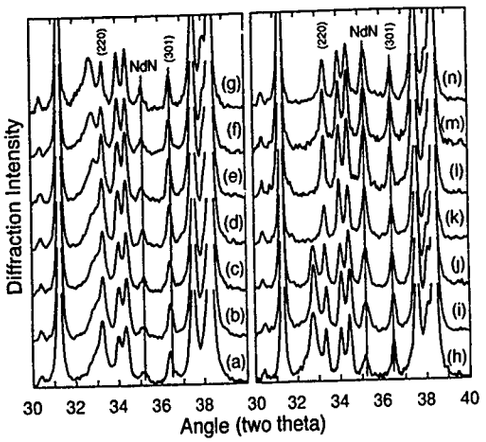

FIG. 2. X-ray diffraction spectra for HD MQ3 powders desorbed at (a) 200 °C, (b) 220 °C, (c) 240 °C, (d) 250 °C, (e) 280 °C, (f) 350 °C, (g) 400 °C, (h) 475 °C, (i) 520 °C, (j) 550 °C, (k) 580 °C, (l) 620 °C, (m) 660 °C, and (n) 720 °C. The vertical line at 36.55° indicates the (301) peak of the $Nd_2Fe_{14}B$-type phase and at 35.2° indicates the (111) peak of NdN.

The minor phase peaks are obvious from a comparison of the observed spectra, Fig. 2, with a calculation for unhydrided $Nd_2Fe_{14}B$, Fig. 3(b). The peak near 35.2°, which increases in intensity monotonically with T_d, is the (111) peak of NdN due to a small amount of nitrogen contamination, and this has been observed previously in heat-treated Nd-Fe-B-based materials.[23] Another minor phase peak occurs near 32.8°. In the fully hydrided material, Fig. 3(a), the (220) peak of the $Nd_2Fe_{14}B$-type phase shifts from ~33.3° to ~33.0° and obscures this minor phase peak. In the desorbed samples, the 32.8° peak is a broad shoulder and has low intensity at low T_d values, Figs. 2(a)–2(d). It becomes a true peak at 280 °C, Fig. 2(e), grows in intensity and sharpens, Figs. 2(f)–2(j), until 580 °C where it disappears, Figs. 2(k)–2(n). This dependence on T_d of the intensity and shape of this mino. phase peak at 32.8° correlates very well with H content and H_{ci}, Fig. 1. This minor phase peak corresponds to a binary Nd-hydride phase and is evidence that H disproportionation during HD occurs for some part of the sample.

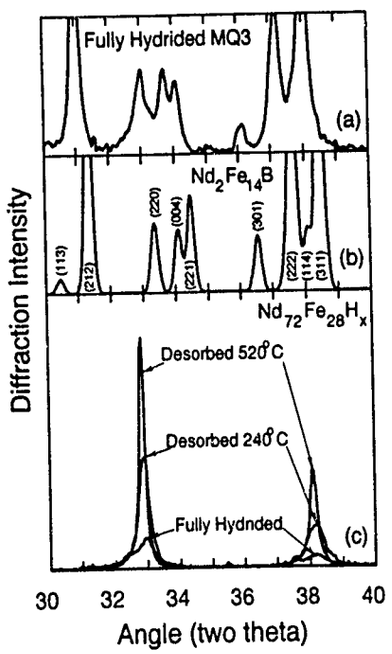

FIG 3. X-ray diffraction spectra for (a) fully hydrided HD MQ3 powder (not desorbed), (b) the $Nd_2Fe_{14}B$-type phase (calculation) where (hkl)'s are the Miller indices of the diffraction peaks, and (c) H disproportionated $Nd_{72}Fe_{28}$ fully hydrided, desorbed at 240 °C, and desorbed at 520 °C

A Nd-rich alloy approximating the intergranular phase in MQ materials, $Nd_{72}Fe_{28}$, was induction melted and then hydrided.[24] The spectra for this alloy after hydriding and after desorbing at 240 and 520 °C consist of Nd-hydride and iron peaks, confirming H disproportionation of this alloy. The Nd-hydride peaks for the fully hydrided $Nd_{72}Fe_{28}$ phase are broad and have low intensity, but as H is removed at higher T_d, the peaks increase in intensity and move slightly to lower diffraction angles, Fig. 3(c). Although the Nd-hydride peaks increase their intensity by a factor of ~7.5 compared to the fully hydrided state, the iron peak (not shown) remains at a very low intensity, approximately that of the peak at ~38.1° for fully hydrided $Nd_{72}Fe_{28}H_x$. H disproportionation of the $Nd_2Fe_{14}B$-type phase, however, results in a very high intensity iron peak.[23] Because iron peaks are not observed in the spectra for any of the desorbed samples, we conclude the Nd-hydride phase in HD MQ3 desorbed powder is a disproportionation product of the Nd-rich intergranular phase and not of the $Nd_2Fe_{14}B$-type phase.

The coercivity of H_{ci} of MQ3 materials arises from both the large IMA of the $Nd_2Fe_{14}B$-type phase that provides rigidity to the underlying magnetism, and a suitable microstructure involving grain boundaries and intergranular phases that provide effective pinning sites for magnetic domain walls.[25] The independent effects of H on these two conditions for large H_{ci} cause the dramatic H_{ci} behavior of HD MQ3 powder as a function of T_d shown in Fig. 1. In the HD process[19] the $Nd_2Fe_{14}B$-type phase and the Nd-rich intergranular phase absorb a considerable amount of H. The H content can be estimated from the total rare-earth (RE) content[20] to be 0.43 wt % for a molar concentration RE:H =1:2 (i.e., corresponding to $RE_2Fe_{14}BH_x$ with $x=4$). Conversely, with no H in the $Nd_2Fe_{14}B$-type phase and assuming that the intergranular phase disproportionates into REH_2, the H content estimated from the amount of RE exceeding $RE_2Fe_{14}B$ stoichiometry in the MQ3 alloy is 0.074 wt %. Thus, the measured H content of 0.055 wt %, region II of Fig. 1, is consistent with all the H desorbed from the $Nd_2Fe_{14}B$-type phase and the residual H only in the intergranular phase. The profound degrading effect of H on H_{ci} via the IMA of the $Nd_2Fe_{14}B$-type phase is therefore limited to low T_c, region I, and this result agrees with our previous conclusions based on first quadrant magnetization data for these materials.[26]

The nature of the hydrided intergranular phase also has a profound effect on H_{ci}. The intergranular phase H disproportionates during HD and only degrades H_{ci} slightly for $T_d<280$ °C, regions I and II. The low H_{ci} in region I is due only to the low IMA of the hydrided $Nd_2Fe_{14}B$-type phase.

The microstructural contribution to H_{ci}, i.e., strong domain wall pinning, remains suitable for high H_{ci} although different from that of prehydrided MQ3 magnets. Once the IMA of the $Nd_2Fe_{14}B$-type phase has recovered its large value, region II, H_{ci} regains a high value of $\geq$10 kOe. The value of $H_{ci} \geq 14$ kOe of the prehydrided MQ3 magnet is not quite achieved, however, implying that H disproportionated intergranular phase microstructure is less effective in domain wall pinning than the original MQ3 microstructure.

Because of the broad Nd-hydride peak at 32.8° in Figs. 2 and 3(c), it is possible that a H-induced amorphous-like phase exists in the intergranular areas below 280 °C, regions I and II, or a microcrystalline Nd_2H_5-type phase, which is a tetragonal superstructure of the face-centered-cubic NdH_2-type phase. Crystallization of the disproportionated intergranular phases occurs above 280 °C, region III, and corresponds to H_{ci} decreasing strongly, some of the residual H desorbing, and the shoulder in x-ray diffraction spectra at 32.8° in Fig. 2 shifting and sharpening into a well-defined peak. This behavior is also evident in the diffraction spectra of hydrided $Nd_{72}Fe_{28}$, Fig. 3(c), as H is desorbed. This result suggests a microcrystalline Nd_2H_5-type phase decomposes to a well-crystallized NdH_2-type phase, where the lattice constants of Nd_2H_5, $a=0.54322$ nm and $c/2=0.5454$ nm,[27] are slightly smaller than that of NdH_2, $a=0.54678$ nm.[28] Eventually, sufficient H desorbs at higher temperatures causing the NdH_2-type phase itself to decompose and react with the other disproportionated intergranular phases to recombine and form the a Nd-rich intergranular phase similar to that of the prehydrided MQ3 alloy. This accounts for the gradual recovery of H_{ci} above 475 °C, Fig. 1, and the correspondingly gradual decrease in H content. Some of the degradation of H_{ci} in region III occurs because of annealing effects on the microstructure. This has been observed for MQ3 materials annealed without H,[29–31] but H seems to cause a much greater degradation of H_{ci}.

Above 580 °C, region IV, NdH_2 diffraction peaks are absent, Fig. 2, H is completely desorbed, and H_{ci} is high, Fig. 1. Although H_{ci} is higher in region IV than region I, it does not return to the prehydrided value of $\geq$14 kOe. We conclude that H disproportionation desorption and recombination of the intergranular phase cause a nonrecoverable decrease in domain wall pinning strength of the intergranular phase relative to prehydrided MQ3 magnets. Also, the NdN contamination indicates a nonrecoverable decomposition of the Nd-rich intergranular phase has occurred and is presumably detrimental to H_{ci}. Finally, the drop in H_{ci} at 800 °C in region IV of Fig. 1 is undoubtedly due to the detrimental effects of annealing and grain growth on the microstructure of MQ3 material generally.

We thank Dr. Raja K. Mishra and Earl G. Brewer for useful discussions, Charles B. Murphy and Daniel J. Van Wingerden for technical assistance, and Dr. Jan F. Herbst and Dr. John J. Croat for much encouragement and support.

The electrochemical hydrogenation of NdFeB sintered alloys

Kuo En Chang and Garry W. Warren
Department of Metallurgical and Materials Engineering, The University of Alabama, P.O. Box 870202, Tuscaloosa, Alabama 35487

The absorption of hydrogen by NdFeB alloys in aqueous solution has been investigated using dc electrochemical methods and x-ray diffraction. Immersion of the NdFeB alloy in 0.1 M H_2SO_4 results in the formation of the $Nd_2Fe_{14}BH_{2.7}$ hydride phase as indicated by x-ray diffraction analysis. The hydrogen entering the NdFeB lattice is believed to result from the preferential acid dissolution or etching of the Nd-rich phase. The hydrogen absorption and desorption behavior of sintered NdFeB alloys, $(NdDy)_{15}Fe_{78.3}Al_{0.7}B_6$ and $(NdDy)_{15}Fe_{67}Co_5V_4Al_2B_7$, have been compared with that of a $LaNi_5$ alloy utilizing an electrochemical technique. $LaNi_5$ is capable of absorbing extremely high quantities of hydrogen as a metal hydride. The level of hydrogen absorbed by the three alloys was compared by "charging" electrodes of each alloy in 6 M KOH at a constant cathodic current, followed by a constant anodic "discharge" current. An arrest in the resulting potential versus time curve during discharge indicates the oxidation of the hydride, i.e., of absorbed hydrogen, formed during the cathodic charging process. Results indicate that both NdFeB alloys absorb hydrogen in aqueous solution. Similar experiments performed on a set of samples with varying total rare-earth (TRE) content showed that the amount of hydrogen absorbed is proportional to TRE content. Anodic potentiodynamic polarization after charging shows that the corrosion rate increases as the level of absorbed hydrogen increases.

I. INTRODUCTION

The magnetic properties of NdFeB and similar alloys are significantly affected by the hydrogen absorption of the $Nd_2Fe_{14}B$ phase.[1–3] Therefore an understanding of the hydrogen absorption behavior of NdFeB materials is important. Cast NdFeB alloy can absorb significant amounts of hydrogen relatively easily at room temperature even at hydrogen pressures as low as 1 bar.[4] The reactive nature of the NdFeB alloy with respect to hydrogen has also been attributed to the presence of the neodymium-rich phase at the grain boundaries, and the amount of hydrogen absorbed by the NdFeB alloys increases with rare-earth content.[5] It has also been suggested that the poor corrosion resistance of the sintered NdFeB alloys is due, at least in part, to the presence of the Nd-rich phase.[6,7] However, until now a correlation between hydrogen absorption and corrosion behavior of the sintered NdFeB alloys has not been demonstrated.

The preferential dissolution of the Nd-rich phase in the grain boundaries in acidic solutions, due to its lower electrochemical potential with respect to the $Nd_2Fe_{14}B$ phase,[7] results in the simultaneous evolution of hydrogen. Results presented in this work suggest that part of this hydrogen is absorbed by the $Nd_2Fe_{14}B$ matrix, producing a lattice expansion of the $Nd_2Fe_{14}B$ unit cell which can be measured by x-ray diffraction analysis.[8]

Hydrogen absorption of similar rare-earth materials, e.g., $LaNi_5$,[9,10] have been widely examined using an electrochemical charge/discharge technique. The method involves the application of a constant (galvanostatic) cathodic current resulting in hydrogen evolution, a portion of which forms a metal hydride. Stored hydrogen can then be removed by reversing the current flow. This reaction can be represented by the redox equation

$$M + xH_2O + xe^- = MH_x + xOH^-,$$

where x represents the number of hydrogen atoms absorbed by the alloy and MH_x is the hydride phase of the alloy. A plot of the potential versus time during discharge shows an arrest (a region of constant potential) characteristic of materials which absorb hydrogen and which represents the oxidation of the hydride. The charge passed during this arrest is a measure of the hydrogen absorbed.[9–12]

This technique has been used to examine the tendency of NdFeB alloys to absorb hydrogen from aqueous solution, to compare NdFeB with the known behavior of $LaNi_5$, and to examine its potential effect on the corrosion behavior of NdFeB. Results presented here show that the corrosion mechanism of NdFeB must involve hydrogen and that absorbed hydrogen has a detrimental effect on corrosion resistance.

II. EXPERIMENTAL MATERIALS AND TECHNIQUES

Four types of materials were utilized in this investigation, as follows: (1) $(NdDy)_{15}Fe_{78.3}Al_{0.7}B_6$, in both powder and sintered form, subsequently referred to as NdFeB alloy, (2) $(NdDy)_{15}Fe_{67}Co_5V_4Al_2B_7$ in both powder and sintered form, subsequently referred to as NdFeB-Co-V alloy, (3) cast $LaNi_5$, containing about 0.14 wt % of a catalyst, and (4) a set of four sintered NdFeB alloys, similar to those in (1), but with varying total rare-earth (TRE) content (29, 31, 33, and 37 wt %). All samples were supplied by Rhone Poulenc Basic Chemicals Co. A Rigaku D/Max-2BX x-ray diffractometer with Cu K_α radiation was used for structure determinations of NdFeB powders before and after etching in 0.1 M H_2SO_4. A Nikon optical microscope with image analysis system was used for microstructural observations. dc electrochemical techniques were performed using an EG&G model 273A potentiostat, and a three electrode glass cell. Working electrodes were prepared using samples of the sintered or cast materials described above. The reference electrode was

saturated calomel, and the counterelectrode was Pt. The 6 M KOH electrolyte was purged with nitrogen for at least 1 h prior to each experiment. The working electrode was polished to 600 grit, rinsed, dried, immersed in the electrolyte, and the open circuit or rest potential allowed to equilibrate for at least 1 h. Current densities were obtained by dividing measured current by the geometric cross-sectional area.

III. RESULTS

A. Hydrogen absorption from aqueous solution

Upon immersion of the NdFeB alloy powder (38–53 μm diameter) in 0.1 M sulfuric acid solution, gas evolution was observed to occur. After filtering, the powders were thoroughly rinsed with distilled water, and dried in a dessicator for 24 h. Dry powders were then pressed into pellets for x-ray diffraction analysis. Figure 1 shows x-ray diffraction data of NdFeB alloy powders after immersion in H_2SO_4 for 1 and 10 min. For comparison, patterns are also included for as-received powder and $Nd_2Fe_{14}B$. As can be seen, the patterns are similar but show a distinct shift toward smaller diffraction angles as etching time increases This shift reveals that the overall tetragonal structure of the NdFeB is retained but with measurably larger lattice parameters. Lattice constants were calculated from the x-ray data and are presented in Table I. Results indicate that the amount of hydrogen absorbed by the NdFeB powder increases in the first minute, rapidly achieving "saturation" and relatively constant a- and c-axis lattice parameters. The changes in total volume during the etching process for as-received and hydrided NdFeB alloys are in good agreement with those reported by Oesterreicher.[13] Based on these results the hydride phase formed after etching in 0.1 M H_2SO_4 is close to $Nd_2Fe_{14}BH_{2.7}$.

B. Electrochemical absorption/desorption of hydrogen

The relationship between the charge/discharge process for the sintered NdFeB and $LaNi_5$ alloys was compared using the galvanostatic charge/discharge technique. Samples were charged for 5 h at a constant cathodic current of −0.5 mA, immediately followed within 30 s by the application of a 0.5 mA constant anodic current until the sample was fully discharged as indicated by an increase in potential to about 0.45 V. Additional cycles were obtained by repeating the process. Experimental results for the first cycle of the NdFeB, NdFeB-Co-V, and $LaNi_5$ alloys are shown in Fig. 2. The lengthy arrest in potential of the $LaNi_5$ alloy at −1.0 V is characteristic of the discharge of stored hydrogen and is the basis for the proposed use of this material in metal hydride batteries.[14] By comparison, the NdFeB and NdFeB-Co-V alloys also show evidence of hydrogen absorption, though to a lesser degree than $LaNi_5$ in this measurement.

C. Effect of total rare-earth content

Since previous researchers have shown that hydrogen absorption increases with TRE[5] and have suggested a connection between TRE and corrosion resistance,[6] this effect has also been investigated. Results of the microstructural examination and image analysis of a set of samples with vary-

TABLE II. The volume fraction and the average grain size of the $Nd_2Fe_{14}B$ phase for sintered NdFeB alloys with varying TRE.

TRE (wt %)	TRE (at. %)	Vol. fraction of the $Nd_2Fe_{14}B$ phase	Avg of grain size of the $Nd_2Fe_{14}B$ phase
29 0	12 9	0.83	25 0±9.5 μm
31 0	14 0	0 79	19.5±5 8 μm
33.0	15 2	0.77	18 5±5 8 μm
37.0	17 5	0.73	15 8±4 8 μm

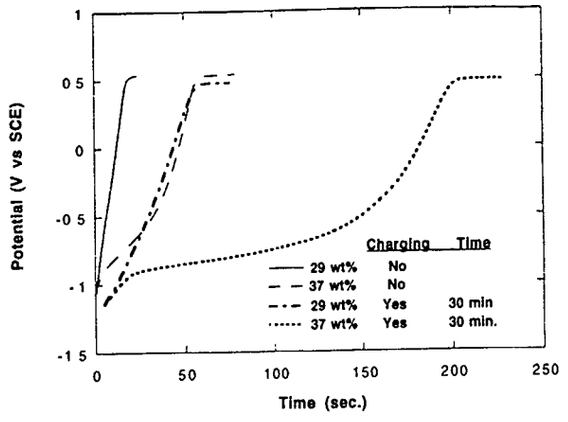

FIG. 3. Potential vs time for sintered NdFeB (29 and 37 wt % TRE) during anodic discharge (1 mA) in 6 M KOH with and without prior cathodic charging

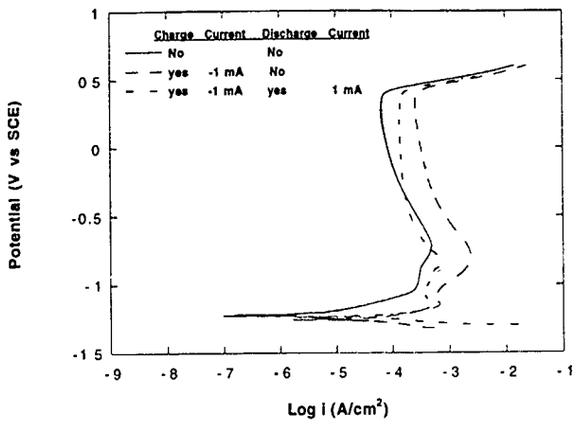

FIG. 4. Anodic polarization curves for sintered NdFeB (37 wt % TRE) in 6 M KOH; scan rate=2 mV/s.

ing TRE (29, 31, 33, and 37 wt %) after polishing to 0.05 μm and a 10 s etch in 10% nital are given in Table II. As expected, the volume fraction of the $Nd_2Fe_{14}B$ phase decreases with TRE, corresponding to an increase in the Nd-rich grain-boundary phase.[5] A slight decrease in grain size of the $Nd_2Fe_{14}B$ matrix with increasing TRE was also observed.

These samples were also subjected to a charge/discharge process. Charging was accomplished with a cathodic current of -1.0 mA for 30 min, followed by discharging with an anodic current of 1.0 mA. The potential during discharge was measured and results are shown in Fig. 3 for sintered NdFeB alloys with 29 and 37 wt % TRE, respectively. For comparison data are also shown for the same samples but without prior cathodic charging. Interestingly, the samples without cathodic charging show some evidence of a discharge process, which likely indicates the presence of a small amount of absorbed hydrogen even in the as-received state. Figure 3 also shows a clear increase in hydrogen absorption with increasing TRE. Over the range of TRE contents examined, the increase in hydrogen absorbed is roughly linear with TRE.

D. Effect of hydride formation on anodic polarization

Anodic potentiodynamic polarization curves were also measured for the four alloys with varying TRE before and immediately after the charge/discharge process. Results for the 37 wt % TRE alloy are shown in Fig. 4; behavior of the other samples was generally the same. Three curves are shown in Fig. 4: (1) as-received, without charging or discharging, (2) with charging only but without anodic discharging, and (3) with charging and discharging. As can be seen, after a complete charge/discharge cycle the observed current at low applied potentials is significantly higher than that of the as-received sample. This suggests that the corrosion resistance of the sintered NdFeB alloys is degraded upon absorbing and desorbing hydrogen.

IV. CONCLUSIONS

(1) The $(NdDy)_{15}Fe_{78.3}Al_{0.7}B_6$ powder has been shown to absorb hydrogen upon exposure to 0.1 M H_2SO_4. Based on the change in lattice constants the level of hydrogen absorbed corresponds fairly closely to an overall composition of $Nd_2Fe_{14}BH_{2.7}$.

(2) This study clearly shows that the sintered NdFeB and NdFeB-Co-V alloys both absorb hydrogen during the application of a cathodic current. Furthermore, these results suggest that the amount of hydrogen absorbed increases with increasing TRE as has been suggested by Scholz.[5]

(3) A comparison of anodic potentiodynamic polarization on samples before charging, after charging, and after complete discharging shows that the corrosion resistance of the sintered NdFeB alloys is degraded upon absorbing and desorbing hydrogen.

For sintered permanent magnets based on $Nd_2Fe_{14}B$ having magnetically oriented crystallites, a simple method of measuring the degree of alignment by x-ray diffraction is described, using the inverse pole figure technique. The results are related to a distribution function for the easy axis which is a direct measure of remanence. The fraction of the ideal [001] texture component in both Nd-Fe-B and Nd,Dy-Fe,Co-B magnets is enhanced by doping with oxygen, resulting in a measurable increase in remanence and improved loop squareness. The observed increase of the intrinsic coercivity ${}_iH_c$ with better crystallite orientation is also discussed.

I. INTRODUCTION

The remanence in sintered permanent magnets based on the phase $Nd_2Fe_{14}B$ is maximized by aligning the powdered particles of the magnet alloy in a magnetic field before pressing. While this results in a large fraction of crystallites with the easy axis in or near the field direction, the orientation is never perfect. The purpose of this study is twofold: (i) to describe a simple method of measuring the degree of alignment and relate it to the remanence and (ii) to report a method of enhancing the fraction of the ideal [001] texture component by doping with oxygen. In particular, it will be shown what improvement in the remanence can be expected when the easy axis lies within a cone described by an orientation distribution of a given angular width. The effect of orientation on the intrinsic coercivity ${}_iH_c$ will also be discussed.

II. TEXTURE

The methods of quantitatively assessing the crystal orientation in a sintered magnet are essentially twofold: (i) The intensity of an x-ray reflection corresponding to the easy axis, i.e., $(00l)$ for Nd-Fe-B magnets, is measured directly as the magnet axis is tilted out of the reference orientation, the normal to the magnet surface. The angle at which the intensity drops to 1/2 is a measure of the textural quality. A way of doing this by using a pole figure device for full orientation has been described by Chang *et al.*[1] A simpler modification of this technique utilizes the decoupled θ scan for an $(00l)$ reflection and describes a line through a pole figure which is assumed to be that of a fiber texture.[2] Again, the width of tilt at half maximum is a measure of texture. (ii) A specimen with the reflecting surface normal to the magnet axis is subjected to a standard Bragg 2θ scan. In an anisotropic magnet only reflections with low (h,k) and high (l), including $(00l)$, are observed. Then the orientation is derived from the known angles between the observed (hkl) and $(00l)$, or their poles, and the orientation distribution is derived by comparing their intensities to the corresponding intensities in a specimen with random orientation of the crystallites. Meisner and Brewer[3] have performed a more sophisticated analysis in which two reference directions are used. They have also shown that calculated powder intensities are in good agreement with those measured on a random powder sample of Nd-Fe-B, and our analysis will use the former. This method has been described by Tenaud *et al.*[4] and used by Kawai *et al.*[5] in connection with axial to conical spin reorientation in Nd-Fe-B. The technique has been known to metallurgists for some time as the "inverse pole figure" method.[6,7] It uses a single reference direction (the axis of the anisotropic magnet), which is assumed to be the direction of the scattering vector. In the present study, the fraction of $(00l)$ in a direction tilted by a given angle from the scattering vector is determined from the set of available (hkl) and is used to determine the cause of remanence enhancement resulting from the addition of oxygen under otherwise equal experimental conditions. It should be pointed out that the texture difference between specimens observed here can be seen by visual inspection of a pair of diffraction patterns. The goal is to make this observation more quantitative and, specifically, to determine whether the improvement in remanence can be accounted for by the sharpening of the texture. As for the distribution function used in Sec. IV, it has not been suggested previously but has the advantage of mathematical simplicity.

III. EXPERIMENT

Sintered magnets were prepared with two compositions, in wt %, 30.5Nd, 2.5Dy, 63.4Fe, 2.5Co, 1.1B (in at. % 14.0Nd, 1.0Dy, 75.4Fe, 2.8Co, 6.8B) referred to as A and B and 32.5Nd, 66.4Fe, 1.1B (14.9Nd, 78.4Nd, 6.7B), specimens C and D. Of each composition one batch (A and C) was prepared by conventional methods, employing rigid tool compaction of the powder, and another batch (B and D) was subjected to additional oxygen pickup during powder processing prior to pressing. The final oxygen analyses of the magnets (in wt %) were: A (0.22), B (0.50), C (0.24), D (0.41). The method of adding oxygen was apparently not critical to its effect on grain orientation and it could be introduced during jet milling or following milling. The hysteresis loops were measured on a hysteresisgraph, independently at both laboratories. The x-ray diffraction patterns

were taken on a standard diffractometer (Cu $K\alpha$ radiation). The specimen surface that was perpendicular to the magnet axis was placed in the Bragg reflecting orientation to provide a measure of the deviation from the ideal grain orientation. No useful intensities are obtained unless the samples are metallographically polished to remove the surface layer disturbed by grinding (it is known that the 2-14-1 phase can undergo plastic deformation[8]). The intensities of the six prominent reflections were normalized to calculated intensities for a random orientation of the crystallites following the procedure for obtaining inverse pole figures.[6,7]

IV. ORIENTATION AND REMANENCE

If the magnet were a single crystal, or had an ideal grain orientation with the easy axis normal to the surface, the diffraction pattern would show only reflections $(00l)$ with even values of l, namely (004) and (006) in the range investigated (Bragg $2\theta\leqslant 50°$). Because of the imperfect orientation, additional reflections having low (h,k) and high l are observed and permit the assessment of the preferred orientation. In a cylindrical magnet the crystal orientation represents a fiber texture with the magnet axis as the fiber axis. For a given (hkl) the corresponding tetragonal c axis (001) lies on a cone with half-angle θ, where θ is now the colatitude in spherical polar coordinates. Therefore the observation of reflections having high l that are aligned with the magnet axis contain information on the distribution of the (001) poles. This is necessarily so because in the tetragonal system there exists one and only one off-axis (001) pole for every pole (hkl) that is in line with the magnet axis.

The distribution of (001) poles can be modeled to describe the impact of misorientation on the remanence. In the range $0\leqslant\theta\leqslant\pi/2$, let this distribution be $f(\theta)$. Then the number of poles in a ring of width $d\theta$ on the surface of a unit sphere is $2\pi f(\theta)\sin\theta d\theta$. The contribution of these poles to the magnetization in the direction of the magnet axis is obtained by multiplying with $\cos\theta$. It follows directly that the ratio of remanence to saturation polarization for an assumed square hysteresis loop must be

$$\frac{\int_0^{\pi/2} f(\theta)\sin\theta\cos\theta d\theta}{\int_0^{\pi/2} f(\theta)\sin\theta d\theta},$$

where the denominator serves to normalize the expression to a constant total number of poles in the hemisphere. A useful distribution function is $\cos^m\theta$ because for it the integrals have simple solutions so that the ratio J_r/J_s takes on the form $(m+1)/(m+2)$. It is immediately obvious that for $m=0$, $J_r/J_s=1/2$ (familiar result for random orientation) and for $m\to\infty$, $J_r/J_s=1$ (delta function, perfect orientation). Table I gives some examples of J_r/J_s for various orientation distributions $f(\theta)$ characterized by the cone angle at half maximum $(f=1/2)$. It shows the improvement in remanence that can be expected from sharpening the orientation. For example, when the cone angle is decreased from 18° to 9.5°, J_r/J_s increases by 4.6%. A corresponding set of plots of $f(\theta)=\cos^m\theta$ is shown in Fig. 1; the significance of the data points is discussed in the next section.

TABLE II Observed reflections with low (h,k) and high l showing (i) calculated intensities for a random orientation, normalized to $I/I_0=100$ for the strongest reflection (140), (ii) angles between (hkl) and (001) poles, and (iii) experimental intensities treated as inverse pole figure data

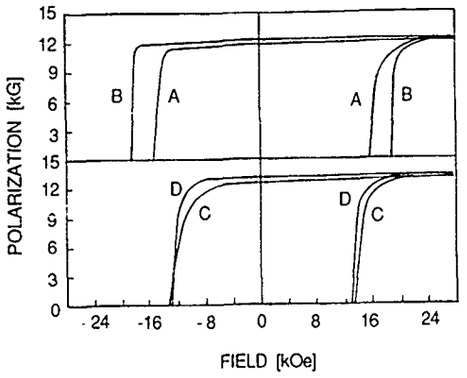

FIG. 2 Hysteresis loops of undoped (A and C) and oxygen-doped (B and D) sintered magnets.

V. EXPERIMENTAL RESULTS

The intensities as processed for an inverse pole figure are proportional to the volume fraction of grains with (hkl) poles in the direction of the magnet axis and, conversely, to the volume fraction of (001) poles in a direction tilted away from the axis by θ. Therefore they can be plotted directly over the distributions of Fig. 1. Table II shows the angle θ by which the easy axis [001] is tilted against the magnet axis for a given (hkl). It is derived from $tg^2\theta=(c/a)^2(h^2+k^2)/l^2$, and obviously the higher the (h,k) and the lower the l, the larger θ will be. Table II also contains information on the four test specimens A, B, C, D: calculated intensities for a powder pattern[9] with a random orientation of the crystallites and inverse pole figure intensities normalized by setting a weighted average intensity of (004) and (006) equal to 1. The reduction in the non-$(00l)$ reflections by going from A to B and from C to D is evident. It is also seen that the particle alignment in the Co-, Dy-containing magnets A and B is superior to that in the simpler ternaries. The reduced intensities in Table II represent a distribution for which the data points are plotted in Fig. 1. It is obvious from Fig. 1 that the experimental data show considerable scatter and do not follow the $\cos^m\theta$ distribution closely (nor do they fit a Gaussian distribution function) but tend to have steeper flanks. Nevertheless, the trend is clear: untreated specimens A and C have a broader orientation distribution than the corresponding oxygen-treated specimens B and D. Fitting the data to the curves allows a rough estimate of the expected improvement in remanence A→B and C→D, namely, 3.6% and 3.9%, respectively. The corresponding experimental increments are 4.2% and 4.7%. Supporting magnetization curves are shown in Fig. 2. The improvement in loop squareness in the oxygen-doped magnets B and D is evident.

VI. COERCIVITY

The coercivity is also affected by the oxygen treatment that causes the sharpening of the orientation. In the Co-, Dy-containing specimens A and B, one sees a concomitant increase in ${}_iH_c$ that is intuitively plausible from the orientation effect in the Stoner–Wohlfarth theory for a single-domain particle. The detailed model of Schrefl *et al.*[10] describing the reduction of the nucleation field for reversed domains at the grain boundaries of $Nd_2Fe_{14}B$ also predicts this orientation effect for coercivity. The crossing of the magnetization curves C and D in Fig. 2 is contrary to this behavior so that the curve with the higher remanence and the better alignment now has the lower intrinsic coercivity. Unlike the pair A and B, magnets C and D apparently have an orientation dependence of the critical field for magnetization reversal that does not decrease with the loss of alignment. It has to be conceded that the influence of oxygen on coercivity may well be a more complex one and simply results from changes in the "grain boundary phase," which is known to be fcc rather than hexagonal in many magnets, an effect that has long been attributed to the oxygen impurity, see e.g., Yang *et al.*[11]

VII. CONCLUSIONS

It has been shown that by using a simple powder diffractometer technique, information on grain alignment in sintered magnets can be obtained without resorting to a full pole figure determination. The trend of permanent magnet properties found in the Co-, Dy-containing magnets is already present in Stoner–Wohlfarth theory for single-domain particles. For it the remanence goes with $J_s\cos\theta$, and both remanence and coercivity decrease together when the orientation deviates from $\theta=0$. Therefore it is plausible that the remanence enhancement resulting from the oxygen treatment is an orientation effect, and the x-ray diffraction data support this interpretation. To what should the observed ability of the oxygen-treated magnets to show improved orientation be attributed? This can only be speculated, but it appears to be based on the ability of the powder particles to better maintain their magnetic orientation in the pressing operation. This might be loosely described as a reduction in friction between the particles that results from the oxygen treatment of the powder. It is remarkable that the ability of the powders to retain their orientation during pressing is so sensitive to alloy chemistry, as seen not only in the effect of oxygen doping but also in the difference between the alloys containing Co and Dy and the simpler ternary alloys.

The singular point detection (SPD) technique as well as a least-mean-square procedure of fitting trial texture functions to demagnetization curves (DMC) were applied in order to determine the orientation density of the tetragonal axes of the $Nd_2Fe_{14}B$ crystallites in sintered Nd-Fe-B magnets with different degrees of grain alignment. Both methods are less complicated than calculating the texture function from x-ray-diffraction data. The orientation densities obtained by both methods agree fairly. Analytically, they can be described as a Gaussian or a sum of cosine-power functions of the angle between the local tetragonal axis and the texture axis. This agreement is a test for the DMC method which can also be used for materials showing much larger anisotropy fields than the maximum available measuring field. The SPD and DMC methods can also be applied to measure the temperature dependence of the anisotropy field H_A of the magnetic main phase in noncompletely textured polycrystalline materials. By means of the DMC method additionally the spontaneous polarization J_s as well as the anisotropy constants K_1 and K_2 can be determined. As expected, the values of H_A of our sintered Nd-Fe-B samples, measured up to 140 °C, are nearly independent of the degree of texture and are in agreement with those reported in literature. This confirms that SPD as well as DMC can be used to measure intrinsic magnetic properties for materials which can hardly be prepared as single crystals, such as interstitial compounds made by gas–solid reactions.

I. INTRODUCTION

In typical modern permanent magnet materials such as sintered Nd-Fe-B the magnetic main phase is crystallographically uniaxial and the crystal c axis is a magnetically easy one. The orientation density of the easy axis is rotationally symmetric in a good approximation and can be described by a texture function $f(\alpha)$, normalized by

$$\int_0^{\pi/2} d\alpha \sin\alpha\, f(\alpha)=1, \tag{1}$$

where α is the angle between the local easy axis and the texture axis.[1] The classical procedure to calculate $f(\alpha)$ from an adequate set of x-ray-diffraction data[2] is expensive. Alternative methods, based on magnetic measurements, have been reported.[1,3,4] The angular dependence of remanence induction B_r can be used, as described in Ref. 1, if B_r is controlled by rotational demagnetization processes only. Unfortunately, the remanence of nucleation controlled materials such as sintered Nd-Fe-B or Zn-bonded $Sm_2Fe_{17}N_3$ is affected by the presence of domains in the grains of the sample surface. This difficulty is avoided by the singular point detection (SPD) technique[5] which was applied to texture analysis in Ref. 3. In fact, by this method one detects a sharp peak in the second derivative d^2J/dH^2 of the polarization J versus the applied magnetic field H, exactly located at the anisotropy field H_A. The amplitude of the peak is proportional to the volume fraction of crystallites oriented with their easy axes perpendicular to H. In Ref. 4 the width σ_g of a Gaussian density,

$$f(\alpha)\sim\exp(-\alpha^2/2\sigma_g^2), \quad 0\leq\sigma_g<\infty \tag{2}$$

was fitted to major demagnetization curves in the first quadrant of the J-H plane, where H is the applied field corrected for demagnetization effects. Additionally, this fitting procedure yields the anisotropy constants K_1, K_2 and the spontaneous polarization J_s (if the volume fraction of the main phase is known) and works even for measuring fields H considerably smaller than $H_A=(2K_1+4K_2)/J_s$. It was successfully applied to bonded $Sm_2Fe_{17}N_x$[4,6] and sintered Nd-Fe-B.[7]

Fitting parameters such as σ_g from Eq. (2) are texture parameters summarizing the information included in $f(\alpha)$.

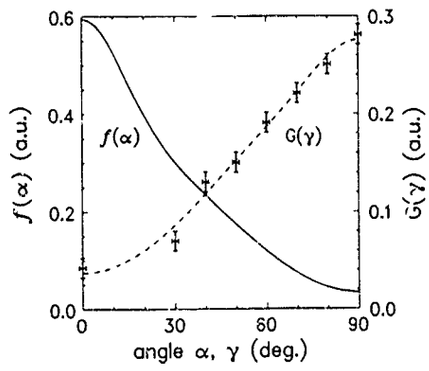

FIG. 1. SPD peak amplitude $G(\gamma)$ of the sintered $Nd_{16}Fe_{78}B_6$ sample A2 and its fitted texture function $f(\alpha)=0.034+0.34\cos^2\alpha+0.22\cos^{20}\alpha$

 0021-8979/94/76(10)/6268/3/$6.00 © 1994 American Institute of Physics

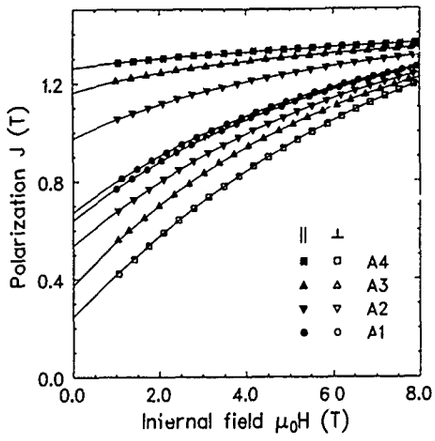

FIG. 2. Demagnetization curves of the sintered $Nd_{16}Fe_{78}B_6$ samples A1–A4 with different degrees of texture, measured at $T=20$ °C, parallel (∥) and perpendicular (⊥) to the texture axis. The solid lines are fitted demagnetization curves based on the trial texture function from Eq. (2)

The definition of a texture parameter may also be independent of the special type of $f(\alpha)$, as in the case of the standard deviation σ, which is given by

$$\sigma^2 \equiv \overline{\alpha^2} = \int_0^{\pi/2} d\alpha \sin\alpha\, f(\alpha)\alpha^2. \tag{3}$$

II. EXPERIMENTAL AND THEORETICAL METHODS

Sintered $Nd_{16}Fe_{78}B_6$ magnets were prepared in the usual powder metallurgical way.[7] To obtain four samples A1–A4 with different degrees of texture, various values of the magnetic field were used during the compacting process. Magnetic properties from room temperature up to 140 °C were measured by a vibrating-sample magnetometer with applied fields up to 8 T.

The SPD measurements were performed as described in Ref. 3. A computer program has been developed for the automatic measurement of the amplitude of the SPD peak. The adopted criterion is to measure the difference in the slope of d^2J/dH^2 at the two inflection points located at both sides of the peak. The applied field H forms an angle γ with the texture axis z and is in the x-z plane. The SPD peak amplitude $G(\gamma)$ is proportional to the volume fraction of crystallites having their c axes in a plane perpendicular to H. If ϕ denotes the azimuth of the c axis with respect to x-z plane, we have $\cos\alpha = \cos\phi \sin\gamma$ and

$$G(\gamma) = 2/\pi \int_0^{\pi/2} d\phi\, F(\cos\phi \sin\gamma), \tag{4}$$

where $F(\cos\alpha) = f(\alpha)$ is the texture function from Eq. (1).

The integral equation (4) was numerically solved by fitting the power series

$$F(\cos\alpha) = \sum_i b_i \cos^{2n_i}\alpha \tag{5}$$

to measured values of $G(\gamma)$, where a small number of terms turns out to be sufficient.

Trial demagnetization curves were computed taking into consideration only coherent rotational processes based on anisotropy constants up to K_2, neglecting the internal magnetic

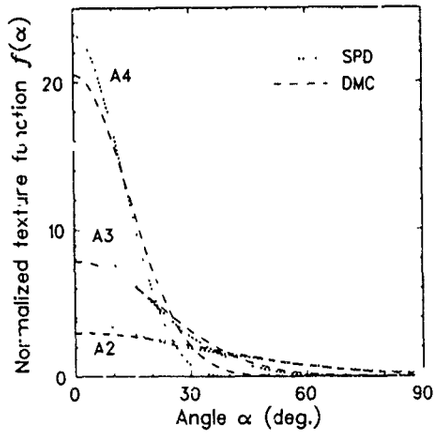

FIG 3 Texture functions for samples A2, A3, and A4 SPD $f(\alpha) = b_0 + b_1 \cos^{n_1}\alpha + b_2 \cos^{n_2}\alpha$ fitted to SPD data DMC $f(\alpha) \sim \exp(-\alpha^2/2\sigma_g^2)$ fitted to the curves of Fig 2

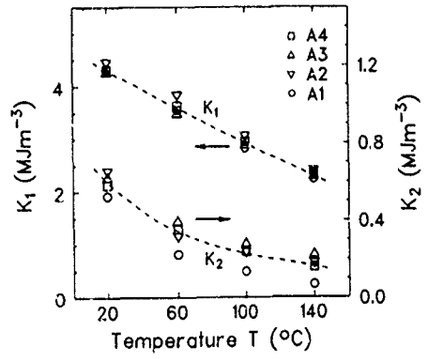

FIG 5 Temperature dependence of the anisotropy constants K_1 and K_2 of samples A1–A4, calculated from fitted demagnetization curves

stray fields, using the trial texture function of Eq. (2). Then the calculated J vs H curves, depending on trial values of σ_g, J_s, K_1, and K_2, were fitted by a least-mean-square fit to the experimental curves, measured above $\mu_0 H = 1.5$ T in order to avoid domain-wall processes. Three criteria were used to test the applicability of the trial function: (i) the remaining variance of the numerical fit should be sufficiently small, (ii) the texture parameter must not depend on temperature, and (iii) the fitted values of K_1, K_2, J_s must not depend on the degree of easy-axis alignment. Finally, the fitted texture function as well as the obtained anisotropy field H_A were compared with those determined by the SPD method.

TABLE I. Texture parameter σ [from Eq. (3)] fitted to SPD and DMC measurements In the case of SPD data Eq (4) was approximately solved using the series expansion (5) as well as the Gaussian (2).

A3	27.8	28 6	29 2
A4	15 7	15.8	18.6
Ideally textured		0.0	

III. RESULTS AND DISCUSSION

In Fig. 1 the angular dependence of the measured peak amplitude $G(\gamma)$ of the little textured sample A2 and the corresponding fitted texture function $f(\alpha)$ are shown as a typical example for the SPD analysis.

The Gaussian texture function (2) yields a very good fit for the demagnetization curves (DMCs) of our samples A1–A4, measured perpendicularly and parallel to the texture axis (see Fig. 2). A typical value of the residual variance of the numerical calculation is 10^{-7} T^2.

The texture functions obtained from demagnetization curves are fairly similar to those calculated from SPD data, as shown in Fig. 3. This is an encouraging result because very different experimental procedures are used. Due to the normalization factor $\sin \alpha$ in Eqs. (1) and (3), the deviations of $f(\alpha)$ at $\alpha \approx 0$ in Fig. 3 have only a small weight for physical quantities.

As a consequence of this result, the values of standard deviation σ summarized in Table I do not much depend on the type of the applied measuring procedure.

Figure 4 presents the temperature dependence of the anisotropy field H_A and the standard deviation σ, both obtained from demagnetization curves, as well as the corresponding room-temperature values calculated from SPD data. For all the samples, σ shows a small temperature dependence as expected for a correct texture parameter. The small difference in the values of H_A obtained from SPD and DMC measurements, respectively, may be due to the magnetostatic interaction between the $Nd_2Fe_{14}B$ particles, which was neglected in this study. The effect of this interaction on SPD measurements was considered in Ref. 8. In the case of DMC analysis the influence of internal magnetostatic fields has not yet been systematically investigated.

The DMC results of the anisotropy constants K_1 and K_2 determined from differently textured samples yield sufficiently small variations for all investigated temperatures (Fig. 5). The temperature dependence of K_1 and K_2 is in good agreement with the data from Ref. 9. The room-temperature value of H_A is comparable to that presented in Ref. 10 for a single crystal, but $K_2 = 0$ at $T = 293$ K was obtained there.

In summary, DMC as well as SPD analysis yield fairly correct data on texture and intrinsic magnetic properties because both techniques are based on reversible rotation of the local magnetic polarization. Contrary to other elementary magnetization processes, reversible rotation is not very sensitive to chemical and topological details in the nanometer range of microstructure.

Magnetic-field orientation and coercivity

D. I. Paul
Materials Science and Engineering Department, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

The relationship between the coercive force and the angle of the applied field of an infinite magnetic medium containing a planar defect have been analyzed. A domain-wall pinning dominated coercivity was assumed and the spatial dependence of the magnetization in the direction normal to the plane of the defect was taken into account. The results show that the coercivity must be about two orders of magnitude smaller than the anisotropy field for the inverse cosine curve to be a good approximation. Some of the results with experimental work on $Fe_{77}Nd_{15}B_s$ are compared. In addition, the existence of a decrease in the domain-wall pinning coercivity as a function of the angle between the applied magnetic field and the anisotropy for certain ranges of parameters—a behavior previously thought to have only occurred in the angular dependence of a nucleation dominated coercivity—is shown.

A central issue in the study of permanent magnets such as NdFeB and SmCo has been the understanding of the magnetic reversal mechanism at the coercive field H_c.[1,2]

An important aspect of this problem is the angular dependence of the coercive field. The angular dependence in sintered RFeB magnets has been measured by the group at CNRS in Grenoble.[3] They find that for $H_c=10$ kOe at room temperature the increase of H_c with θ_H, the angle of the applied field with respect to the easy direction of magnetization, corresponds approximately to a $1/\cos(\theta_H)$ relationship, a theoretical derivation of which had been carried out in a previous paper.[4] For $H_c \sim 17$ kOe, there is a reduced increase in H_c with θ_H. Finally, a decrease in H_c as θ_H increases occurs at small θ_H values in PrFeB magnets. The authors of Ref. 3 state that they are unable to understand the last result on the basis of either coherent rotation or domain-wall propagation.

Results by both Sakuma *et al.*[5] and Kronmuller *et al.*[6] indicate that there exists ranges of magnetic parameter values wherein coercivity limited by the nucleation of domain walls shows deviations from the $1/\cos(\theta_H)$ or inverse cosine angular dependence, but it is generally accepted that coercivity limited by domain-wall pinning follows the inverse cosine relation, thus yielding insight into the mechanism of magnetic reversal through analyzing the angular dependence of the coercivity of different materials. We shall show that this is not so, that there also exist strong deviations from the inverse cosine relation when domain-wall pinning is the mechanism limiting magnetization reversal.

In 1990, Sakuma *et al.*[15] presented theoretical derivations of the coercivity as a function of the angle of the applied field for the case of a domain-wall nucleation dominated coercivity in a material containing a defect. Their methods, first introduced by Friedberg and Paul,[7] took into account the spatial dependence of the magnetization.

In this paper, we derive the angular dependence of the coercive force for domain-wall pinning. We also take into account the spatial dependence of the magnetization.

Let us consider an array of magnetic dipoles representing the host magnetic material containing a defect lying within the region $x=-D/2$ to $x=D/2$. The host matrix has uniform magnetization M_1, first-order anisotropy constant K_1, and first-order exchange energy constant A_1. The impediment has entirely independent magnetic properties K_2, M_2, and A_2. The easy axis of magnetization is in the direction of the z axis and an external magnetic field H is being applied at an angle θ_H as measured from the z axis in the y-z plane. The orientation of a given dipole in the array is taken as the angle θ measured from the z axis in the y-z plane. We assume a one dimensional spatial dependence for the angle θ. The orientations of the end dipoles are fixed with $\theta=0°$ at $x=-\infty$ and $\theta=180°$ at $x=\infty$, signifying the presence of a Bloch wall along the array. We wish to find the value, H_c, of the external magnetic field for which the wall can no longer be held by the impediment and thus magnetic reversal of the entire medium occurs. This model has already been discussed for the case in which the external magnetic field is applied in the same direction as the easy axis of magnetization ($\theta_H=0°$).[7,8]

The total energy for the ith region ($i=1,2,3$) is given by

$$E_i=\int_{x_1}^{x_2}\left[K_i \sin^2(\theta)-HM_i \cos(\theta-\theta_H)+A_i\left(\frac{d\theta}{dx}\right)^2\right]dx. \tag{1}$$

Minimizing the energy in the three regions using the boundary conditions that $\theta=0°$ and $180°$ at $x=-\infty$ and ∞, respectively, and that $A_i(d\theta/dx)$ is continuous at $x=-D/2$ and $D/2$, we get Eq. (2) where η is given by Eq. (3):

$$W=\int_{\cos(\theta_1)}^{\cos(\theta_2)}(\sin\theta)^{-1}[\sin^2(\theta)-hFE^{-1}\cos(\theta-\theta_H)+\eta]^{-1/2}d\cos(\theta), \tag{2}$$

$$\eta=(E^{-1}-1)\sin^2(\theta_1)-hE^{-1}(1-F)\cos(\theta_1-\theta_H)+hE^{-1}\cos(\theta_H). \tag{3}$$

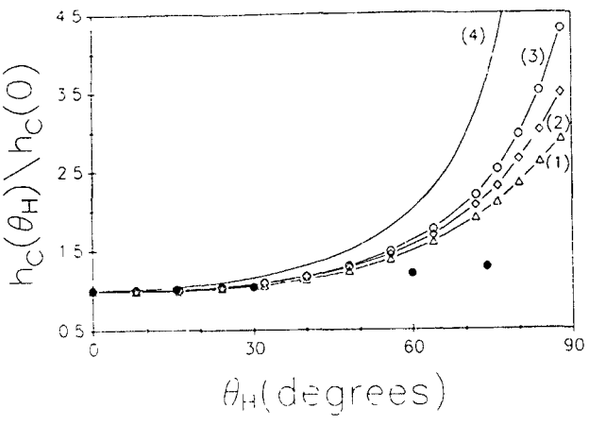

FIG 1. Ratio of the normalized coercive forces $h_c(\theta_H)/h_c(0)$ as a function of the angle of the external field with respect to the anisotropy axes θ_H, for a constant normalized defect width $W=2$ and constant ratio $F=0.8$ Curve (1) is for $E=0.4$, curve (2) is for $E=0.5$, and curve (3) is for $E=0.6$ Curve (4) shows the $1/\cos(\theta_H)$ angular dependence generally accepted to be characteristic of a domain-wall pinning dominated coercivity The solid circles are measurements on the angular dependence of $Fe_{77}Nd_{15}B_8$ (see Ref. 6)

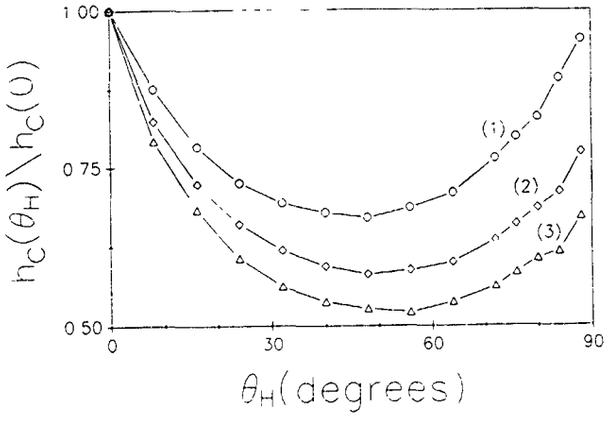

FIG 2 Same as Fig 1 with the normalized defect width $W=2$. Curve (1) is for $E=F=0.1$, curve (2) is for $E=F=0.05$, and curve (3) is for $E=F=0.025$.

The relationship between the quantities θ_1 and θ_2 (the orientation of the dipoles at $x=-$ and $D/2$, respectively), are given by

$$(1-E^{-1})\sin^2(\theta_2)+hE^{-1}(1-F)\cos(\theta_2-\theta_H)+hE^{-1}\cos(\theta_H)+\eta=0, \quad (4)$$

along with the condition $\cos(\theta_1)>\cos(\theta_2)$.

Here we have also introduced the dimensionless parameters E, F, h, and W:

$$E=\frac{A_2K_2}{A_1K_1}, \quad F=\frac{A_2M_2}{A_1M_1}, \quad h=\frac{HM_1}{K_1}, \quad W=\frac{D}{\delta},$$

used in Ref. 8, where D is the actual width of the defect and $\delta=(A_2/K_2)^{1/2}$ is the domain-wall half-width within the defect region.

Given a value for the normalized external field h and θ_H, there is a set of θ_1's for which a θ_2 in $(\theta_1,180°)$ satisfying Eq. (4) will exist and $W(\theta_1,\theta_2)<\infty$, where $W(\theta_1,\theta_2)$ is determined by Eq. (2). This gives rise to a set $\{W_{\theta 1}\}$ of normalized defect widths. These are values of W for which there exists a static domain-wall solution that satisfies the given boundary condition. In particular, $\theta(-\infty)=0°$ and $\theta(\infty)=180°$ are satisfied and thus a domain wall is still present. Thus, for all widths W in $\{W_{\theta 1}\}$, the field h is insufficient to drive the wall over the defect.

The minimum W_c of the set $\{W_{\theta 1}\}$ corresponds to the critical width at which h is sufficient to drive the wall over the defect region and magnetic reversal begins. As one would suspect, it was found that W_c increases as a function of h. Thus any field smaller than h would be insufficient to drive the wall across a defect of width $W_c(h)$ as contrasted to a field greater than h. Therefore $h_c=h$ is the coercive force corresponding to the given defect width $W_c(h)$.

Figure 1 shows the ratio of the normalized coercive forces $h_c(\theta_H)$ and $h_c(0)$ versus the angle of deviation θ_H of the external field with respect to the anisotropy axes. The normalized defect width W and ratio F are held constant at values 2 and 0.8, respectively. The ratio E ranges from 0.4 to 0.6, corresponding to a large change in the magnetic parameters A_t and/or K_t across the boundaries $x=-D/2$ and $x=D/2$. We have included for comparison the normalized angular dependence $h_c(\theta_H)/h_c(0)=1/\cos(\theta_H)$, generally accepted as the angular dependence curve characteristic of a domain-wall pinning dominated coercivity. We notice that our curves deviate significantly from the inverse cosine curve for this range of E and value of F and W with the deviation decreasing as E approaches unity. Also included in this figure are measurements of the normalized angular dependence of the coercive force for $Fe_{77}Nd_{15}B_8$ done by Kronmuller *et al.*[6]

In Fig. 2, the ratios E and F take on very small values ranging from 0.025 to 0.1 and the normalized defect width W is again held constant at the value of 2. This range for E and F corresponds to differences within the material parameters A_t, K_t, and M_t between the host matrix and the defect region of up to two orders of magnitude. For these small values of E and F, we see a very pronounced decrease in $h_c(\theta_H)/h_c(0)$ as θ_H increases from zero. Physically, the external field required to drive the domain wall across the defect is decreased when applied in directions deviating from the anisotropy axes, with the minimum required field occurring at $\theta_H\approx 50°$. Note that for $E=F=0.025$, applying the external magnetic field at 55° with respect to the anisotropy axes will reduce the coercive force by approximately one half that required to demagnetize the material with a field parallel to the anisotropy axes.

The last figure, Fig. 3, plots h_c vs W rather than $h_c(\theta_H)/h_c(0)$ vs θ_H. We do this for the values of θ_H ranging from 5° to 80°. The ratios E and F are held constant at 0.5 and 0.75, respectively. Notice that for a given value of θ_H, when W is greater than approximately 1.5, there are essentially no further changes in h_c.

In Fig. 1 as well as in subsequent work we see that as E and F approach 1, the angular dependence approaches the inverse cosine relation. Physically, the parameters E and F

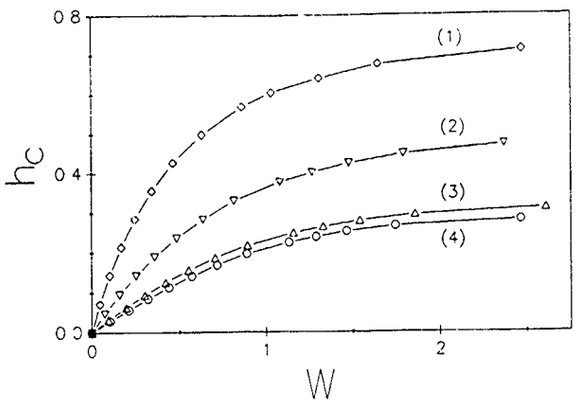

FIG. 3 Normalized coercive force h_c as a function of the normalized defect width W for the values $E=0.5$ and $F=0.75$. Curve (1) is for $\theta_H=80°$, curve (2) is for $\theta_H=65°$, curve (3) is for $\theta_H=35°$, and curve (4) is for $\theta_H=5°$.

approach 1 when the changes in the magnetic parameters A_t, M_t, and K_t between the host material and defect become negligible. This is the basic criterion for the $1/\cos(\theta_H)$ angular dependence to take over. In the analysis of the normalized coercive force for $\theta_H=0°$ done by Friedberg and Paul,[7] it was shown that as E and F converge to 1, $H_c(0)/H_A$ goes to zero. Therefore the criterion mentioned above is similar to the arguments made in previous works for the occurrence of a $1/\cos(\theta_H)$ curve for values $H_c \ll H_A$.[4,6,9]

We find that a change in A_t between the host and defect material, causing a decrease in both E and F, produces the greatest deviation from the inverse cosine curve while a change in K_t, causing a decrease in E alone, produces a slightly smaller deviation, and finally, the smallest deviation is produced by a change in M_t between the host and defect material, causing a decrease in F alone. Therefore the exchange energy seems to be the most influential in determining the appearance of the inverse cosine angular dependence.

As seen in Fig. 3, at any given θ_H, $h_c(\theta_H)$ as a function of W becomes essentially constant for $W>1.5$. This asymptotic behavior in $h_c(\theta_H)$ as a function of W was shown for $\theta_H=0°$ by Paul.[8] We see now that it is exhibited at values of θ_H other than 0° and from this conclude that the behavior of an angular dependence curve, $h_c(\theta_H)/h_c(0)$, is only a function of W for W less than approximately 1.5.

Figure 2 shows a "dip" in the normalized coercive force as θ_H increases. Indeed, not only is the increase with θ_H shown in our model not as great as that predicted by the inverse cosine curve, but for small E and F (<0.5 if $W\sim2$), h_c actually decreases as θ_H increases from 0°. Physically, this means that for these values of the parameters E, F, and W it is easier in general to demagnetize the material by applying the external field in directions other than along the anisotropy axes. The maximum decrease in h_c for small E and F occurs at $\theta_H\sim50°$.

We have found that little or no dip is seen in the angular dependence when either E or F has value close to unity. It appears that both E and F must be small together in order for a significant dip to be present. This suggests that the exchange energy, present in both of the parameters E and F, takes on a dominant role in the cause of this dip.

It has been shown by Friedberg and Paul[7] that as W approaches zero, the value of $H_c(0)/H_A$ approaches zero. Therefore we would expect that for small values of W, the angular dependence curve will be close to $1/\cos(\theta_H)$. However, the "critical width" above which the angular dependence significantly deviates from $1/\cos(\theta_H)$ will depend on the values of A_2/A_1, H_2/H_1, and M_2/M_1. In particular, we have found that if A_2/A_1 decreases from 0.75 to 0.03 (a factor of 25), this critical width is reduced by one order of magnitude. Calculations along these lines suggest that it is necessary for H_c to be approximately two orders of magnitude smaller than H_A for $1/\cos(\theta_H)$ to be a good approximation for the angular dependence.

The normalized angular dependence of the coercivity measured as a function of the applied field angle for $Fe_{77}Nd_{15}B_8$[6] has been included in Fig. 2 for comparison with our theoretical curves. As will be noticed, the fit of this data to our curves leaves something to be desired, as was the case when this data was compared to other theoretical work.[5,6] There needs to be more experimental work.

The nucleation dominated angular dependence curves derived in Ref. 5 as well as the pinning dominated curves in this paper show a decrease in h_c as a function of θ_H for certain parameter values. Although for given values of E, F, and W, the model in Ref. 5 and our model may give entirely different looking curves; as a whole one cannot look at an angular dependence curve to determine the coercive force mechanism without explicit knowledge of the parameters E, F, and W. These qualitative similarities are seen to be true when comparing our curves to nucleation dominated angular dependence curves derived from other models as well.[6,9] This indicates that caution must be used if one is trying to determine whether a certain material's coercivity is pinning or nucleation dominated by comparing its angular dependence curve with theory.

Magnetic structures and interactions in Ho/Y, Ho/Lu, and Ho/Er superlattices (invited)

Ho/Y and Ho/Er superlattices have been grown by molecular-beam epitaxy using a Balzers UMS 630 instrument. The superlattices were grown on a sapphire substrate with an Nb buffer and Y seed layer. X-ray-diffraction techniques were used to characterize the crystallographic structure and neutron-diffraction techniques to determine the magnetic structures. The results for the Ho/Y systems were consistent with long-range order being formed coherently through the whole superlattice. The moments in the Ho layers were aligned in the basal plane and most of the structures could be described by helical structures with a turn angle between holmium planes of Ψ_H and between nonmagnetic Y planes Ψ_Y. Ψ_Y is found to be largely independent of temperature or superlattice, while Ψ_H decreases with decreasing temperatures and at low temperatures takes a commensurate value, so as to take advantage of the basal plane anisotropy. The results for the Ho/Er superlattices differ because the Er has a magnetic moment and the anisotropy favors alignment along the c axis. Between the ordering temperature of bulk Ho and bulk Er, the results are similar to those of the Ho/Y superlattices. The ordering propagates through the Er layers but the Er moments are not ordered. At lower temperatures the Er moments order in a cycloidal (a/c) structure with the basal plane components having fairly long-range coherence with the Ho moments, but the c-axis components having no coherence from one Er layer to the next.

I. INTRODUCTION

Rare-earth superlattices show a number of novel and interesting properties as has been reviewed by Majkrzak *et al.*[1] We have extended this work particularly to the superlattices containing Ho, and have studied superlattices of Ho with the nonmagnetic elements Y[2] and Lu,[3] and also Ho and the magnetic element Er. Bulk Ho orders magnetically below 132 K into a helical magnetic phase in which the moments align ferromagnetically in each basal plane but rotate from one plane to the next by an angle Ψ_H which decreases on decreasing temperature from 52° at the T_N to an average of 30° below 18 K, when the moments also tip out of the basal plane to form a cone phase. One of the interesting aspects of Ho is the existence of a series of long period commensurate spin-slip structures,[4] due to the basal plane anisotropy. Our choice of Ho superlattices was therefore made to see if Ho/Y superlattices behaved similarly to the Dy/Y superlattices previously studied, to determine the effect of the basal plane anisotropy on the magnetic structures, and to determine the structures of the Ho/Er superlattices in which the Ho and Er have competing anisotropies.

The superlattices were grown by molecular-beam epitaxy in Oxford using a Balzers UMS 630 facility. The technique followed was developed by Kwo *et al.*[5] and has been described in detail.[2] The superlattices are grown on a sapphire substrate with a 500 Å Nb buffer layer and a 1000 Å Y seed layer before the superlattice and capped by a 300 Å Y layer to prevent oxidation of the magnetic material. The chemical and crystallographic quality of the superlattice is then determined using x-ray diffraction. Typically the superlattices have a mosaic spread of 0.16°, a chemical coherence length of about 2200 Å, and an interface width of about 5 atomic planes.

The magnetic structures were determined by neutron-scattering techniques using triple axis spectrometers at the DR3 reactor of the Risø National Laboratory. Typically, 5 meV incident neutrons were selected with a pyrolytic graphite monochrometer, and second-order contaminant neutrons were suppressed with a cooled Be filter. A pyrolytic graphite analyzer was used to ensure that only elastically scattered neutrons were detected. The collimation was typically from reactor to detector $60'-30'-30'-120'$ and gave a resolution in the scattering plane of 0.01 $Å^{-1}$. The samples, whose growth direction is always perpendicular to the c axis, were aligned with the (hol) plane in the scattering plane and mounted in a variable-temperature cryostat so that the temperature could be controlled to 0.1 K. The scattered intensity was determined as the wave-vector transfer was scanned along the $(00l)$ and $(10l)$ directions. The former provides information about the basal plane ordering of the magnetic moments, while the latter gives intensities dependent on both the basal plane and c-axis moments.

II. RESULTS FOR HO/Y SUPERLATTICES

The results for the Ho/Y superlattices have been published[2] and so the results will only be briefly summarized

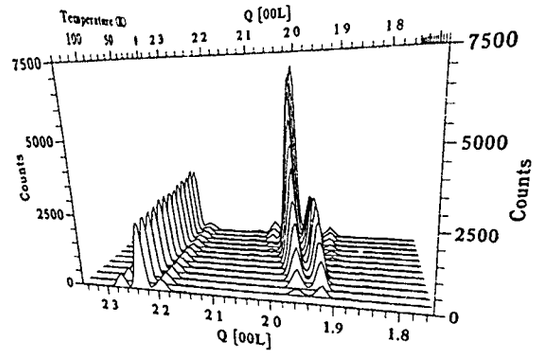

FIG 1. The neutron-scattering intensity (Ref. 2) observed from a $(Ho_{40}Y_{15})_{50}$ superlattice along $(00l)$ at a series of temperatures at intervals of 10 K from 130 to 10 K. The nuclear (002) scattering is temperature independent and the magnetic scattering grows with decreasing temperature. Note that even at 120 K, the magnetic scattering is two peaks showing long-range coherence.

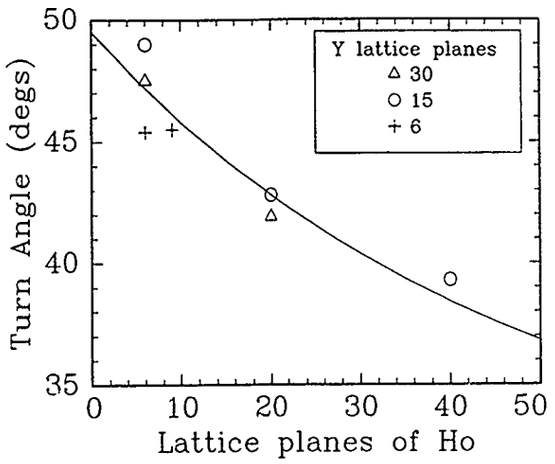

FIG. 3 The turn angle (Ref 2) Ψ_H for Ho in various superlattices showing that at least for thick superlattices, Ψ_H is largely independent of the Y thickness and that Ψ_H is close to a commensurate spin-slip value The solid line is a guide to the eye, and the errors are about the symbol size

here. The neutron scattering as a function of temperature from the $Ho_{40}Y_{15}$ superlattice is shown in Fig. 1 and shows the growth of the magnetic scattering with decreasing temperature. The magnetic scattering at every temperature shows several separate peaks showing that the ordering is always coherent through the nonmagnetic Y blocks. In this respect the result is similar to that found for the Dy/Y system.[1]

A more detailed description requires a model. We have used a model in which there is a turn angle between the magnetic moment direction on successive Ho planes Ψ_H, and one between successive Y planes Ψ_Y, and moments on both the Ho and Y planes. The fits showed that the data were consistent with no moment on the Y planes, and the same Ho block lengths and interface widths as the crystallographic fits to the x-ray data. Consequently, in the final fits, only Ψ_H, Ψ_Y, and the moment on the Ho planes were allowed to vary while the block lengths and interface thicknesses were taken from the x-ray results.

The model gave a good description of the results and the parameters for the $Ho_{40}Y_{15}$ sample are shown in Fig. 2. The Y turn angle Ψ_Y is independent of temperature and was indeed found to be the same and constant for all the Ho/Y superlattices. The Ho turn angle Ψ_H was found to decrease with decreasing temperature but less markedly than for a pure Ho film or bulk Ho. Presumably the decrease with decreasing temperature arises largely from the effect of the ordering on the turn angle[6] as in bulk Ho, while the difference between the behavior of bulk Ho and the Ho superlattices is due at least in part to the clamped lattice parameters and consequent strain of the Ho in the superlattice, as found in Dy/Y superlattices.[1]

The low-temperature Ho turn angles for several Ho/Y superlattices are shown in Fig. 3, and are largely independent of the Y block thickness and increase steadily with decreasing Ho block thickness. The samples with more than eight Ho planes, for which interdiffusion is not too severe, all have Ψ_H close to the turn angle for a commensurate spin-slip structure, 40°, 42 9°, 45°, and 48°. These spin-slip structures also show higher harmonics of the magnetic satellites, but interestingly these did not show the separate peaks of the main magnetic satellites, only a single broad peak, whose width was consistent with the scattering from an isolated Ho block. The conclusion is that, while the primary magnetic satellites show coherence in phase and chirality through the nonmagnetic Y blocks, the extra spin-slip features of the structures are not coherent from one magnetic block to the next.

Similar measurements[3] have been made for the Ho/Lu system. The basic results are very similar to those obtained for the Ho/Y system except for:

(1) The Lu turn angle Ψ_L is 40° and possibly varies more from system to system than that of Ψ_Y.
(2) The turn angles for Ψ_H are less than those of bulk Ho at the same temperature.

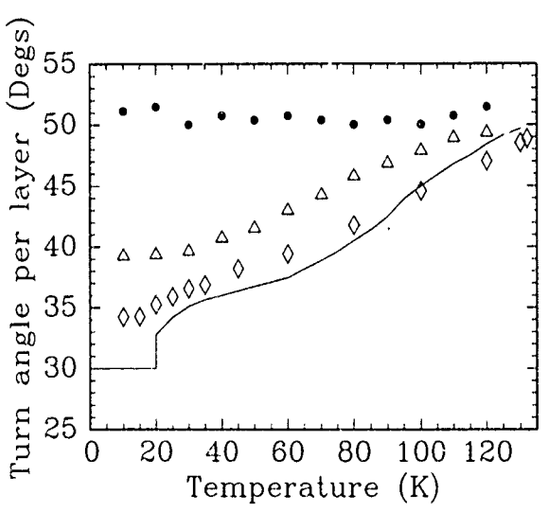

FIG 2. The temperature dependence (Ref. 2) of the turn angles Ψ_H (△), Ψ_Y (○) for the $Ho_{40}Y_{15}$ superlattice. Also shown is Ψ_H (◇) for an epitaxially grown Ho film and for bulk Ho (solid line) The errors of the fitting are shown by the point size

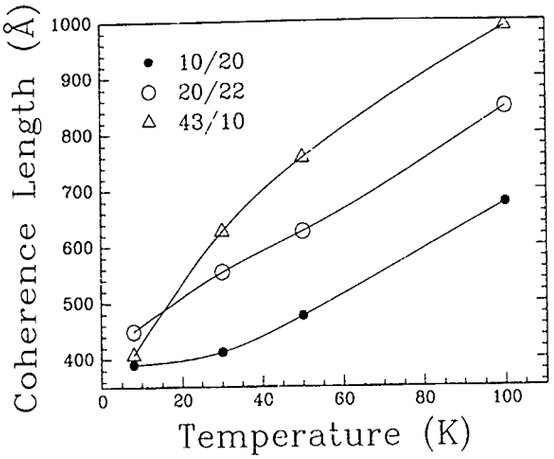

FIG. 4. The temperature dependence of the coherence length for the basal plane ordering of Ho/Er superlattices. The data were obtained from the scattering along (00l) and have been corrected for the resolution effects (Ref 10).

(3) A basal plane ferromagnetic phase with $\Psi_H=0$ was obtained at low temperatures below 30 K in samples such as $Ho_{20}Lu_{15}$, and successive Ho blocks then ordered parallel or antiparallel, dependent on the number of Ho layers. This structure does not occur in bulk Ho and probably results from the strain of the Ho in Ho/Lu superlattices as shown for Dy/Lu superlattices.[7]

III. RESULTS OF Ho/Er SUPERLATTICES

The Ho/Er superlattices are of interest because the crystal field anisotropy for Er favors alignment of the magnetic moments along the c axis. Bulk Er has a longitudinally modulated structure below $T_N=84$ K, which on cooling below 52 K becomes a cycloidal phase[8] with the moments largely confined to the a/c plane above 18 K and a cone phase below 18 K. Thus, between 84 and 20 K, the crystal fields in Er and Ho favor alignment in different directions.

We have studied several different Ho/Er superlattices. At high temperatures, above the ordering temperature of bulk Er, the results are qualitatively similar to those of the Ho/Y systems. There is a long-range coherent basal plane helical structure, and fits suggest that there is a negligible moment associated with the Er atoms and that the turn angle in the Er is 51±1°. The turn angle associated with the Ho is similar to that of bulk Ho. This result shows that the long-range basal plane order propagates through the Er layers even without simultaneously ordering the Er moments. The magnetic coherence length of the structure is many superlattice periods ~600 Å. Similar results[9] have been found in Dy/Er superlattices above 85 K.

On cooling below the erbium transition temperature the scattering changes. First, the width of the peaks along (00l) increased, showing that the correlation length associated with the basal plane structure decreases; see Fig. 4. Second, the scattering along (10l) consisted of sharp peaks, presumably associated with the basal plane structure and, in addition, a broad peak, as shown for the Ho_{20}/Er_{22} sample at 8 K

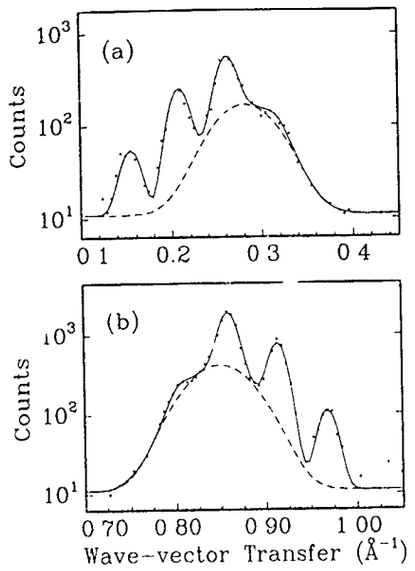

FIG. 5. The scattering (Ref. 10) observed for a scan along (10l) for the $Ho_{20}Er_{22}$ system at 8 K. The fit is to a series of Gaussian peaks, the narrow peaks arise from the basal plane ordering and the broad peak from the longitudinal ordering. The latter peak gives a correlation length of about the thickness of a single Er layer.

in Fig. 5. Fits to Gaussian peaks show that the widths of the sharp components increase in the same way with decreasing temperatures as the peaks observed along (00l), while the broad peak has a width corresponding to scattering from a single Er block and a position to a turn angle similar to that of bulk Er at the same temperature, see Fig. 6.

A model which accounts for this behavior assumes that the Ho moments align in a basal plane helix, while the Er moments align in an a/c cycloid with the basal plane components of the cycloid coherent with the Ho moments, but the sense of rotation of the cycloid is randomly clockwise or anticlockwise, destroying any coherence of the c-axis mo-

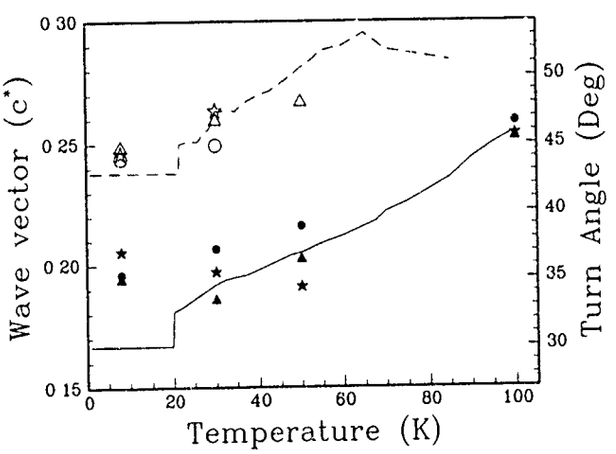

FIG 6 The turn angles Ψ_H and Ψ_E for the holmium and erbium moments (from the broad longitudinal peak) The Ho values are the filled symbols and solid line for the bulk while the Er values are the dashed line and open symbols The symbols correspond to $Ho_{20}Er_{22}$ (△), $Ho_{10}Er_{20}$ (*), and $Ho_{43}Er_{10}$ (○)

ments between the different Er layers. This model is clearly consistent only if the Ho and Er turn angles have values such that the different structures match up at the boundaries of the layers. Full details of the models will be published elsewhere.[10]

The lack of the long-range coherence, particularly for the c-axis, was surprising because long-range coherence has been observed in the Er/Y system.[11]

IV. SUMMARY AND DISCUSSION

The magnetic structures of Ho/Y, Ho/Lu, and Ho/Er superlattices have been determined using neutron-scattering techniques. The results for Ho/Y and Ho/Lu superlattices are qualitatively similar to those of Dy/Y and other superlattices, in that long-range coherent magnetic structures are produced in which the order propagates through the nonmagnetic layers. As for Dy/Y and Dy/Lu superlattices,[1,7] the strain in the Ho/Y layers means that the Ho turn angle is larger than in bulk Ho, while in the Ho/Lu layers it is smaller. The basal plane anisotropy leads, at low temperatures, to spin-slip commensurate structures within each Ho layer, but there is no coherence of the spin-slip aspects of the structure from one layer to the next. In the case of the Ho/Lu superlattices, there is a new phase in which the Ho forms basal plane ferromagnetic layers which are oriented either ferromagnetically or antiferromagnetically with neighboring layers.

The Ho/Er structures are more complicated because the Er moments are aligned by the crystal field along the c axis. Above the ordering temperature of Er, the structure is a long-range helical ordering, similar to that of the Ho/Y superlattices but with zero net moment on the Er atoms. On cooling Er below the ordering temperature, the correlation length decreases for the basal plane ordering and the results are consistent with the holmium ordering as a basal plane helix and the erbium in a cycloidal, a/c-plane structure. The basal plane moments of both the Ho and Er are coherent over several superlattice repeats, but the c-axis Er moments are coherently ordered only over single Er layers. Different parts of the cycloidal ordering are randomly clockwise or anticlockwise in sense.

Part of the importance of these results lies in the information they provide about the nature of the magnetic interactions in the superlattices. Conventionally the magnetic interactions are taken to be of the RKKY form, which suggests an interaction of the form $\mathbf{S}_1.\mathbf{S}_2$, of a magnitude which oscillates in sign with a period determined by the Fermi surface. This interaction is of long range and has usually been taken to explain the propagation of the magnetic ordering through quite large nonmagnetic Ho blocks. In the absence of more detailed calculations, however, we do not find this wholly convincing. The long-range order propagates through Y and Lu layers containing as many as 30 planes of Y in each layer. This is much longer range than the exchange constants deduced from spin-wave measurements of the bulk rare earths[8] which we believe give a better estimate of the RKKY interaction than the calculations.[1] Furthermore, the transition temperatures of the Ho/Y superlattices decrease only slightly as the Ho layer thickness decreases, and are largely independent of the Y layer thickness.[2] They are consistently higher than those of the Ho/Y alloys with the same average composition. Finally, when the Ho/Lu superlattices[3] or the Gd/Y or Dy/Y superlattices[1] order into basal plane ferromagnetic layers, the ordering through the Lu layers changes from propagation of a helical ordering to an ordering which is either ferromagnetic or antiferromagnetic. This change in the effect of the Y layers is inconsistent with the simple RKKY interaction, and not convincingly explained by existing calculations.[12]

The results for the Ho/Er system are also not readily understood. How does the order propagate through the Er layers above T_N for Er without producing ordering in the Er layers? Once the Er moments begin to order, it is difficult to understand why the coherence length of the basal plane ordering decreases, or why there is no propagation of the longitudinal ordering through the Ho layers, as would be expected if the interaction had the simple $\mathbf{S}_1.\mathbf{S}_2$ form.

One possible explanation of the results is to consider the band structure of the magnetically ordered structure, when the electrons at the new superzone gaps must have conduction-band spin-wave functions associated with the nature of the magnetic ordering.[6] This then leads to a long-range interaction only if the metals have similar band structures and for only the spin ordering which forms the initial spin-density wave. We intend exploring this model elsewhere.

We have studied structural and magnetic properties of epitaxial MnAs thin films with various thicknesses (L=1.0–200 nm) on GaAs substrates. The MnAs thin films were grown at 200–250 °C on an As-rich disordered $c(4\times4)$ (001) GaAs surface by molecular-beam epitaxy (MBE). The growth direction of the MnAs was found to be along the $[\bar{1}100]$ axis of the hexagonal unit cell. X-ray spectra of the MnAs at room temperature have two peaks, indicating that the present MBE-grown MnAs films consist of the hexagonal ferromagnetic phase and orthorhombic paramagnetic phase. Magnetization measurements revealed that the MnAs thin films have perfectly square hysteresis characteristics with relatively high remnant magnetization M_r=300–567 emu/cm^3 and low coercive field H_c=65–926 Oe, compared with those of epitaxial MnGa and MnAl thin films reported previously.

Epitaxial ferromagnetic thin films grown directly on semiconductors have generated much interest, since (1) high structural quality and submicrometer uniformity is expected in epitaxial monocrystalline thin films, leading to high reliability in small scale devices and (2) such heteroepitaxy of dissimilar materials can lead to a new class of device applications having properties both of ferromagnetic materials and of semiconductors.[1] Among a number of material choices, using III-V compound semiconductors like GaAs as a substrate allows the coupling of magnetism with high-speed semiconductor electronics/photonics, offering a wide range of possibilities for the fabrication of new hybrid magnetic-semiconductor devices. However, none of the elemental metals can meet the following stringent requirements: the ferromagnetic metals must grow epitaxially on GaAs, must be thermodynamically stable with no reaction with GaAs, and must be morphologically stable on GaAs.[2]

We have found that some metallic compounds can satisfy these requirements.[3–6] Ferromagnetic tetragonal MnAl[3,4] and MnGa,[5,6] Mn-based metallic compounds having common III-column atoms with AlAs and GaAs, have been grown by molecular-beam epitaxy (MBE) on GaAs substrates. Furthermore, very recently, we have successfully grown another ferromagnetic metallic compound, MnAs, by MBE on GaAs substrates.[7] This magnetic binary compound based on arsenic is more compatible with conventional III-V MBE. Though we have reported the initial results on the MBE growth on MnAs thin films on GaAs,[7] no detailed and systematic studies have been done on the MnAs/GaAs system. In this paper, we present structural and magnetic properties of the epitaxial MnAs with various thicknesses (L =1.0–200 nm) grown on (001) GaAs substrates.

In the bulk Mn-As system, MnAs at the stoichiometric composition ($Mn_{50}As_{50}$) has a thermodynamically stable ferromagnetic phase (α phase) at room temperature.[8] The Curie temperature of the ferromagnetic αMnAs is 40 °C, slightly above room temperature. The crystal structure of the αMnAs is hexagonal of NiAs type, with lattice constants of a=0.3725 nm and c=0.5713 nm, as shown in Fig. 1. At the stoichiometric composition, this ferromagnetic MnAs phase extends up to 40 °C, and paramagnetic βMnAs of a MnP-type orthorhombic structure (with lattice constants of a=0.366 nm, b=0.636 nm, and c=0.572 nm) and paramagnetic γMnAs of a NiAs-type hexagonal structure exist at 40–125 °C and above 125 °C, respectively.

The MBE growth was performed in a conventional III-V MBE machine (Riber 2300) with a Mn effusion cell. After growing a 100 nm thick undoped GaAs buffer layer on a (001) GaAs substrate at 5°0 °C, the substrate temperature T_s was cooled to ~200 °C, watching the reflection high-energy electron-diffraction (RHEED) patterns. During the cooling process, the surface reconstruction of the GaAs changed from (2×4) to $c(4\times4)$ in the RHEED. When the As_2 flux

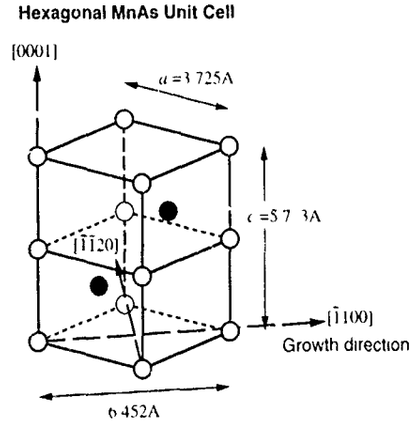

FIG 1 The crystal structure of the ferromagnetic MnAs is hexagonal of NiAs type, with lattice constants of a=0 3725 nm and c=0 5713 nm The growth direction is also shown in the figure

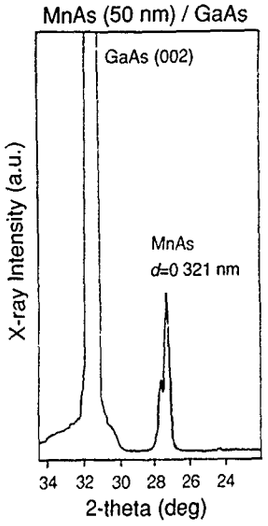

FIG 2. X-ray spectrum of a MBE-grown 50 nm thick MnAs film along the direction perpendicular to the substrate, measured at room temperature (20 °C).

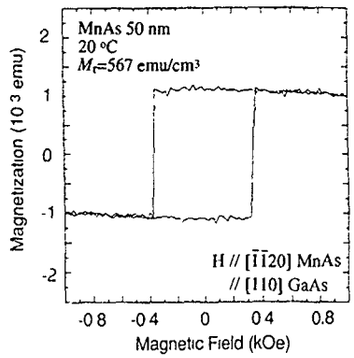

FIG 3. M-H characteristics of a 50 nm-thick MnAs at room temperature (20 °C), when the magnetic field was applied along the [1̄1̄20] axis of MnAs (//[110] GaAs). Almost perfectly square hysteresis characteristics are seen.

was supplied to the $c(4\times4)$ GaAs surface for a few minutes at 200 °C, the surface reconstruction changed from $c(4\times4)$ to *disordered* $c(4\times4)$ surface [$d(4\times4)$], where the half order streaks in the RHEED are weakened, indicating disorder caused by the accumulation of extra As atoms.[9] Then the Mn shutter was opened to grow MnAs thin films with various thicknesses ($L=1.0$–200 nm) on the $d(4\times4)$ GaAs surface at 200–250 °C with a growth rate of ~50 nm/h. The As/Mn ratio was set at 2.0–5.0. Under these growth conditions, the growth rate of MnAs is determined only by the Mn flux as in the growth of GaAs and related III-V semiconductors.

Figure 2 shows an x-ray spectrum of a 50 nm thick MnAs along the direction perpendicular to the substrate, measured at room temperature (20 °C). Similar x-ray results were obtained for all the other MnAs thin films grown under the same growth procedure and conditions. A huge peak at 31.6° is the (002) reflection of the GaAs substrate. The other two peaks around 28° are from the MnAs thin film. The stronger peak shows a lattice spacing of $d=0.321$ nm, corresponding to the (1100) reflection of hexagonal αMnAs. This indicates that the growth direction of the ferromagnetic MnAs is along the [1̄100] (see Fig. 1). A minor peak is also seen at the shoulder of the major peak, showing a lattice spacing of 0.317 nm, which corresponds to the (020) reflection of the orthorhombic βMnAs. In bulk MnAs, the hexagonal-orthorhombic transition is known to occur at the Curie temperature ($T_c=40$ °C) through very slight lattice distortions, since the two structures are very similar. In the present MBE-grown MnAs films, the paramagnetic βMnAs coexists with ferromagnetic αMnAs at room temperature (20 °C), though the major part of the film is the α phase. The reason for the existence of the β phase below T_c is unclear, but its formation might be the way MnAs relaxes the strains caused by the misfit to the GaAs substrate.

To investigate the epitaxial relationship in the present MnAs/GaAs system, RHEED patterns were observed along various azimuths during the growth. The RHEED measurements showed that the in-plane lattice constants are very close to those of hexagonal αMnAs, and the epitaxial relationship was found to be [1̄1̄20] [0001] MnAs//[110][1̄10] GaAs.

We have performed magnetization measurements on the MnAs thin films, with the thicknesses ranging from 1 to 200 nm, at room temperature using vibrating sample magnetometry. All the MnAs films have strong magnetic anisotropy, and the easy magnetization axis was found to be in plane, along the [1̄1̄20] axis of the hexagonal lattice of MnAs, which is parallel to the [110] axis of GaAs. Almost perfectly square hysteresis characteristics were seen as shown in Fig. 3, which is taken from the 50 nm thick MnAs, when the magnetic field was applied along the [1̄1̄20] axis of MnAs (//[110]GaAs), whereas almost no hysteresis was observed when the field is applied along the [0001] (c axis) of MnAs (//[1̄10]GaAs) or perpendicular to the film plane. This indicates that the MBE-grown MnAs thin films have strong magnetic anisotropy. We find this to be true for all thicknesses studied (1.0–200 nm). The values of remnant magnetization M_r and coercive field H_c of the 50 nm MnAs are 567 emu/cm^3 and 396 Oe, respectively, as shown in Fig. 3. This M_r value is slightly lower than that of bulk MnAs (600–700 emu/cm^3), but much higher than the best values (225–270 emu/cm^3) we have obtained for MBE-grown MnGa[5] and MnAl[10] thin films. The H_c value of the MnAs is much lower than that (1.1–5.0 kOe) of the MnGa and MnAl. The high M_r and low H_c with perfect squareness in the hysteresis characteristics are very attractive for future device applications including magnetic digital memory.

Figure 4 shows the thickness dependence of the room-temperature (20 °C) magnetic properties, saturation magnetization M_s and coercive field H_c of the epitaxial MnAs thin films on GaAs. The thickness dependence of the M_s is peculiar, having its maximum value at a thickness of 50 nm. The decrease of M_s when the thickness is greater than 50 nm could be related to the increase of surface roughness and deterioration of the epitaxial quality, as observed in the RHEED. The value of H_c increases from 65 Oe at 1 nm to 926 Oe at 10 nm, taking the maximum value, and then decreases again to 108 Oe at 200 nm. Some very thin films of

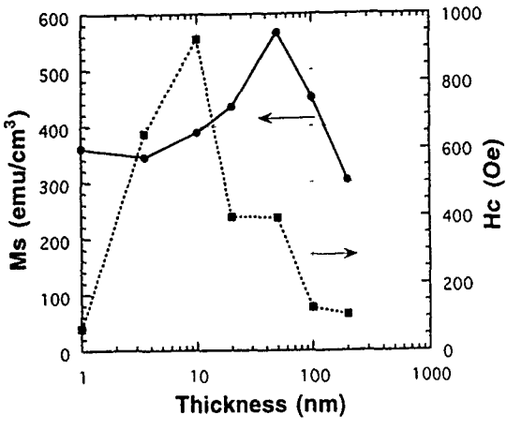

FIG. 4. Thickness dependence of the room-temperature (20 °C) magnetic properties, saturation magnetization M_s and coercive field H_c of the epitaxial MnAs thin films on GaAs

Fe and Co have been reported to show low coercive fields that increase with thickness.[11,12] On the other hand, the decrease of H_c may result from structurally related phenomena that affect the nucleation and movement of magnetic domains. These behaviors of M_s and coercive field H_c are not fully understood at this stage, but it is important for some applications to achieve high M_s(>300 emu/cm^3) and tailorable H_c (50–1000 Oe) in the low-field range (<1 kOe).

In summary, we have obtained epitaxial ferromagnetic MnAs thin films on (001) GaAs substrates by MBE. The growth direction of the ferromagnetic αMnAs was found to be along the [$\bar{1}$100] axis. X-ray measurements showed that the MBE-grown MnAs films consist of ferromagnetic αMnAs and paramagnetic βMnAs. Magnetization measurements revealed that the MnAs thin films have perfectly square hysteresis characteristics with relatively high remnant magnetization M_r=301–567 emu/cm^3 and low coercive field H_c=65–926 Oe.

Co/CoAl magnetic superlattices on GaAs

J. De Boeck, C. Bruynseraede, H. Bender, A. Van Esch,[a] W. Van Roy, and G. Borghs
IMEC, 75 Kapeldreef, B3001 Leuven, Belgium

Co/CoAl multilayers are grown by molecular beam epitaxy on AlAs/GaAs (001). CoAl is used as a template for the epitaxy of Co. From RHEED and lattice matching considerations bcc Co is expected, but thicker Co layers are probably fcc with stacking faults. The crystallographic structure of the Co layers is unclear at present. Room-temperature magnetization and magnetoresistance data are presented. Co/CoAl multilayers with various CoAl thickness all show in-plane magnetic anisotropies along ⟨110⟩. Uniaxial anisotropy along ⟨110⟩ is found to increase with increasing thickness of the CoAl layers in the multilayers. The magnetoresistive effect as a function of the orientation of the current path and the applied field is ascribed to domain-wall effects and internal Lorentz magnetoresistance.

I. INTRODUCTION

Metal epitaxy on semiconductors has received great interest over the past years, motivated by the need for stable ohmic contacts and Schottky barriers for submicrometer device structures and buried metal layers for novel devices.[1] Recently, progress has been made in epitaxy of ferromagnetic metal thin films on III-V's such as elemental Fe[2] and Co[3,4] and Mn-III compounds such as MnAl,[5] MnGa[6] on GaAs. The combination of ferromagnetic thin films and semiconductor heterostructures is expected to lead to novel device concepts. Epitaxy of elemental metals on III-V is a problem because single-variant epitaxy, morphological smoothness, and thermodynamical stability are never simultaneously achieved. Fe and Co are known to react with the semiconductor at relatively low temperatures and buried thin films coalesce upon regrowth. Intermetallic phases, however, are more suitable as candidates for stable metal epitaxy on semiconductors and a lot of effort has been invested in the study of transition-metal aluminides (TMAl) such as NiAl and CoAl.[7,8] The lattice parameter of, e.g., CoAl (a_0=0.2861 nm) is close to half the lattice parameter of GaAs and to that of bcc Co (a_0=0.2819 nm), while the large fraction of group-III elements reduces the reactivity at the metal/III-V interface. Furthermore, the use of TM aluminides as templates and interlayers in magnetic superlattices has shown to be successful in ferromagnetic/metallic thin-film heterostructures such as MnAl/NiAl on AlAs/GaAs.[9] In this work we study the use of CoAl as a template for Co epitaxy on GaAs and as interlayer in a magnetic Co/CoAl multilayer and present data on the magnetic properties of multilayers with varying CoAl thicknesses.

II. EXPERIMENT

The samples were grown using a Riber 2300 molecular-beam epitaxy system equipped with a 10 keV electron gun for reflection high-energy electron-diffraction (RHEED) observations during growth. For the evaporation of Co an EPI high-temperature cell is used with either a BeO or Al_2O_3 crucible. For the III-V growth, standard *K* cells and an EPI valved As-cracker source are employed.

The structure of the samples is characterized using transmission electron microscopy (TEM) and the magnetic properties are studied using an alternating gradient field magnetometer (AGFM 2900, Princeton Meas. Corp.) in addition to magnetoresistance measurements.

III. RESULTS AND DISCUSSION

Prior to the metal epitaxy, a GaAs buffer is grown on the GaAs (001) undoped substrates. On top of the GaAs buffer an AlAs layer of 10 nm is grown, the thickness of which is controlled using RHEED oscillations. The substrate is subsequently cooled to about 150 °C while the As background pressure is reduced by shutting the As valve and reducing the temperature in the cracking zone to about 300 °C. At that time the Co cell temperature is increased to the operating point. Co and Al beam equivalent pressures are equalized for CoAl growth using a Bayard–Alpert gauge. The background pressure was reduced below 3×10^{-10} Torr.

For the CoAl template, we have adopted the growth sequence as described[8] by Tanaka *et al.* Upon the AlAs (001) $c(4\times4)$ reconstructed surface, a ML of Co is deposited, followed by CoAl codeposition. Although CoAl can be grown at 350 °C on AlAs, the lower substrate temperature (150 °C) is chosen in an attempt to stabilize Co "bcc."[4] In this paper we report on a set of samples with a heterostructure of $10\times$(6 Å Co/t Å CoAl) with 2.5 Å$<t<$15 Å. The Co thicknesses are estimated from CoAl RHEED oscillations and assuming a_0(Co)=0.2819 nm. All samples are terminated by a CoAl layer.

The growth of the heterostructure is monitored using RHEED. The intensity of the RHEED specular spot decreases during cobalt deposition at 150 °C on the AlAs buffer. Upon deposition of the CoAl layer, the intensity recovers and clear oscillations are visible. CoAl adopts the structure of the ordered variant of the bcc CsCl (a_0=0.2861 nm). Initially, the RHEED streaks are relatively broad, suggesting that initial roughness is present, probably due to interaction of the Co with the As present on the AlAs $c(4\times4)$ surface. The RHEED patterns demonstrate the desirable ep-

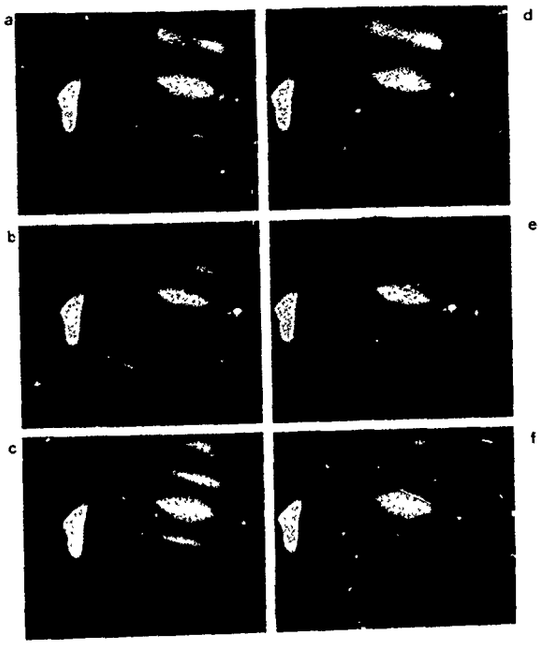

FIG. 1. RHEED images of (a)–(c) Co and (d)–(f) CoAl layers, forming the last period of a (6 Å Co/5 Å CoAl)×10 multilayer on AlAs/GaAs. The images are taken along different azimuths: (a) and (d) ⟨100⟩, (b) and (e) ⟨110⟩, and (c) and (f) ⟨1$\bar{1}$0⟩.

itaxial relation (001)[110] CoAl‖(001)[110]AlAs. Both the interface roughness and the epitaxial relation are confirmed by TEM.

A first Co layer was subsequently deposited on the CoAl template while rotating the sample holder for optimum uniformity until completion of the heterostructure. The rest of the structure is fabricated by keeping the Co cell open and shutting the Al periodically. The deposition times for each layer are in the range of 30–90 s. The RHEED images during growth of all multilayer samples are indicative of epitaxy in a cubic phase for both the Co and CoAl layers. Figure 1 shows a set of RHEED pictures taken from Co [Figs. 1(a)–1(c)] and CoAl [Figs. 1(d)–1(f)], forming the last period of a 10×(6 Å Co/5 Å CoAl) multilayer.

The crystallographic structure of the Co layers is presently still unclear. Given the close lattice match to CoAl and the RHEED data suggesting cube-on-cube epitaxy, one would expect the bcc Co phase to appear. Preliminary NMR[10] data on multilayer samples with thicker Co (≈9 Å) layers where RHEED showed additional spots around the central streak for Co suggest that the Co structure is fcc with stacking faults, which is surprising given the lattice constant of fcc Co (a_0=0.3545 nm) which does not correspond closely to CoAl (misfit≈24%). A more detailed structural investigation is under way.

Figures 2(a)–2(f) show the results of the room-temperature in-plane magnetization measurements (M/Ms) as a function of crystallographic direction, for samples with different CoAl spacer thicknesses. For all the samples we find an anisotropy in the plane. The saturation magnetization (Ms) typically ranges between 650 and 700 emu/cc.

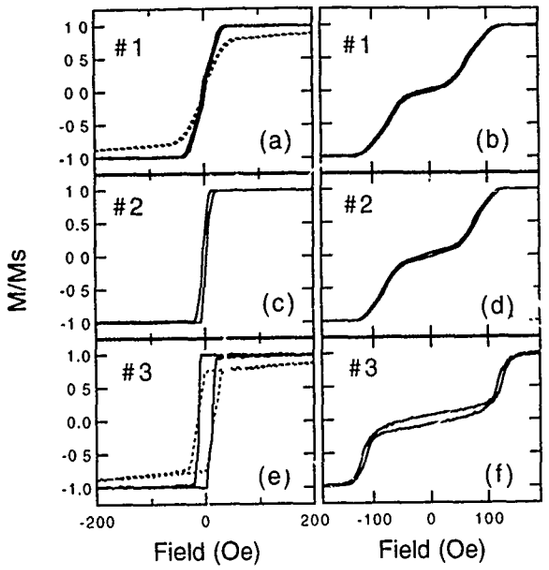

FIG. 2. AGFM magnetization measurements (300 K) for 10×[Co (6 Å)/CoAl (t Å)] along the different crystallographic directions. (a), (c), and (e) [1$\bar{1}$0] (full line) (b), (d), and (f), [110], and (d) and (e) ⟨100⟩ (dotted line). The CoAl thickness t is varied: 5 (No 1), 10 (No. 2), and 15 Å (No 3).

The samples with 5 Å CoAl spacers [Figs. 2(a) and 2(b), No. 1] exhibit a steplike M-H behavior with very little remanence in all directions. A difference between the two orthogonal ⟨110⟩ directions is visible. One of these directions has a saturation field which is a factor of 3 larger (Hs[110] =120 Oe, 9.55 kA/m) compared to the orthogonal [1$\bar{1}$0]. With increasing thickness of the CoAl spacers {No. 2: 10 Å [(c),(d)] and No. 3: 15 Å [(e),(f)]}, the uniaxial anisotropy becomes more pronounced. The remanence of the [110] direction increases to nearly 100% ($Mr=Ms$) for CoAl≈15 Å, while a steplike hysteresis with small remanence is observed in the orthogonal direction. The ⟨100⟩ directions represent a hard magnetic axis of the thin film as illustrated by

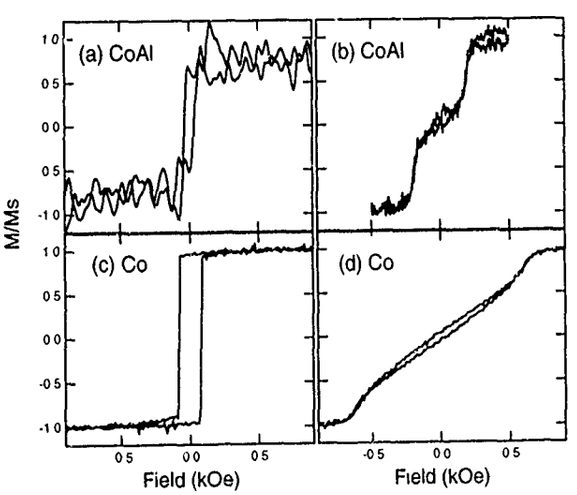

FIG 3 AGFM magnetization measurements (300 K) and for (a) and (b) 60 Å CoAl and (c) and (d) 36 Å Co along (a) and (c) [1$\bar{1}$0] and (b) and (d) [110]

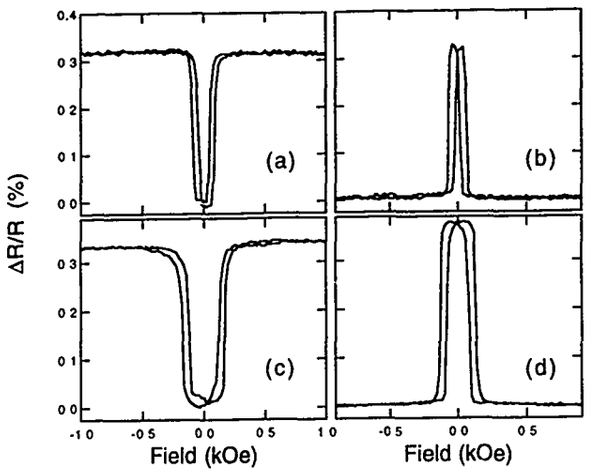

FIG. 4. Room-temperature magnetoresistance data from two Co/CoAl multilayers [(a) and (b), No. 1 and (c) and (d), No. 2; see text and Fig. 2] with different CoAl thicknesses. In all cases the applied magnetic field (H) is orthogonal to the easy axis ([1$\bar{1}$0]), and either (a) and (c) orthogonal or (b) and (d) parallel to the current direction.

the dotted curves in Fig. 2 [(a) and (e)]. Similar uniaxial anisotropic behavior has been observed for single layers of Fe[11] on GaAs (110) and Co[4] on GaAs (001).

Besides the thickness of the CoAl spacer layer, its magnetic properties will influence the magnetic and transport behavior of the heterostructure. It is known[12] that Co-rich CoAl behaves ferromagnetically. AGFM measurements (300 K) on a 60 Å thick CoAl layer on AlAs/GaAs show a very weak ferromagnetic behavior of about 17 emu/cc [Figs. 3(a) and 3(b)]. We also tested a 36 Å thick Co layer on a CoAl template. RHEED showed a complex pattern of additional spots indicating structural changes in the cobalt layer. AGFM measurements of this sample are shown in Figs. 3(c) and 3(d). These thicker, single layers of Co and CoAl display the same in-plane anisotropic behavior as the Co/CoAl multilayers discussed above.

Figure 4 shows the in-plane magnetoresistance curves (300 K) for samples No. 1 and No. 3 (see Fig. 2). The magnetic field is applied perpendicular to the easy direction. When the current is along the easy axis (and orthogonal to the applied field), the resistance increases from its zero-field value to its saturation value (+0.3%) [Figs. 4(a) and 4(c)]. When the current and the applied field are parallel, the resistance at saturation is about 0.3% lower than the zero-field resistance [Figs. 4(b) and 4(d)]. In each case, when the magnetic field is applied in the direction of the easy axis, the resistance of the film does not change appreciably around $H=0$. For the measurements repeated at 77 K identical results were observed. This resistance behavior is attributed to a combined effect of domain wall and carrier interaction and Lorentz magnetoresistance.[13] In the case of resistance decrease, the internal Lorentz magnetoresistance is removed at saturation. In the case of resistance increase, a larger Lorentz action is present at saturation. The influence of the domain (wall) structure on the resistance can be important, but the actual domain configuration is unknown at present.

IV. SUMMARY

The epitaxial growth of Co/CoAl multilayers on AlAs/GaAs is described, using CoAl as a template for cobalt epitaxy. The crystallographic structure of the Co layers is unclear at present. From RHEED and lattice matching considerations bcc Co is expected but thicker Co layers are probably fcc. Co/CoAl multilayers with various CoAl thickness all show in-plane magnetic anisotropies along ⟨110⟩. Magnetoresistive effects at low fields are ascribed to domain-wall effects and internal Lorentz magnetoresistance.

Investigations of the interplay between crystalline and magnetic ordering in Fe_3O_4/NiO superlattices

Using SQUID magnetometry and both x-ray- and neutron-diffraction techniques, we have studied the structural and magnetic ordering of a series of Fe_3O_4/NiO superlattices grown by MBE. X-ray diffraction reveals that the superlattices are coherent, single phase crystals with narrow interfaces. Symmetry differences between the Fe_3O_4 spinel and NiO rocksalt structures lead to interfacial stacking faults, manifested in some diffraction intensities. Analysis of the neutron-diffraction spectra show that the NiO antiferromagnetic ordering is coherent through several superlattice bilayers, while the Fe_3O_4 magnetic ordering is confined to individual interlayers by stacking faults in all superlattices but those with thinnest ($\leq$10 Å) NiO interlayers. Neutron diffraction and SQUID magnetometry have been used to study the Fe_3O_4 Verwey phase transition in thin-layered superlattices. The charge ordering in superlattices such as $[Fe_3O_4$ (75 Å)$|$NiO (9 Å)$]_{500}$, below the Verwey transition, directly observable in (4, 0, 1/2) neutron intensities, indicates a shift to higher temperature of the charge ordering transition from the bulk Fe_3O_4 T_{Verwey} at 123 K. We also describe ongoing efforts to extract the moment distribution in these superlattices from field dependent high-angle neutron diffraction.

I. INTRODUCTION

We report recent studies of the magnetic ordering in multilayers composed of iron oxide and nickel oxide. The iron oxide is prepared in the magnetite spinel (Fe_3O_4) phase which orders ferromagnetically, and the nickel oxide in its rocksalt-structured cubic phase which orders antiferromagnetically. Both of these materials order magnetically with short-range coupling, allowing us to study effects due to the local interfacial magnetic coupling and interfacial-driven strain. Studies of the structural and magnetic ordering of these layered materials have been performed by combining SQUID magnetometry with neutron- and x-ray-diffraction techniques.

II. CRYSTAL GROWTH AND CHARACTERIZATION

For this work oriented single-crystalline thin films of NiO and Fe_3O_4, and superlattice structures composed of these two materials, have been grown on polished (100)-oriented MgO substrates using oxygen plasma-assisted molecular-beam epitaxy.[1] NiO, MgO, and Fe_3O_4, each cubic crystalline structures, exhibit good pseudomorphic growth on each other due to the small lattice mismatch (0.3%–0.9%) among the cubic rocksalt structure of NiO and MgO and the half spacing of the cubic spinel Fe_3O_4 structure. These single-crystal structures have excellent repeat regularity and high crystalline coherence. The high degree of superlattice coherence is observable in data taken for x-ray (400) and neutron (222) peaks, in Fig. 1, for scans along the crystal growth direction for a $[Fe_3O_4$(75 Å)$|$NiO(9 Å)$]_{500}$ superlattice. The sharpness of the interfacial structures formed is indicated by the large number of superlattice sidebands, and the fact that the peaks do not broaden with increasing Q is a function of the high repeat regularity of the superlattices. The growth mode and structure of these films has been studied using x-ray, neutron, and *in situ* electron diffraction, with supportive work done using electron microscopy.[1–3] We report briefly the characterization of our films with these methods, and then address the present work.

X-ray and neutron diffraction indicate that individual layers down to 8.5 Å thick grow single crystalline, with the in-plane lattice spacing expanded to align in registry with the MgO substrate lattice. This is accompanied by a small layer-thickness-dependent tetragonal lattice distortion due to the

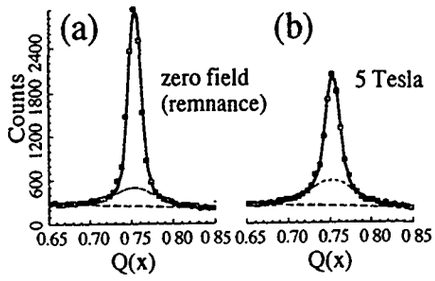

FIG. 2. Intensity profiles for (111) neutron reflection along [100] from a $[Fe_3O_4(33\ Å)|NiO(67\ Å)]_{300}$ superlattice at 30 K (a) at zero field (in remnance) and (b) at 5 T applied field. The dashed line is the Gaussian fit to the intensity of the broad (Fe_3O_4) component, and the solid line is the sum of the two (NiO and Fe_3O_4) Gaussian fits. Note the trends in the broad (Fe_3O_4), and narrow (NiO) components with field.

epitaxial and interfacial lattice mismatches.[2] The crystalline coherence of the layered structures are long range (>1500 Å),[1,2] although coherence of the Fe_3O_4 layers across intervening NiO interlayers (of thickness ≥15 Å) is limited by interfacial stacking faults. Although the underlying oxygen sublattice in the NiO and Fe_3O_4 structures is continuous across the interfaces, alignment of Fe tetrahedral sites in Fe_3O_4 is not uniquely defined with respect to that oxygen sublattice, and thus there is not a unique alignment of Fe_3O_4 unit cells across the intervening NiO spacer layers. The accompanying reduction in Fe_3O_4 coherence has been modeled[3] using a Hendricks–Teller description of the stacking faults.[4]

III. NEUTRON DIFFRACTION

Neutron diffraction indicates that the NiO orders antiferromagnetically in alternating (111) planes with a magnetic coherence that extends over several superlattice bilayers, and that coupling to adjacent Fe_3O_4 layers with a higher (T_c=858 K) ordering temperature causes an enhancement in the NiO Néel temperature above bulk T_N (520 K) in thin-layered superlattices.[2,3] The Fe_3O_4 magnetic coherence is limited to individual layers in all superlattices but those with the thinnest NiO interlayers by the structural stacking faults. The nature of this extended coherence in thinnest NiO-layered superlattices is not entirely understood. Although the highest temperature accessible with those studies (675 K) is far below the Fe_3O_4 Curie Temperature in the films, the results indicated that the NiO ordering enhancement is consistent with a mean field-type model that includes strong magnetic coupling across the interfaces.[3]

In the present work, one of our studies focused on the magnetic ordering of layered Fe_3O_4 and NiO structures as a function of applied field between 0 and 5 T. The studies were performed on BT-9, a triple-axis spectrometer at the National Institute of Standards and Technology reactor. During the experiments, the superlattices and thin films were aligned with the surface normal [400] and one of the [022] in-plane axes in the scattering plane to allow access to the (222), (111), and (022) reflections. The normal to the scattering plane (the [0$\bar{2}$2] direction) is chosen to be the externally applied field direction. We find changes with increasing field in the (111) and (022) neutron reflections, comprised in part from the magnetic scattering from the individual Fe_3O_4 and NiO layers. These changes suggest that the spins reorient with respect to the applied field direction in a manner consistent with bulk results. Figure 2 shows intensity profiles along [100] for the (111) reflection from a $[Fe_3O_4$ (33 Å)|NiO (67 Å)$]_{300}$ superlattice (a) at zero applied field (in remnance) and (b) at 5 T.

Because of the short-range magnetic ordering of the Fe_3O_4 layers and the long-range ordering of the NiO layers within the superlattices, the (111) neutron reflection intensity can be separated into two overlapping profiles, one short and broad, and the other tall and narrow.[3] The former has a large contribution from the Fe_3O_4 ferrimagnetic ordering, and the latter is due entirely to NiO antiferromagnetic ordering. In the superlattices, the NiO peak intensity decreases, and the Fe_3O_4 intensity increases, with increasing applied field. These changes in intensity may indicate an in-field low-energy state for the NiO layers with moments aligned perpendicular to the applied field (and probe direction), while in the Fe_3O_4 layer moments align parallel to the applied field. Neutron scattering also indicates that the saturation fields for these samples are larger than in bulk. In addition, in the superlattice spectra, Fe_3O_4 neutron linewidths show no change with field, but the NiO peak shows a small but consistent broadening trend with increasing field. This broadening indicates a reduction of NiO coherence length and domain size with increasing field. An equivalent broadening of neutron reflections with increasing field is not seen in either bulk or single-thin-film NiO samples.

Another sequence of studies we performed dealt with the influence of superlattice layering on the Verwey transition manifested in the iron oxide layers. The interlayer coupling and strain of the superlattice structure affects temperature and form of the Fe_3O_4 Verwey transition, a magnetic, conductivity, and structural transformation that accompanies a charge ordering of the Fe^{+3} and Fe^{+2} ions in magnetite. The Fe_3O_4 Verwey transition in the bulk (~123 K) is highly sensitive both to the exact stoichiometry of the iron oxide and to the presence of strain, and is accompanied by a lattice distortion to an orthorhombic structure, a large step downward in electron conductivity, and a shift in magnetic anisotropy, as the sample is lowered below the ordering temperature in the iron spinel materials.

Recently, Aragon *et al.*[5] have used neutron-diffraction techniques to investigate the Verwey transition in bulk Fe_3O_4, on single-crystalline samples of about 1 cm^3 volume. One sample in their study was prepared with exact Fe_3O_4 stoichiometry, while another was deficient in iron ($Fe_{3-\delta}O_4$ with δ=0.006). The charge ordering was manifested by the presence of reflections which appear below the Verwey transition (T~123 K) at the ($4n$, 0, 1/2) positions. The line shapes and temperature dependence of these peaks were used to study the nature of the charge ordering of the below-Verwey state. The charge ordering present below the transition temperature loses its long-range coherence due to lack of available charge in the nonstoichiometric sample, as evidenced by a broadening of the peak line shape, and a smear-

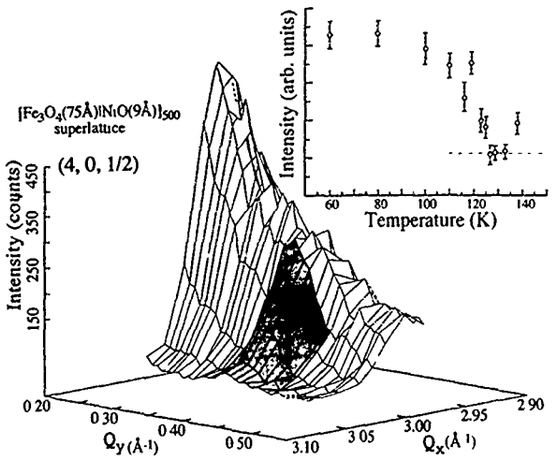

FIG. 3. Two-dimensional plot of the intensity for neutron reflection around the (4, 0, 1/2) peak at 80 K for scattering from a $[Fe_3O_4(75\ Å)|NiO(9\ Å)]_{500}$ superlattice. The reflection is partially obscured by a ridge of intensity due to the (400) reflection from the MgO substrate, and appears as a shoulder on the edge of the ridge (shaded area). Inset: Temperature dependence of the (4, 0, 1/2) reflection. The total intensity decays to the ridge background intensity (dashed line), indicating the extinction of the reflection peak intensity by 127 K

ing and lowering of the transition temperature, when compared to the pure Fe_3O_4 sample.

We have performed comparable measurements to probe the Verwey transition in a small subset of our grown films and superlattices,[6] which have a sample volume a factor of 1000 times less than those used by Aragon *et al.* The charge ordering, manifested by the appearance of the (4, 0, 1/2) peak, is seen both for a thick (3 μm) Fe_3O_4 film and for one of our superlattices, a sample containing very thin NiO layers—$[Fe_3O_4\ (75\ Å)|NiO\ (9\ Å)]_{500}$. Figure 3 shows the (4, 0, 1/2) peak for this latter sample superimposed on an intensity ridge associated with the MgO substrate (400) peak. The data in the figure were taken at 80 K, well below the Verwey ordering temperature. The inset in Fig. 3, also for the $[Fe_3O_4\ (75\ Å)|NiO\ (9\ Å)]_{500}$ superlattice, shows the integrated intensity of the (4, 0, 1/2) peak as a function of temperature near the Verwey transition. We can track this intensity to obtain an order parameter for the Verwey charge ordering, and obtain a transition temperature of about 128 K, several degrees above the bulk stoichiometric T_{Verwey}. Resolution limits do not allow for a full determination of whether the Verwey charge ordering is truly long range.

The amplitude of the temperature-dependent (4, 0, 1/2) peak follows another signal of the Verwey transition quite well: SQUID measurements at low applied fields (~1000 Oe) of the moment in the film, a technique for probing the Verwey transition first employed by Weiss and Forrer.[7] This method also gives a transition temperature for the superlattice *increased* to about 128 K. Since only a depression of the transition temperature due to nonstoichiometric samples has been previously observed, either by Aragon *et al.*[5] or in earlier work by Honig and co-workers,[8] we feel it is likely that the increase seen here is due to the strain in the superlattice, an effect which is being studied further.[6] For other superlattice samples, the ordering due to the Verwey transition with increasing NiO layer thickness is found to be entirely suppressed by the superlattice structure, and may be further evidence of increasing strain in the Fe_3O_4 layers.

We conclude that neutron diffraction, when supported by other complementary techniques, shows strong evidence for the influence of interfacial coupling and strain on the magnetic and structural ordering of layered iron oxide and nickel oxide heterostructures. The magnetic-field response of the ordering shows modifications from bulklike behavior influenced by interfacial coupling. Also, the Verwey transition, clearly associated with both structural and magnetic ordering effects, is *shifted to higher temperature* in the thin NiO-layered superlattice, and entirely suppressed in thicker NiO-layered samples.

Epitaxial $Y_3Fe_5O_{12}$(YIG)/$Bi_3Fe_5O_{12}$(BIG) and YIG/$Eu_1Bi_2Fe_5O_{12}$(EBIG) heterostructures have been grown on [111] oriented single-crystalline gadolinium-gallium-garnet substrates by pulsed laser deposition. The effects of the layer thickness ratios on the composition, microstructure, and magnetic properties of the films have been studied employing x-ray diffraction, Rutherford backscattering spectroscopy, vibration sample magnetometry, and Kerr magnetometry. All films under investigation are single crystalline, in the [111] orientation. The multilayered heterostructures displayed superior magnetic properties in comparison to their single crystalline monolayer counterparts, deposited at the same conditions. The YIG/BIG heterostructures indicate increased in-plane saturation magnetic moments, approaching the maximum saturation value in bulk YIG. The YIG/EBIG heterostructures show a definite reorientation of the magnetic moment in the out-of-plane direction, a new set of increased saturation magnetization values that go even above that recorded for the bulk YIG, as well as an increase in coercivity.

The magneto-optical rewritable media embody the combination between the relatively infinite writing capability of a magnetic material with the mechanical system stability of an optical reading device and the high recording density of an optical medium. However, this imposes new constraints on the properties of these novel materials, as well as raising new challenges from a materials science point of view. Such requirements as perpendicular magnetic anisotropy, large magnetic coercivity, stable material structure, good corrosion resistance, low medium noise, fairly low Curie temperatures, and high magneto-optical effects are just a few in a large list. The launch of the first generation of commercially viable rewritable magneto-optical devices has already increased the storage capacity of the 3.5 in. disk format by an order of magnitude, compared to magnetic floppies. Yet this first generation of magne o-optical media is operating in the long-wavelength (infrared) range of the spectrum, intrinsically implementing a density limit on the read information (since the physical size of the data unit is diffraction limited by the wavelength of the reading radiation). The operation of the present media in a lower wavelength regime (such as green or even blue radiation) is made impractical by the low magneto-optical effect response of the material. Hence new materials are being considered for the next generation of magneto-optical storage media.

Three material systems are considered the front runners on the list of new potential candidates for magneto-optical applications: the rare-earth transitional metal alloys, the Co/Pt multilayers, and the ferrimagnetic iron garnets. Each of these systems offer attractive features, while displaying a series of disadvantages.

The rare-earth iron garnets have the highest magneto-optical response in the green blue range, display an unsurpassed corrosion resistance, and the rather loose structure, while extremely complicated, is capable of accommodating a large variety of ionic species. Furthermore, the position of the ions in the structure, being solely determined by the ionic radius, is completely unambiguous (such as in the spinel structure). Among the disadvantages, one can cite the high deposition temperature of the garnet phase and the relatively low signal-to-noise of the polycrystalline garnet films.

A large variety of chemical species may be substituted in the garnet lattice, resulting in different magnetic and magneto-optical properties. Because the garnet structure contains four sublattices, of which the oxygen sublattice is common to all garnets, an epitaxial deposition of layers of garnets with different compositions can easily be achieved.

We have grown by pulsed laser deposition (PLD) a series of thin-film superlattice heterostructures of rare-earth iron garnets, on [111] oriented single crystalline paramagnetic gadolinium-gallium-garnet (GGG) substrates. Layers with the following stoichiometries were grown: $Y_3Fe_5O_{12}$(YIG), $Bi_3Fe_5O_{12}$(BIG), and $Eu_1Bi_2Fe_5O_{12}$(EBIG). A 248 nm KrF excimer laser, with an energy density of 3.3 J/cm^2 and a frequency of 10 Hz, was used for film depositions. The depositions were carried out in O_2 ambient at pressures between 100 and 700 mTorr, and temperatures were between 500 and 800 °C for all single layer structures. The multilayer films were all grown at 600 °C for reasons out-

 0021-8979/94/76(10)/6287/3/$6.00 © 1994 American Institute of Physics

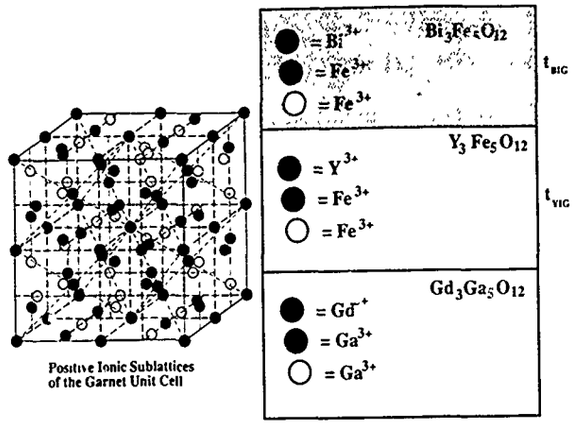

FIG. 1. Typical two layer YIG/BIG heterostructure with the corresponding unit cell.

lined elsewhere.[1] All films were cooled at an average 10 °C/min, in an O_2 ambient with a pressure of 1 atm.

Figure 1 shows a typical two layer YIG/BIG heterostructure with the corresponding unit cell. For simplicity, only the positive ions positions are shown. Note that in going from the YIG layer to the BIG layer, the composition changes solely by substituting Bi^{3+} ions in all Y^{3+} positions, without changing the unit-cell symmetry from one film to another.

Before growing thin-film heterostructures, we had to calibrate the laser system and optimize the different garnet structures' deposition conditions. As part of the initial calibration experiments we tried to replicate the results of a similar study on epitaxial growth of YIG on single crystalline GGG by PLD announced previously in the literature.[2] In their report, Dorsey *et al.* indicated that the variation of deposition ambient oxygen pressure affected the anisotropy direction, such that a low oxygen pressure growth generated an in-plane magnetic anisotropy while a high-pressure deposition led to an out-of-plane anisotropy. We have deposited single crystalline single layers of YIG on GGG, at 800 °C, and at ambient pressures of 100, 200, and 700 mTorr, respectively. Figure 2 shows the three hysteresis loops for in-plane (VSM) measurements (made by applying a magnetic field parallel to the surface of the film). A close study of the figure reveals that while the saturation magnetization of the low-pressure specimen (100 mTorr) is the lowest of the three, its hysteresis loop displays the most squareness. The saturation magnetization values of the three films do not show a systematic variation with pressure. Dorsey *et al.* hinted that the reduction of the in-plane magnetization loop squareness could be associated with a change in anisotropy direction as a function of deposition ambient pressure.

Figure 3 shows the results of the out-of-plane VSM measurement of the three variable deposition pressure samples. The comparison of these hysteresis loops with the ones in Fig. 2 indicate that for all three specimens the anisotropy is in plane. Although the 700 mTorr film displays a relative squareness of the loop, the low saturation values and the high applied field required to achieve an out-of-plane saturation suggest that the increased O_2 pressure during deposition is negatively affecting the magnetic behavior of the single crystalline YIG films grown at 800 °C on GGG substrates. Hence we carried all our depositions at 100 mTorr ambient pressure.

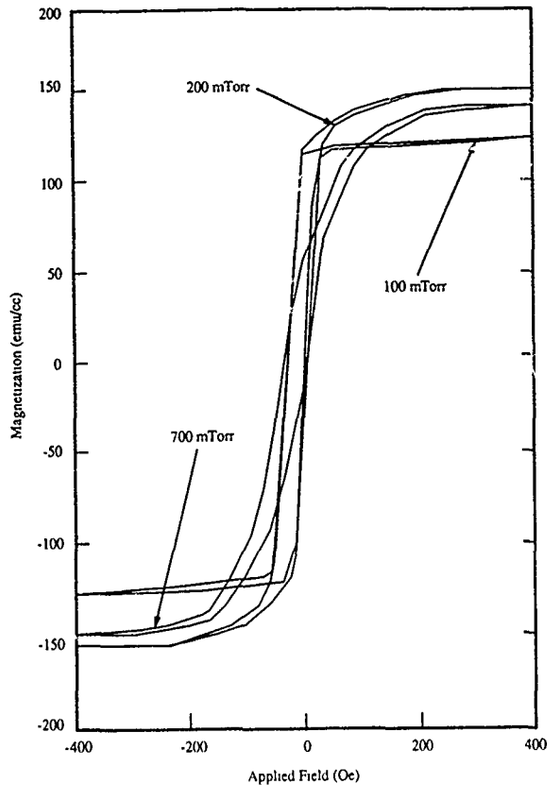

FIG. 2. The three hysteresis loops for in-plane (VSM) measurements.

The x-ray θ-2θ measurements were made normal to the film surface. As indicated elsewhere,[3] the x-ray spectra consistently contained only two peaks: the [444] peak of the garnet film phase and the [444] peak of the garnet substrate phase. The conclusion of these experiments is that, even if the films are polycrystalline, all the grains are oriented such that the [111] direction is normal to the film surface.

It was noted that the saturation magnetizations of the multilayer heterostructures do not follow the rule of mixtures using as limits the bulk values (of the single layers grown at the same temperature), but rather using as the upper limit the bulk value for YIG grown at 800 °C. A close study of the x-ray-diffraction pattern also shows that the out-of-plane lattice parameter of the YIG layers varies with the YIG content of the 600 °C heterostructures, approaching the lattice parameter of the YIG monolayer deposited at 800 °C, not of the one grown at 600 °C.[1]

The YIG/BIG series, while generating some very encouraging results, could not be considered as potential materials for magneto-optical applications, since the anisotropies of all of the samples were in plane.

The role played by partial substitution of the ions occupying the dodecahedral sublattice of the garnet structure with rare-earth atoms has been widely investigated.[4,5] Of the rare earths, Sm, Eu, and Tb are known to give high positive K_u values in substituted garnets $R_{3-x}Bi_xFe_5O_{12}$, while Y, Gd, and Dy generate small K_u values. We have attempted to sub-

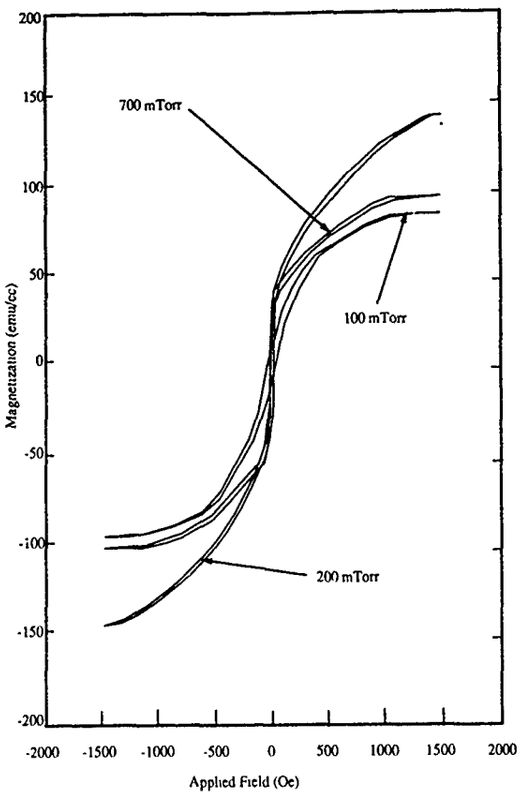

FIG. 3. The results of the out-of-plane VSM measurement of the three variable deposition pressure samples.

stitute one Eu^{3+} ion/formula unit, and deposited a new heterostructure series by growing alternating YIG and EBIG single crystalline layers.

The immediate effect of replacing one third of the Bi ions in the BIG structure by Eu ions is the change in anisotropy direction of the EBIG films, of similar thickness, from in plane to out of plane. The addition of Eu also seems to increase the coercive field.

Figure 4 shows a comparison of out-of-plane hysteresis loops of four multilayer EBIG/YIG films. Similar to the YIG/BIG series, the overlaying of YIG and EBIG monolayers produces increased saturation values. The increments appear to linearly follow the content of YIG. The highest saturation value is achieved for a ratio of 5:1 between the YIG layers and the EBIG layers thicknesses, while the lowest saturation magnetization is achieved for the film containing excess EBIG in a ratio of 3:1 to YIG. Note that while the value of the saturation goes up with the YIG content, the squareness of the hysteresis loops is also reduced, indicating an apparent change in the magnetic anisotropy direction from out of plane to in plane. This is consistent with the total composition of the film, which approaches the YIG single layer condition. In contrast, the films containing excess EBIG show decreasing saturation magnetization with the increased EBIG content, as they approach the EBIG single layer condition. At the same time, the films containing excess EBIG have displayed increased coercivity values in comparison to the specimens with large YIG content.

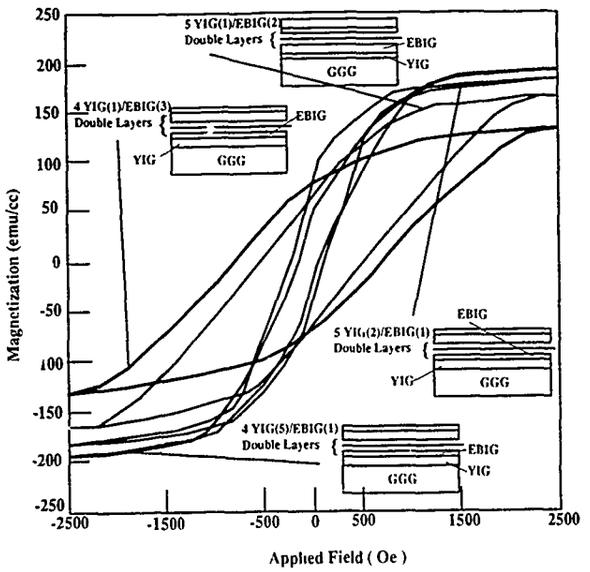

FIG. 4. A comparison of out-of-plane hysteresis loops of four multilayer EBIG/YIG films.

A magneto-optical hysteresis loop of a thin-film superlattice which has a ratio of EBIG to YIG layer thicknesses of 3:1 showed the best Kerr effect response in the series. The maximum rotation angle measured is 13 250 deg/cm, while the coercivity is 1.10 kOe. The values measured for coercivity during the Kerr rotation analysis are usually larger than those measured by VSM. This can be explained by the highly localized interaction with the specimen of the Kerr measurement and by the averaging character of the VSM analysis.

The exact effect of Eu addition on the magnetic and magneto-optical properties of the YIG/EBIG series are not completely understood at the present time. In contrast to the YIG/BIG series, the x ray of the YIG/EBIG series did not show any kind of structural fluctuation as a result of thickness modifications in the constituent layers. The tendency of the EBIG rich heterostructures to have high coercivities and a distinct out-of-plane anisotropy can be linked to the Eu substitution. However, further detailed measurements of new films must be carried out before we can conclusively decide if the observed effects are due solely to the Eu addition, to an increased stress in the film structure, or to a combination of factors.

Mn-VI/II-VI superlattices belong to the family of artificial multilayered structures composed from zinc-blende II-VI semiconducting compounds and Mn chalcogenides using MBE and ALE. While all naturally existing crystals of MnTe have the NiAs (hexagonal) structure, the zinc-blende form is a fcc Heisenberg antiferromagnet with dominant nearest neighbor interactions. The magnetic properties of such frustrated systems are strongly influenced by lattice mismatch strain. For example, *tensile* strain produces an incommensurate helical antiferromagnetic phase with an *in-plane* axis.[1] The strain and therefore helical period increases with thickness of CdTe, but in the presently studied samples is weak enough to allow investigation of the onset of incommensurate helical effects. In previously studied MBE-grown Mn-VI/Zn-VI systems,[1,2] the nonmagnetic spacers were too thick to allow interlayer coupling. We report neutron diffraction studies of new MnTe/CdTe superlattices prepared by ALE with extremely thin CdTe spacers (from 2 to 6 monolayers). The results indicate the formation of spin helices, consistent with the tensile nature of strain in the MnTe layers. In addition, the widths of the AF diffraction peaks and the presence of satellite peaks clearly indicate that the magnetic interactions propagate through the CdTe spacers, introducing coherence between the helices in different MnTe layers. The nature of the interaction responsible for this transfer is not yet clearly understood. Some possible mechanisms are discussed.

We report neutron diffraction studies of magnetic correlations in MBE-grown (111) EuTe/PbTe multilayers. Bulk EuTe is a type-iI fcc antiferromagnet. This structure consists of ferromagnetic (FM) sheets of spins on (111)-type planes which are coupled antiferromagnetically to one another. In EuTe/PbTe the lattice mismatch strain selects an arrangement of the FM sheets parallel to the multilayer plane. Thus, in the case of an odd number of EuTe monlayers, there should be a nonzero magnetic moment—in other words, such superlattices are expected to behave as ferrimagnets, not anitferromagnets. This has been confirmed by recent SQUID studies.[1] As suggested by the above model, the dipolar fields arising from the lack of total moment compensation may introduce interlayer magnetic coupling, even though in this system there are no carriers that can transfer magnetic interactions across the nonmagnetic spacers through the RKKY mechanism, which is usually the case in coupled magnetic multilayered systems. Our experiments have indeed revealed clear magnetic superlattice peak patterns in several samples. The results of measurements in high external fields (up to 6 T) bring further support for the dipolar nature of the observed interlayer coupling. However, in some contrast to the expected scenario, the most pronounced coupling effects were seen in the case of an even number of monolayers. Possible explanations of this fact (e.g., higher-order terms in dipolar fields, or structural imperfections) are discussed.

We present heat capacity and magnetic measurements of antiferromagnetic (AFM) CoO/$Ni_{0.5}Co_{0.5}O$ superlattices grown by reactive sputtering. X-ray data verify the structure and the high quality of the superlattice. Neutron-diffraction studies of similar superlattices have shown AFM ordering through several bilayers despite the short-range nature of the spin interaction in the constituent materials.[1] We have recently developed a unique thin film microcalorimeter capable of measuring thin films from 1.5 K to well above room temperature,[2] permitting specific heat measurements on these superlattices for the first time. Magnetic measurements were made by coupling the superlattices to a 30 nm $Ni_{81}Fe_{19}$ overlayer and measuring the temperature dependence of the exchange anisotropy field. We examine the effect of exchange coupling at the interfaces by varying the thickness of the bilayers and their constituents. When the layers of the CoO/$Ni_{0.5}Co_{0.5}O$ superlattice are thin, we observe a single broad heat capacity peak at a temperature between the Néel temperatures of bulk CoO and $Ni_{0.5}Co_{0.5}O$. This peak is at a temperature that corresponds to the superlattice magnetic blocking temperature, the temperature at which the exchange field goes to zero. For thicker layers, we observe the disappearance of the superlattice peak, and the emergence of two broad peaks close to the individual Néel temperatures of CoO and $Ni_{0.5}Co_{0.5}O$. We compare the temperature dependence of the specific heat of the superlattices to various models.

Exchange coupling, interface structure, and perpendicular magnetic anisotropy in Tb/Fe multilayers (abstract)

J. Tappert, J. Jungermann, B. Scholz, R. A. Brand,
and W. Keune
Laboratorium für Angewandte Physik, Universität Duisburg, D 47048 Duisburg, Germany

Tb/Fe multilayer films are known to show perpendicular magnetic anisotropy (PMA), which is interesting for potential applications in magneto-optical data storage. We demonstrate by using ^{57}Fe Mössbauer probe layers and x-ray diffraction that part of the Tb-deposited-on-Fe (Tb/Fe) interface remains chemically sharp and crystalline bcc Fe. This part is associated with an unexpectedly strong antiferromagnetic exchange coupling of the Fe to the Tb layers. We find by using both conventional and circularly polarized radiation that part of the interface and core bcc Fe but none of the amorphous Fe is strongly coupled to Tb. This behavior is qualitatively explained by a structural model including regions with a sharp Tb/bcc-Fe interface, where PMA originates from Tb ions that experience the broken symmetry of the crystal electric field at the interface. The extrapolated isomer shift at $T=0$ K of the amorphous phase located at the Fe-deposited-on-Tb (Fe/Tb) interface was found to be different from that of the amorphous phase located at the Tb/Fe interface, suggesting a different amorphous structure at both interfaces.

Interfacial contributions to magnetic anisotropy in metal/semiconductor systems (abstract)

B. T. Jonker, H. Abad, and J. J. Krebs
Naval Research Laboratory, Washington, D.C. 20375-5343

It has been empirically established that the net anisotropy exhibited by even a simple metal epitaxial film is strongly effected by the interactions at the metal/semiconductor interface, although the mechanisms have not been systematically addressed and remain an open issue. An Fe(001) film, for example, is expected to exhibit a four fold symmetry in the in-plane magnetic anisotropy, consistent with the crystalline surface symmetry. Such films grown on a bulk GaAs(001) surface, however, exhibit a significant uniaxial anisotropy (twofold symmetry). It has been speculated that this uniaxial anisotropy arises from the strongly directional bonds of the substrate surface, based on a model that assumes a bulk-terminated, unreconstructed zinc-blende (001) surface.[1] This model fails to explain, however, the nearly ideal fourfold symmetry observed for similar Fe(001) films on the ZnSe(001) surface,[2] which has an identical crystalline structure as GaAs and differs in lattice constant by only 0.25%. We propose here a conceptual model to account for these pronounced differences, which describes how contributions to the net magnetic anisotropy arise from the formation of the interface and early stages of the metal film growth. We suggest that these contributions originate in the initial metal adsorption sites and subsequent bond or site filling, and are strongly dependent on the semiconductor surface reconstruction. We compare this model with results for Fe growth on several surface reconstructions.

We report the measured atomic and magnetization densities of a nickel twist grain boundary averaged over its lateral dimensions as a function of distance from the interface plane. The presence of a reconstructed interface region (the grain boundary) sandwiched between two single-crystal nickel films that were hot-pressed together was confirmed with grazing incidence x-ray diffraction. From reflection data taken using unpolarized neutrons, the atomic density profile of the grain boundary was determined to be (85±5)% of the bulk density when averaged over twice the grain-boundary width of (8±1) nm. Using this information in conjunction with the reflectivity data taken from the nickel sample with polarized neutrons reflection, the magnetic moment of a nickel atom was found to be between 18% and 52% larger in the twist grain boundary than in the bulk. The enhancement of the magnetic moment at the grain boundary is believed to result from the reduced atomic density of the interface region. Owing to this reduction in density, the magnetization density of the nickel interface is only somewhat enhanced, about 10%, compared to that of bulk nickel.

I. INTRODUCTION

Interesting magnetic behavior with great technological potential has been observed in a number of materials, particularly those containing a large fraction of internal interfaces. For example, interfaces play an important role in the giant magnetoresistance[1] and magnetic anisotropy[2] of some nanocrystalline and multilayered systems that may be used in future recording media or in magnetic reading and writing heads. The magnetocrystalline anisotropy of grain boundaries may determine whether a material is magnetically hard[3]—making a good permanent magnet, or soft[4]—making a good transformer core.

Considerable emphasis has been placed on studies of interfacial magnetism using calculational methods. In one calculation, Tersoff and Falicov[5] report a 34% enhancement in the magnetization of the (001) nickel surface compared to the bulk. The enhancement is a consequence of a narrowing of the *d*-orbital density of states and a dehybridization of the *sp-d* bands of nickel. These effects are attributed to the reduced coordination of a nickel atom at a (001) surface. Recently, Chrzan *et al.*[6] have calculated a reduction in the magnetization of a {111} stacking fault in nickel of about 2% compared to the bulk. They attribute the reduction to a broadening of band states caused by the close proximity of atoms in the [111] direction in the region of the stacking fault. Schaefer[7] has deduced from magnetometry measurements of consolidated ultrafined-grained nickel that the magnetic moment of nickel in the interfacial regions is reduced compared to bulk nickel. In the present work, we report an enhancement in the magnetic moment of nickel atoms in a planar grain boundary that we believe to be related to its *reduced* atomic density.

II. FABRICATION OF THE NICKEL TWIST GRAIN BOUNDARY

A. Bicrystal sample preparation

The grain boundary was manufactured by hot-pressing two thin single-crystal films of nickel to form a nickel bicrystal. An electron-beam evaporator was used to deposit nickel [Ni(1) in Fig. 1] onto the polished surface of a (001)MgO substrate heated to 825 K in a vacuum chamber with a base pressure of 10^{-5} Pa.[8] A second deposition of a mixture of naturally occurring nickel and ^{62}Ni was made onto a cleaved (001)NaCl single-crystal substrate.[9] The mass fractions of the natural nickel and ^{62}Ni used in the second deposition were chosen so that the average scattering length density of the nickel mixture was close to zero. By making the second film [Ni(2) in Fig. 1] nearly transparent to neutrons, the neutron reflectivity of the grain boundary was enhanced. During the second deposition, the NaCl crystal was

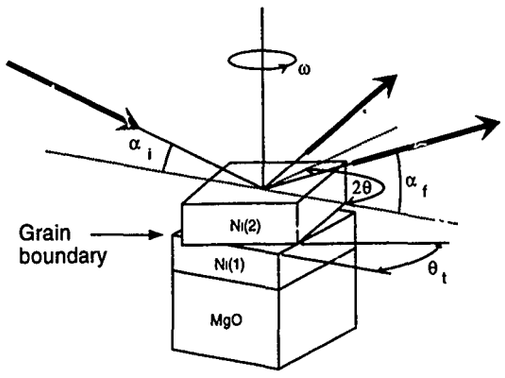

FIG. 1. Schematic diagram showing radiation incident on the nickel bicrystal at an angle of α_i, and reflected from the sample by α_f. The rotation of the sample about its surface normal is ω, and the rotation of the detector about the surface normal is 2θ. The crystal labeled as Ni(1) was grown on a MgO single-crystal substrate. The [001] edge of this crystal is misoriented by $\theta_t = 19.7°$ relative to that of the lower nickel crystal Ni(2), which was grown on a NaCl substrate.

heated to 600 K, and a potential of +1 kV was applied to the substrate relative to the vacuum chamber. After deposition, the two nickel films, with lateral dimensions of 3 cm by 3 cm, were placed face to face in a pressure cage such that the [100] edges of the films formed a twist angle of $\theta_t = 19.7°$ in the (001) plane. The twist angle for a $\Sigma = 37$ twist grain boundary, in which the positions of 1 in every 37 atoms coincide when projected onto the interface plane, is 18.9°. The small difference between the twist angles of the sample and that of a $\Sigma = 37$ boundary suggests that the boundary studied here is likely to have a special geometry with a high degree of symmetry, i.e., one with a relatively small unit cell.

After heating the substrates to 333 K, carbon monoxide was introduced into the oven at a pressure of 1 atm for 20 min. During this time, the native oxide on the nickel films was reduced into nickel carbonyl (the Mond process).[10] Next, the carbon-monoxide and nickel-carbonyl gases were evacuated, restoring the base pressure of the oven (10^{-5} Pa), and the bicrystal sintered at 773 K for 3 h. After cooling to room temperature in vacuum, the sample was removed from the pressure cage, and placed in water to dissolve the NaCl substrate. The resulting sample consisted of a grain boundary sandwiched between the two nickel crystals on the MgO substrate (see Fig. 1).

B. X-ray-diffraction measurements of the bicrystal and grain boundary

X-ray-diffraction measurements were made under conditions of grazing incidence, using the HASYLAB synchrotron in Hamburg, Germany, in order to characterize the quality of the bicrystal and grain boundary.[11] The mosaic spread of the nickel film on its MgO substrate was 1.3°, while that of the upper film, which was grown on NaCl, was 0.3°. Transmission electron microscopy of the latter film showed it to be relatively free of microtwins. The diffuse scattering of x rays reflected from the bicrystal was observed in order to determine whether the interface between the two nickel films contained voids. No modulation of the diffuse scattering with departure angle (α_f in Fig. 1) was observed, suggesting that the bicrystal interface was free of voids.[11]

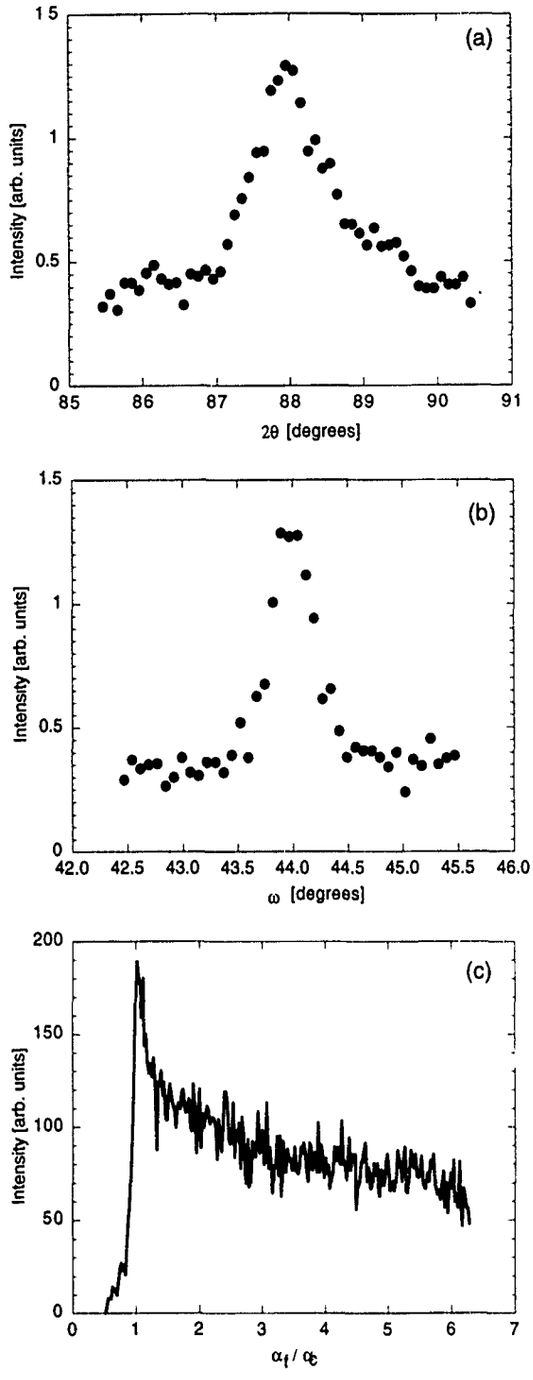

FIG. 2. The x-ray intensity measured under conditions of grazing incidence and integrated over departure angle α_f is shown as a function of (a) scattering angle 2θ, when the sample was optimized to excite a Bragg reflection from the grain boundary, and (b) sample orientation ω, when the detector was positioned at the intensity maximum in 2θ. (c) The x-ray intensity measured as a function of α_f normalized to the critical angle α_c for nickel and the radiation used, when 2θ and ω were optimized to produce a maximum of diffracted radiation. The smoothly varying profile beyond $\alpha_f/\alpha_c = 1$ is characteristic of a thin interfacial region.

A plot of the x-ray intensity integrated over the length of the position sensitive detector, i.e., α_f, as a function of scat-

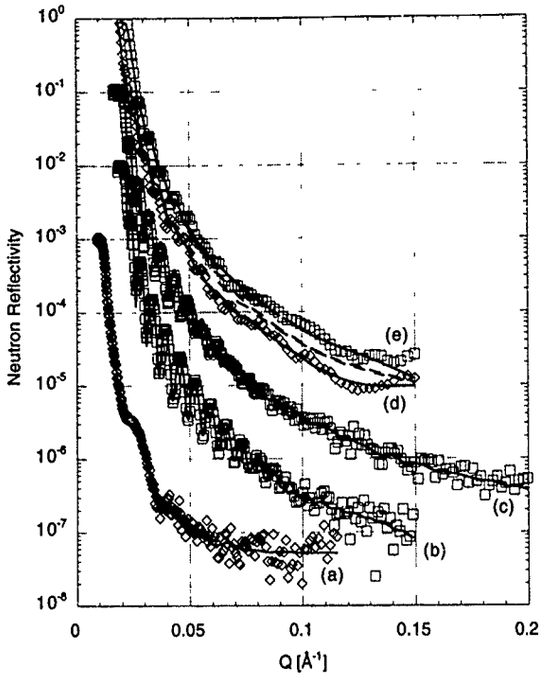

FIG. 3. The unpolarized-neutron reflectivities of the nickel films on (a) NaCl (◇) and (b) MgO (□) substrates, and (c) the nickel bicrystal (□). The solid lines for (a) and (b) were calculated from the scattering length density profiles shown in Fig. 4. The solid line for (c) was calculated using the atomic density profile of the grain boundary shown in Fig. 5(a). The polarized-neutron reflectivities for the R_- (◇) and R_+ (□) cross sections are shown in (d) and (e). The dashed lines were calculated using a magnetic moment for nickel that was constant throughout the bicrystal. The solid lines were calculated using an enhanced magnetic moment [Fig. 5(b)] at the grain boundary.

tering angle 2θ (see Fig. 1), when the sample was oriented to excite a grain-boundary reflection (one corresponding to the 12,12,0 reflection indexed in the coordinate system of a $\Sigma=37$ grain boundary) is shown in Fig. 2(a). A plot of the intensity measured as a function rotation angle about the normal to the sample surface, ω (see Fig. 1), when the detector is positioned at the intensity maximum in Fig. 2(a) is shown in Fig. 2(b). These measurements demonstrate that Bragg reflection is well localized within the reciprocal-lattice plane corresponding to the projection of atom positions onto the interface plane of the bicrystal. When the detector position and sample orientation were optimized to produce a maximum of intensity at the position corresponding to the 12,12,0 grain-boundary reflection, the rodlike intensity profile shown in Fig. 2(c) was measured as a function of departure angle α_f from the sample surface. The rodlike form is characteristic of scattering from spatially limited or thin reconstructed interfaces. The presence of the rodlike distribution of intensity at the position of a grain-boundary reflection, and its absence in single-crystal films containing no grain boundary, is evidence that the bicrystal interface had reconstructed during the sintering process to form a grain boundary.[11–13]

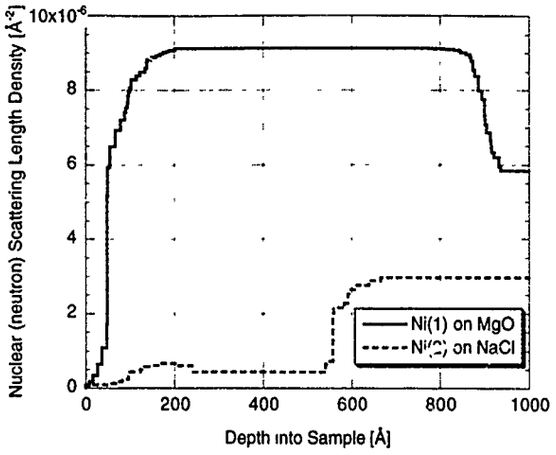

FIG. 4. The nuclear (neutron) scattering length density profiles deduced for the nickel on MgO sample (solid line) and the nickel on NaCl sample (dashed line) from fits to the reflectivity data in Figs. 3(a) and 3(b).

III. EXPERIMENTAL RESULTS AND DISCUSSION

A. The atomic density profile of the nickel grain boundary

The reflectivities of two nickel films, which were grown under conditio. s identical to those used to make the bicrystal but on different NaCl and MgO substrates, were obtained with unpolarized neutrons at the Manuel Lujan Jr. Neutron Scattering Center (LANSCE).[14] These reflectivity curves are shown in Figs. 3(a) and 3(b) (open symbols) as a function of scattering vector magnitude, $Q=4\pi\sin(\alpha_i)/\lambda$, where λ is the wavelength of the radiation (determined using the time-of-flight technique), and α_i is the angle of incidence of the radiation onto the sample surface. The scattering length density profiles $\beta(z)$, deduced as a function of depth into the nickel films from the reflectivity data, are shown in Fig. 4. The solid curves in Figs. 3(a) and 3(b) were calculated from the density profiles using the Parratt formalism.[15] From the fit to the nickel-MgO data, and using the published scattering length for natural nickel (10.3×10^{-5} Å[16]), the average atomic (number) density of the nickel film, $n_0=0.0895\pm0.0005$ Å^{-3}, was deduced. This density is somewhat less than the density of bulk nickel, 0.0913 Å^{-3}. Similar reductions in the densities of thin films compared to their bulk counterparts have been observed in other metal systems.[11,17] Using the value of n_0, the neutron-scattering length of the null scattering ^{62}Ni-nickel mixture was deduced to be $(4.8\pm0.5)\times10^{-6}$ Å (more than 20× smaller than that of natural nickel) from the fit to the nickel-NaCl data. This information is used later.

The reflectivity of unpolarized neutrons from the nickel bicrystal is shown in Fig. 3(c). In determining the scattering length density profile of the nickel bicrystal, the air-nickel and nickel-MgO interfaces of this sample were assumed to be identical to those previously determined. This assumption is reasonable, since no significant differences between the air-nickel and nickel-MgO interfaces of other similarly prepared samples have been observed. The portions of the scattering length density profile for the bicrystal that were per-

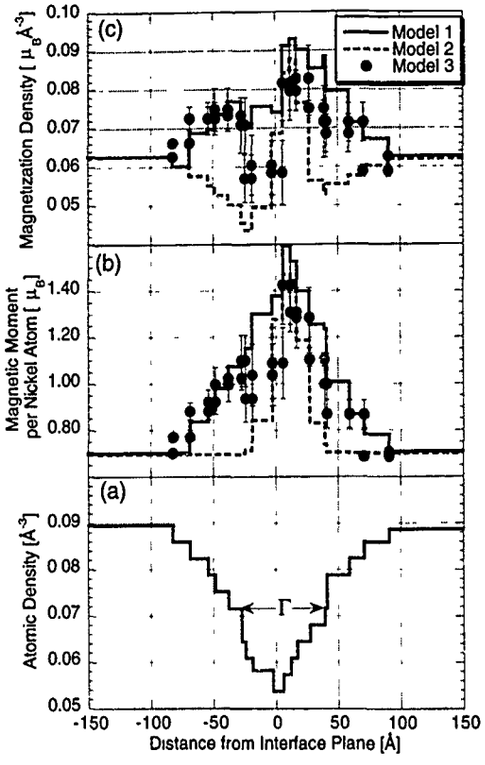

FIG. 5. (a) The atomic density of the grain boundary deduced as a function of distance away from the interface plane from a fit of the bicrystal model (described in the text) to the reflectivity data in Fig. 3(c). (b) The magnetic moment of nickel deduced as a function of distance from the interface plane for model 1 (solid curve), model 2 (dashed curve), and model 3 (●) described in the text. (c) The magnetization density of the grain boundary calculated for the three models.

turbed to fit the data were those belonging to the overall thicknesses of the two nickel films and the atomic density of the grain-boundary region. The atomic density profile deduced for the grain boundary is shown in Fig. 5(a). The reflectivity curve calculated for this model is shown as the solid curve in Fig. 3(c). The minimum density of the grain boundary, occurring at the interface plane, is (60±6)% of the film density. The full width Γ, where the density is halfway between the minimum and bulk densities, is (8±1) nm. The mean grain-boundary density, when averaged over twice its width, is (85±5)% of n_0.

The mean density is similar to those calculated from atomic structures of gold grain boundaries, which have been deduced from quantitative x-ray-diffraction measurements;[12,13] however, the nickel boundary is considerably broader than the gold boundaries. The boundary widths deduced for the two gold grain boundaries are believed to be about 1 nm.[12,13] Since the twist angles of the two gold grain boundaries (θ_t=36.9° and 22.6°) were larger than that of the nickel grain boundary (θ_t=19.7°), the nickel boundary is expected to be broader than the gold grain boundaries, although perhaps not as broad as observed. Interestingly, grain-boundary widths in nanocrystalline nickel also appear to be quite large. Recently, Aus *et al.*[18] have reported boundary widths of 5 nm deduced from magnetometry measurements, while Valiev[19] has measured widths of 10 nm using high-resolution transmission electron microscopy. The large boundary widths, which seem to be typical of nickel, may be due to the ferromagnetic nature of the material. For example, the magnetic anisotropy of a grain boundary may influence and in turn be influenced by the atomic structure of the boundary. To date, the magnetic effects have been largely ignored in theoretical calculations of grain-boundary structures, so theoretical calculations may be underestimating the structural widths of grain boundaries in magnetic materials.

B. The magnetization profile of the nickel grain boundary

The reflectivities of a nickel-MgO sample and the bicrystal were remeasured at LANSCE using neutrons with polarization states antiparallel and parallel to the 0.1 T magnetic field applied along the sample surface.[20] The field strength is considerably larger than that needed to saturate thin iron films along their hard axes,[21] so both nickel samples, whose saturation magnetizations are much less than iron, should have been fully saturated during the reflectivity measurements. Two reflection cross sections, R_- and R_+,[22] corresponding to the two neutron polarization states (antiparallel and parallel), were measured for each sample. In the case of the nickel-MgO sample, the difference in Q between the critical edges for the R_- and R_+ reflectivity curves was used to calculate the average magnetic moment of μ_{Ni}=(0.7±0.1) μ_B for the sample. This value is in good agreement with the literature value of 0.6 μ_B for bulk nickel.[23]

Since the polarization state of the reflected radiation was not determined in this study, the reflectivity cross sections R_- and R_+ may be contaminated by scattering processes occurring within the sample that actively change the polarization state of the neutron radiation. These processes may occur in samples that are not fully saturated, or have a large degree of magnetocrystalline anisotropy.[22] In the latter case, the magnetic moment deduced from R_+ and R_- would represent the component of the total moment in the direction of the applied magnetic field. Measurements of the polarization state of the reflected radiation, i.e., all four scattering cross sections of the sample, are in progress at LANSCE.

The R_- and R_+ cross sections for the nickel bicrystal are shown as the open symbols in Figs. 3(d) and 3(e). The dashed curves in this figure were calculated from a model that used the atomic density profile previously determined for the bicrystal, the nuclear scattering lengths for each nickel film, and the value of μ_{Ni}, to calculate the nuclear and magnetic contributions to the scattering length density profile of the bicrystal. For $Q>0.07$ Å^{-1}, no splitting is discernible between the calculated profiles (dashed curves), when a clear splitting is seen in the data. Since the large-Q region is most sensitive to spatially limited features like the grain boundary, poor agreement here suggests that the magnetic moments of atoms in the grain boundary may be different from the bulk.

The agreement between the calculated profiles and the data could be significantly improved when the magnetic moment of nickel atoms in the grain boundary were made to be larger than μ_{Ni}. By varying only the decay of the magnetic moment from a maximum at the interface plane (correspond-

ing to an abscissa value of zero in Fig. 5) to μ_{Ni} at a position where the grain-boundary density equals n_0 much better agreement was obtained. This variation in magnetic moment is shown by the solid line in Fig. 5(b) and is called model 1. The optimum value of (1.6±0.3) μ_B at the interface plane produced the solid curves in Figs. 3(d) and 3(e). When averaged over twice the grain-boundary width, 2Γ, the magnetic moments of nickel atoms in the interfacial region are about (52±12)% larger than the magnetic moment measured for the film.

A second model (model 2), which represented the variation of the magnetic moment of nickel by a Gaussian function centered at the interface plane, was also explored. In this model the height and width of the Gaussian function were optimized to produce the dashed curves in Fig. 5. A peak moment of (1.5±0.2) μ_B was obtained. The full width at half maximum in the profile of the magnetic moment was (3±1) nm. In this model the magnetic width of the grain boundary is considerably smaller than its structural width of (8±1) nm. Theoretical calculations suggest that changes in symmetry, coordination number, and density can alter the magnetic moments of atoms. If these predictions are correct, then the magnetic moments of the atoms closest to the interface plane would be most affected by the change of atomic structure that occurs at grain boundaries. In particular, the coordination number of an atom would be expected to remain unchanged unless it were located quite closely to the interface plane. If the magnetic moment of an atom is most affected by its coordination number, rather than changes in atomic density, then the magnetic width of a grain boundary might be smaller than its structural width.

In a third model (model 3), the magnetic moment [(●) in Fig. 5(b)] for each step in the atomic density profile [Fig. 5(a)] was perturbed independently to yield a good fit to the data. Even though the magnetic moments of nickel atoms away from the grain boundary were no longer constrained to be μ_{Ni}, as in the earlier model, the magnetic moments of these atoms, nevertheless, tended toward this value. The optimum magnetic moment at the grain-boundary plane was still enhanced [a value of (1.4±0.2) μ_B was obtained] compared to the bulk, although the increase was not as large as that deduced from the previous models.

All the models predict an enhancement of the magnetic moment of nickel at the grain-boundary interface. When averaged over twice the grain-boundary width, we find enhancements in the magnetic moment of nickel ranging from a low of 18% for model 2 to a high of 52% for model 1. The enhancement deduced from the best-fitting model, model 3, is (38±3)%. Since the magnetization density is the product of magnetic moment and atomic density, which is reduced at the nickel grain boundary, the magnetization density of the interface is only sightly enhanced compared to the bulk. The magnetization densities of the interfaces [Fig. 5(c)] calculated using models 1 and 3 are 20% and 10% greater than the bulk, respectively, when integrated over the grain-boundary region, while a small decrease of 6% is predicted from model 2. In other words, the large enhancements in the *magnetic moments* of nickel at the grain boundary are mostly negated by the reduction of its atomic density to yield a *magnetization density* that is only about 10% greater than the bulk.

IV. CONCLUDING REMARKS

We believe that reduction of atomic density and change in symmetry at a grain boundary will alter its density of states (of *d* orbitals in nickel), leading to the observed enhancement in the magnetic moments of nickel atoms in the grain boundary. In support of this hypothesis, we point out that Chrzan *et al.*[6] have attributed a calculated *reduction* in the magnetic moments of nickel atoms at a {111} stacking fault to the close proximity of atoms near this interface. Another calculation has shown that the reduced coordination of an ideal (100) nickel surface alters its density of states, which produces a 32% enhancement in the magnetic moments of nickel atoms at the surface compared to the bulk.[5] The trend in the two theoretical calculations is in agreement with our observations of an enhanced magnetic moment and reduced atomic density of one particular nickel grain boundary. Nickel grain boundaries with different twist angles and crystallographic orientations will have different crystal structures, and so might have different magnetic structures. Comparisons between these structures, measured with techniques developed for this study, with calculations of theoreticians for a variety of grain boundaries will lead to a better understanding of interfacial magnetism, and its effects on the macroscopic magnetic properties of materials like multilayered and nanophase systems which contain many interfaces.

Interestingly, Schaefer[7] has reported a *reduction* in the magnetic moment of nickel at grain boundaries in samples composed of consolidated nickel crystallites with grain sizes of 10 nm. This conclusion was made based upon magnetization measurements using a SQUID and vibration magnetometer. The difference between the conclusion reached by Schaefer and that in the present study, where evidence for an increase in the magnetic moment of nickel at a grain boundary was seen, may be due to several factors.

First, the magnetometry technique measures the magnetization of the entire sample, and so does not specifically measure the magnetization of interfaces. If, for example, a portion of the nanocrystalline sample were not magnetic when the entire sample was thought to be magnetic, then a reduced magnetic moment would be calculated for the sample, since its measured magnetization would not have been as large as would have been the case had the entire sample been magnetic. We note that antiferromagnetic order is suppressed in 11 nm grains of chromium (to at least 20 K).[24] If magnetic order can also be suppressed in ultrafine-grained nickel, then a portion of the sample studied by Schaefer may not have been ferromagnetic, possibly resulting in a diminished sample magnetization. Depending upon the amount of material which was not ferromagnetic, a diminished magnetization might be measured for the entire sample even if the magnetic moment of nickel is generally increased in the grain boundaries.

Second, microstrain introduced into the nanocrystalline sample during high-pressure compaction, which was not likely to have been relieved at ambient temperature used during the compaction process, may affect the magnetic proper-

ties of the material in a manner that may not have occurred in the bicrystal sample. For example, strain is known to affect the magnetic anisotropy and magnetoelastic energies of ferromagnets[25] and the magnetic structure of coarse-grained chromium.[26] Considerable microstrain is usually found in nanocrystalline metals[24,27] and is likely to be present in nanocrystalline nickel.[28] Since the bicrystal was annealed at high temperature, the grain boundary in this sample should be relatively strain-free compared to those in nanocrystalline nickel. The different conclusions reached by Schaefer and this study might be attributed to differences in the strain contents of two sample, if microstrain can change the magnetic moments of atoms in grain boundaries.

Third, the grain boundary studied in the bicrystal experiment may not be representative of grain boundaries found in nanocrystalline materials. For example, the grain boundary in the bicrystal sample was known from the x-ray-diffraction observations to be reconstructed, i.e., to have formed a relaxed structure. On the other hand, the nanocrystalline sample, at least on the onset of the magnetometry measurements, was likely to contain grain boundaries in unrelaxed configurations owing to the relatively low diffusivity of nickel at ambient temperature compared to the annealing temperature used to make the bicrystal (773 K). The magnetic moment of nickel may be increased in a relaxed grain boundary compared to an unrelaxed one. Furthermore, the grain boundary studied here is special in that its unit cell is reasonably small—containing only 37 atoms per atomic plane. Randomly oriented grain boundaries, which are characterized by large unit cells, should occur more frequently in as-compacted nanocrystalline nickel that the special grain boundary studied in this work. Efforts are in progress to determine whether the magnetic moments of nickel atoms in grain boundaries with other orientations differ from the moment reported for the $\Sigma=37$ twist grain boundary.

Finally, as the grain size of a nickel crystallite becomes comparable to the structural width of a grain boundary, which may be relatively large for nickel,[18,19] interactions across crystallites between different interfaces may perturb their structures from those of interfaces found in coarser-grained materials. If the magnetic structure of an interface is coupled to its atomic structure, then interactions between neighboring grain boundaries that produce alterations in their atomic structures may also lead to changes in their magnetizations, particularly in an ultrafine-grained materials such as that studied by Schaefer. These interactions would not be present in the bicrystal sample, since the surface and nickel-MgO interface of the sample are a few tens to hundreds of nanometers away from the grain-boundary interface.

While bicrystal experiments such as this one may not provide information relevant to as-compacted nanocrystalline materials, these experiments do provide valuable information about the magnetizations of planar interfaces, such as those present in multilayered materials. In particular, model bicrystal experiments can be designed to study specific problems that might be encountered in the development of magnetic multilayer devices. For example, bicrystals containing controlled amounts of impurity solutes can be fabricated and studied to determine how the magnetic properties of interfaces change as impurity atoms segregate to the bicrystal interfaces.

With the object of assessing their magnetocaloric properties, we have prepared Gd_xAg_{100-x} alloys (x=50, 70, 75, 77.5, 80, 100) by melt spinning. The microstructures of the melt-spun ribbons were investigated by x-ray diffraction and transmission electron microscopy. Data from field- and temperature-dependent magnetization measurements were used to calculate the field-induced entropy change ΔS. The Gd-only ribbons are characterized by a single ΔS peak near 280 K. For the Gd_xAg_{100-x} ($70 \leq x \leq 80$) materials ΔS contains another peak in the 100–120 K range which we ascribe to an amorphous, ferromagnetic Gd-Ag component. We find melt-spun $Gd_{50}Ag_{50}$ ribbons to consist primarily of crystalline GdAg (cubic CsCl structure), which is antiferromagnetic.

It is well known that the field-induced entropy change ΔS of a magnetic material can be exploited as a basis for solid-state refrigeration, with potential for application in the room-temperature range as well as at cryogenic temperatures.[1–3] Recent calculations[4,5] and experiments[6,7] have shown that materials containing nanometer-sized magnetic regions can produce larger values of ΔS than conventional ferromagnets or paramagnets over certain intervals of temperature (T) and applied field (H). To maximize this effect, it is important that the magnetic phase have a large intrinsic magnetization and, to minimize heating due to hysteresis, low magnetocrystalline anisotropy. Both of these demands are satisfied by gadolinium. Furthermore, it is desirable for the magnetic particles to be at least partially separated by nonmagnetic material to reduce magnetic interactions between them.

With these considerations in mind we have investigated, and here report, measurements of $\Delta S(T)$ for Gd_xAg_{100-x} alloys which were prepared by the rapid solidification technique of melt spinning. We chose a rapid quenching method with the objective of forming small magnetic particles or clusters, and the Gd-Ag system was selected since its equilibrium phase diagram indicates that ferromagnetic Gd (Curie temperature $T_c \cong 293$ K) and antiferromagnetic GdAg (Neel temperature $T_n \sim 140$ K) are essentially immiscible.

Ingots of Gd_xAg_{100-x} (x=50, 70, 75, 77.5, 80) were prepared by induction melting high-purity elemental constituents. Each ingot was melt spun, again under argon, by ejecting molten alloy through an orifice (0.6 mm diameter) in a quartz crucible onto the surface of a chrome-plated copper disk (25 cm diameter). The quench rate was varied by changing the surface velocity v_S of the disk. A quench rate corresponding to v_S=20 m/s was used for all the silver-containing alloys, and v_S=30 m/s was used to produce the Gd-only material.

Ribbon microstructures were examined by both x-ray powder diffraction and transmission electron microscopy (TEM). Figures 1 and 2 display Cu K_α x-ray diffractograms for the x=100, 80, 77.5 and x=75, 70, 50 materials, respectively. It is clear from Fig. 1(a) that the Gd-only ribbons are comprised of hexagonal Gd grains with some preferential orientation along the [001] direction since the (002) and (004) reflections are of greater intensity than those calculated for an isotropic distribution [vertical bars in Fig. 1(a)]. Selected area diffraction in the TEM confirms this interpretation. Figure 3(a) shows that the Gd ribbons consist of irregular grains approximately 0.5 μm in size and have some alignment along the [001] direction, which was normal to the surface of the quench wheel. In addition to [100]-oriented hexagonal Gd crystallites, the x-ray diagram of the $Gd_{80}Ag_{20}$

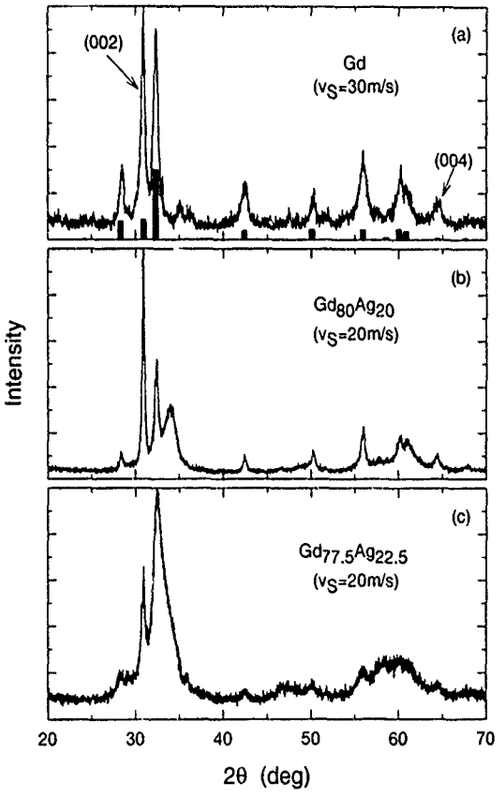

FIG. 1. Cu K_α x-ray powder-diffraction patterns of melt-spun Gd_xAg_{100-x} ribbons. (a) Gd, the vertical bars denote line positions and intensities for isotropic, hexagonal Gd metal. (b) $Gd_{80}Ag_{20}$ (c) $Gd_{77.5}Ag_{22.5}$.

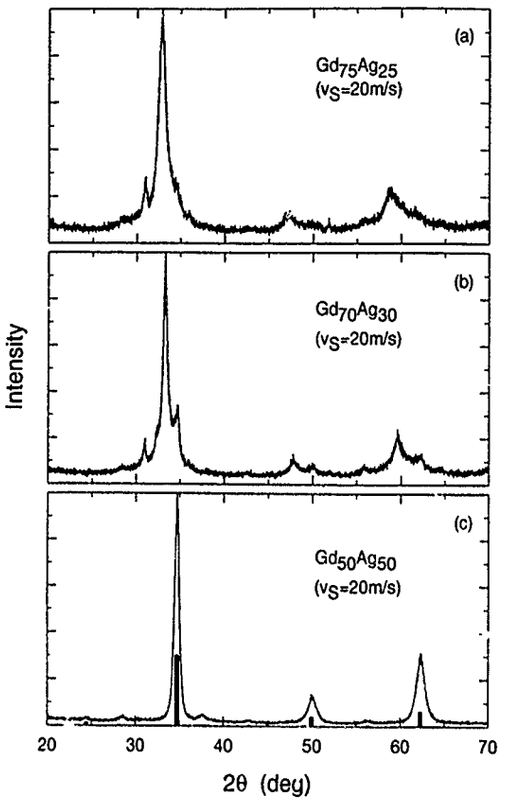

FIG 2. Cu K_α x-ray powder-diffraction patterns of melt-spun Gd_xAg_{100-x} ribbons. (a) $Gd_{75}Ag_{25}$. (b) $Gd_{70}Ag_{30}$. (c) $Gd_{50}Ag_{50}$; the vertical bars denote line positions and intensities for isotropic, cubic GdAg.

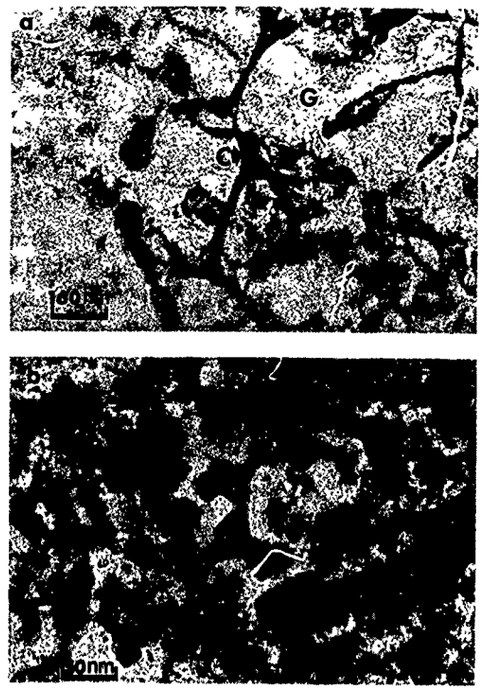

FIG. 3. TEM micrographs of melt-spun (a) Gd (*G* denotes a hexagonal Gd grain and *C* indicates a cubic form of Gd situated at the grain boundaries) and (b) $Gd_{77.5}Ag_{22.5}$ (regions labeled *A* are amorphous $Gd_{50}Ag_{50}$; hexagonal Gd particles are signified by *G*).

ribbons [Fig. 1(b)] also suggests an amorphous Gd-Ag component. Ribbons melt spun from the eutectic composition $Gd_{77.5}Ag_{22.5}$ contain a substantial amorphous fraction, as shown by Fig. 1(c); the corresponding TEM micrograph of Fig. 3(b) reveals small (<100 Å) Gd grains embedded in an amorphous matrix having an overall composition near $Gd_{50}Ag_{50}$ estimated by microchemical analysis.

From the x-ray pattern for the $Gd_{75}Ag_{25}$ ribbons, Fig. 2(a), we infer that the amorphous fraction is even larger than that of the $Gd_{77.5}Ag_{22.5}$ sample since the features are more diffuse than those of Fig. 1(c). Some hexagonal Gd is still present and persists in the $Gd_{70}Ag_{30}$ ribbons as well [Fig. 2(b)]; comparison of Figs. 2(a) and 2(b) indicates less amorphous Gd-Ag phase in the $Gd_{70}Ag_{30}$ ribbons. Similar to Fig. 3(b), TEM analysis of the $Gd_{70}Ag_{30}$ ribbons again reveals Gd grains interspersed in an amorphous matrix having a composition near $Gd_{50}Ag_{50}$, in addition to a small amount of crystalline GdAg. No gadolinium component is apparent in the x-ray diagram of melt-spun $Gd_{50}Ag_{50}$, Fig. 2(c); the ribbons are principally composed of fine-grained crystalline GdAg, whose reflections are illustrated by the vertical bars in Fig. 2(c). TEM of this material shows GdAg grains with an average diameter of ~100 Å.

Magnetic moment versus temperature curves for the melt-spun ribbons investigated here, as well as for a bulk Gd ingot sample, are displayed in Fig. 4; the measurements were performed in a maximum applied field of 9 kOe, which was

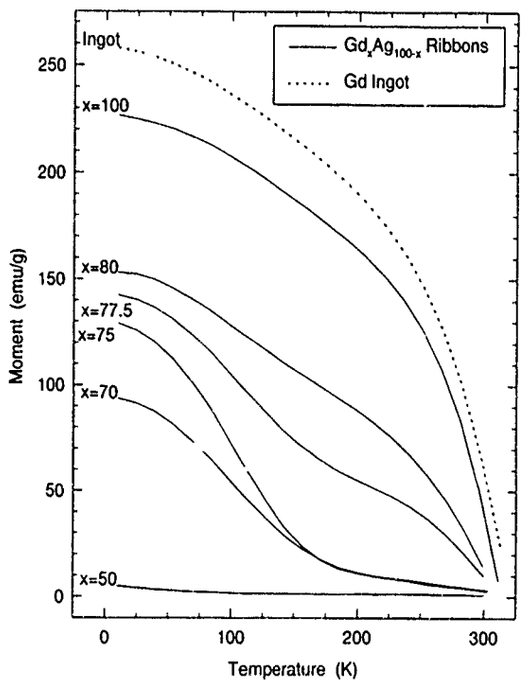

FIG. 4. Magnetic moment vs temperature for melt-spun Gd_xAg_{100-x} ribbons (x=50, 70, 75, 77.5, 80, 100) and for a Gd ingot sample measured in an applied magnetic field of 9 kOe.

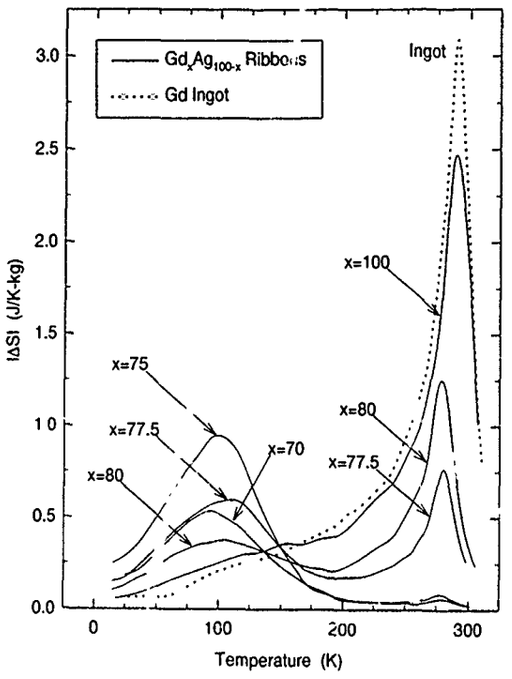

FIG. 5. Entropy change ΔS of melt-spun Gd_xAg_{100-x} ribbons (x=70, 75, 77.5, 80, 100) and of a Gd ingot sample in a 9 kOe applied magnetic field.

sufficient to saturate the magnetization in each case. The observed low-temperature moment for the Gd-only (x=100) ribbons, ~215 emu/g (~6.1 μ_B/Gd), is 20% lower than the 268 emu/g (7.55 μ_B/Gd) value for elemental gadolinium metal, as comparison with the bulk Gd curve in Fig. 4 shows. The disparity is puzzling. Some of it can be attributed to nonmagnetic contaminants such as oxides, but our TEM work indicates that secondary phases comprise no more than 5 vol % of the ribbons. We speculate, therefore, that particle size effects may also contribute to the moment reduction. Gadolinium moments in the 5–7 μ_B range have been reported in several amorphous binary alloys,[8] and a moment of only 3 μ_B/Gd has been observed in clusters containing fewer than 100 Gd atoms.[9]

For the Gd_xAg_{100-x} ribbons with $70 \leq x \leq 80$, the data of Fig. 4 strongly suggest the presence of two ferromagnetic components, one with a Curie temperature in the vicinity of 100 K and a second near the $T_c \cong 293$ K value for bulk Gd metal. Hauser[10] prepared amorphous Gd_xAg_{100-x} alloys in the $20 \leq x \leq 100$ interval by sputtering and found them to be ferromagnetic, with T_c essentially linear in x with $T_c \sim 100$ K at x=50. We conclude, therefore, that the amorphous component detected by x-ray diffraction and TEM in our $70 \leq x \leq 80$ melt-spun ribbons is ferromagnetic Gd_xAg_{100-x} with $x \sim 50$.

In contrast, the magnetization curve for the $Gd_{50}Ag_{50}$ (20 m/s) ribbons in Fig. 4 mirrors the susceptibility versus temperature curve reported by Walline and Wallace[11] for crystalline, antiferromagnetic GdAg, consistent with our microstructural analyses of that material. It is quite surprising that the $x \sim 50$ component of the Gd-richer $70 \leq x \leq 80$ ribbons is amorphous, while $Gd_{50}Ag_{50}$ melt spun at the same quench rate (v_S=20 m/s) is crystalline. To satisfy one of our original objectives it would have been preferable for the former materials to contain crystalline GdAg [which would be paramagnetic at T_c(Gd)] to magnetically isolate the Gd particles.

We calculated the field-induced entropy change ΔS from the magnetization data (measured as a function of both applied magnetic field H and temperature T) by making use of the Maxwell relation $(\partial S/\partial H)_T = (\partial M/\partial T)_H$, which implies

$$\Delta S = \int_0^H \left[\frac{\partial M(H',T)}{\partial T} \right]_{H'} dH'. \tag{1}$$

Figure 5 displays ΔS vs T for the melt-spun $70 \leq x \leq 100$ ribbons and for the Gd ingot sample. The Gd-only ribbon material features a single peak near 290 K which corresponds well with T_c of bulk Gd, as comparison with the Gd ingot curve in Fig. 5 demonstrates. The four other ribbon curves in Fig. 5 exhibit two peaks. One is centered in the 100–120 K interval and is generated by the ferromagnetic, amorphous $Gd_{50}Ag_{50}$ component; the variation of the maximum with x is relatively small and is undoubtedly associated with compositional variation in the amorphous fraction. Most pronounced in the x=77.5 and x=80 ribbons, the second peak occurs at $T \sim 280$ K and arises from the Gd constituent; the ~100 Å particle size reduces T_c somewhat from the bulk value of 293 K.

Both ΔS structures for the $70 \leq x \leq 80$ ribbons in Fig. 5 are quite broad; the height of each is considerably smaller than that of the Gd-only ribbons, which is in turn somewhat reduced from that of the Gd ingot. These results reinforce earlier findings[4–7] that a fine-particle morphology can markedly modify the temperature distribution of ΔS. Figure 5 suggests that the x=70 and x=75 materials may be of interest for magnetic refrigeration in the 100 K regime. While the x=77.5 and x=80 ribbons do contain small Gd particles, further effort is required, at least in the Gd-Ag system, to separate them in a nonferromagnetic matrix. We intend to explore heat treatment as a possible means for converting the amorphous $Gd_{50}Ag_{50}$ component into antiferromagnetic GdAg while minimizing growth of the Gd grains.

Nanocomposite $Fe_{80}(SiO_2)_{20}$ films with thickness from 150 to 5000 Å have been prepared by rf magnetron sputtering from a composite target. The crystallites in the $Fe_{80}(SiO_2)_{20}$ films have a bcc structure with the average size of 46–66 Å which was determined by transmission electron microscopy. As indicated by the thickness dependence of resistivity, the stacking and connectivity of the crystallites depend on the thickness of the films. The magnetic properties also depend on the microstructure which changes with the thickness of the films. The magnetic coercivity of the films increases with the thickness of the film, reaches a maximum, and then decreases. The maximum coercivity of 400 Oe at 300 K and 1200 Oe at 5 K was observed for a film with a thickness of about 700 Å.

I. INTRODUCTION

Nanocomposite materials have the form of small crystallites dispersed in a matrix which may be insulating or metallic. The magnetic properties of nanocomposite materials depend on the microstructure of the films which can be controlled by either changing the size of crystallites and/or the separation distance between the crystallites. It has been shown that the crystallites size and the intercrystallite distance of the nanocomposite Fe:SiO_2 system can be systematically changed by varying the Fe volume fraction.[1–6] The average crystallite size in the films for a fixed volume fraction can also be varied by changing the substrate temperature.[7] For the films with lower metal volume fraction the crystallites are isolated whereas for the films with higher metal volume fraction the crystallites are well connected.[8] For the Fe:SiO_2 films with a Fe volume fraction near 50% the crystallites begin to form a percolating network. As the thickness of the film is decreased, the number of crystallites connecting together in the film-normal direction decreases and a change in the electrical and magnetic properties is expected. In this work we investigated the thickness dependence of magnetic and electrical properties of the Fe:SiO_2 films.

II. EXPERIMENTAL PROCEDURE

The nanocomposite Fe:SiO_2 films were prepared by rf magnetron sputtering from a composite target. The sputtering targets were prepared by sintering a mixture of pressed Fe and SiO_2 powders. The sputtering gas was 5 mTorr of Ar, and the films were deposited on glass substrates at room temperature. The films used in this study have a target composition of $Fe_{80}(SiO_2)_{20}$ (55 vol. % of Fe). The film thickness ranged from 150 to 5000 Å. The microstructure of the films was studied by using a JEOL 2010 high-resolution transmission electron microscope (HRTEM) and electron diffraction. The magnetization and the coercive force were measured using a commercial alternating-gradient force magnetometer and a SQUID magnetometer. The resistivity was measured in a standard four-point probe configuration.

III. RESULTS AND DISCUSSION

The electron-diffraction pattern of the $Fe_{80}(SiO_2)_{20}$ films with a thickness of 700 Å is shown in Fig. 1. The electron-

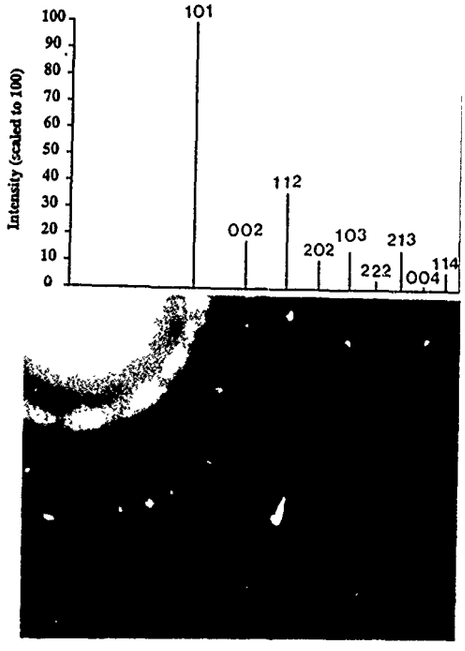

FIG. 1. Electron-diffraction pattern of $Fe_{80}(SiO_2)_{20}$ film with a thickness of 700 Å.

FIG. 2. HRTEM image for the $Fe_{80}(SiO_2)_{20}$ film with a thickness of 700 Å.

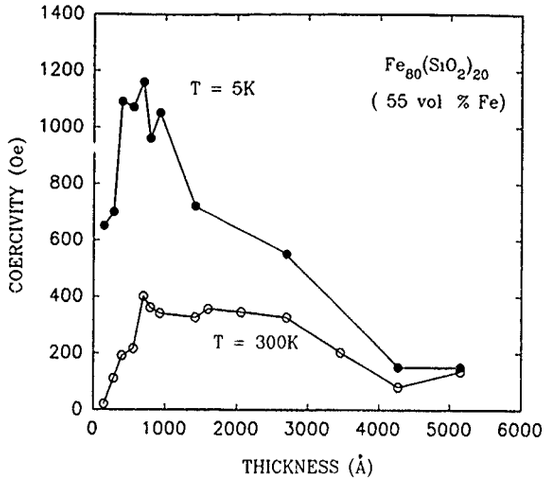

FIG. 4. Magnetic coercivities measured at 300 and 5 K vs thickness for the $Fe_{80}(SiO_2)_{20}$ films.

diffraction pattern of the films show a α-Fe structure with the (110), (200), (211), etc. rings present. The d spacing of the (110) peak as deduced from x-ray diffraction is 2.03 Å, which is close to the lattice parameter of α-Fe. The electron-diffraction pattern of the film can be indexed to α-Fe and there is no evidence of contribution from any Fe oxide phases; this is also confirmed by Mössbauer spectroscopy. The hyperfine field as calculated from the Mössbauer spectra is 330 kOe, which is close to the value for α-Fe. The morphology of the crystallites as revealed by the HRTEM image for the $Fe_{80}(SiO_2)_{20}$ films with a thickness of 700 Å is shown in Fig. 2. The average particle size of the Fe crystallites is 46–66 Å and the Fe crystallites are mostly isolated in an amorphous SiO_2 matrix. The Fe crystallites have a clear boundary with the SiO_2 matrix. The fringes on the crystallites represent the lattice spacing of Fe.

The thickness dependence of the resistivity for the $Fe_{80}(SiO_2)_{20}$ films is shown in Fig. 3. It is seen that the resistivity decreases as the film thickness increases and above 700 Å the resistivity decreases drastically, indicating that the films form a better connecting network of Fe crystallites. The plane view HRTEM image shows that the Fe crystallites are isolated in the SiO_2 matrix, so the drastic change in resistivity for the films with thickness above 700 Å may be likely due to the change in stacking and connection of the Fe crystallites. The inset of Fig. 3 shows the resistivity versus film thickness for 700–4273 Å thick films. As the film thickness increases from 700 to 4273 Å, the resistivity changes from 5.6×10^{-2} to 1.8×10^{-4} Ω cm.

The magnetic coercivity measured at 300 and 5 K of the $Fe_{80}(SiO_2)_{20}$ films versus thickness is shown in Fig. 4. The magnetic properties depend on the thickness of the film. It is observed that as the film thickness increases the magnetic coercivity increases, goes through a maximum, and then decreases The maximum coercivity of about 400 Oe at 300 K and 1200 Oe at 5 K was obtained for a film with a thickness of about 700 Å. As the film thickness increases, the change in magnetic coercivity measured at 5 K is more pronounced compared to the magnetic coercivity measured at 300 K for the films with thicknesses less than 1200 Å.

Figure 5 shows the dependence of magnetic coercivity with temperature for $Fe_{80}(SiO_2)_{20}$ films with different thicknesses. The magnetic coercivity decreases as the temperature

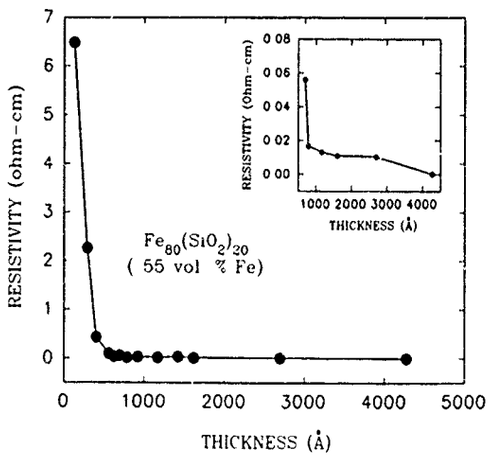

FIG 3. Resistivity vs thickness for the $Fe_{80}(SiO_2)_{20}$ films.

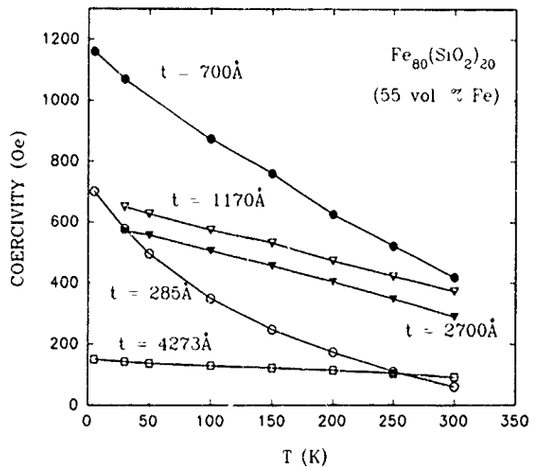

FIG. 5. Magnetic coercivities vs temperature of the $Fe_{80}(SiO_2)_{20}$ films with different thicknesses

increases. The temperature dependence of coercivity with a film thickness more than 1000 Å is almost linear, whereas the film with a thickness of 285 Å has a $T^{1/2}$ dependence. The $T^{1/2}$ dependence of coercivity for a thin film is characteristic of a system of superparamagnetic particles below the blocking temperature.[9] As the film thickness increases the number of connected crystallites also increases, i.e., the interaction between the crystallites increases and one observes a change in the magnetic properties of the films.

IV. SUMMARY

We have prepared Fe:SiO_2 nanocomposite films with different thicknesses. The size of the α-Fe crystallites for the $Fe_{80}(SiO_2)_{20}$ films ranges from 46 to 66 Å. The resistivity of the $Fe_{80}(SiO_2)_{20}$ films decreases with increasing film thickness. Above 700 Å the resistivity drops drastically, indicating that the crystallites form a better connecting network in the thick films. The magnetic coercivity for the $Fe_{80}(SiO_2)_{20}$ films depends on the microstructure which changes with the thickness of the films.

A general approach to the computation of effective magnetic moments in rare-earth carbides is described, and details of this calculation for Ho^{3+} ions in Ho_2C_3 are presented. This calculation is designed to explain the reduced magnetic moments, relative to free ion values, measured by dc SQUID magnetometry for Ho_2C_3 nanocrystals. Crystal-field splittings of the rare-earth ion in a particular symmetry site are determined by the operator equivalent method. Using the eigenvalues and eigenfunctions of the crystal-field Hamiltonian, the effective magnetic moment is then determined. For Ho^{3+} ions in Ho_2C_3, this method predicts a reduced magnetic moment, but the degree of reduction depends on the energy-level splittings and, therefore, the temperature. This magnetic moment is compared with previous experimental results, and the implications of the formal carbon charge, screening, and temperature are discussed.

I. INTRODUCTION

Carbon-coated gadolinium and holmium sesquicarbide nanocrystals have been prepared in a carbon arc, and the details of their synthesis, structure, and measured magnetic behavior have been reported previously.[1,2] The gadolinium ions in Gd_2C_3 have an $^8S_{7/2}$ electronic ground state which is unaffected by the crystal field. However, the Ho^{3+} ions found in Ho_2C_3 do not show the free ion behavior. For a $^5I_8$ electronic ground state, the predicted effective moment, $g[J(J+1)]^{1/2}$, is 10.61 μ_B, but $\mu_{\text{eff}}\sim 7.5$ μ_B was found experimentally.[2] Here we present the details of a crystal-field calculation for Ho^{3+} ions in Ho_2C_3, aimed at understanding the reduced magnetic moment, and in laying the groundwork for similar calculations for other rare-earth sesquicarbides, dicarbides, and rare-earth-containing fullerenes.

II. CRYSTAL-FIELD CALCULATIONS

The free ion energy levels are perturbed by a crystal field. The Hamiltonian for this perturbation, H_{CF}, can be written in terms of operator equivalents, O_n^m,

$$H_{\text{CH}}=\sum_{n,m} B_n^m O_n^m, \quad m\leq n. \tag{1}$$

The crystal-field intensity parameters, B_n^m, are given by the expression

$$B_n^m=[-|e|/4\pi\epsilon_0]\langle r^n\rangle\Theta_n\gamma_{nm}N_{nm}. \tag{2}$$

Here $\langle r^n\rangle$ is the expectation value for the nth power of the f-electron radius and Θ_n is the Stevens' factor, both of which are tabulated for various rare earth ions.[3,4] N_{nm} is the coefficient for the Tesseral harmonic Z_n^m, and γ_{nm} is the lattice sum over the neighboring ions, which have fixed positions and charges for a particular structure. The operator equivalents O_n^m are functions of J_+, J_-, J_z, and J. The eigenstates for the ion perturbed by the crystal field are generated from superpositions of free ion $|JM\rangle$ states. This method, reviewed by Hutchings,[3] has recently been used to calculate the energy levels of the rare-earth ions inside C_{60} molecules.[5] Here we use this information to calculate the effective magnetic moment per ion μ_{eff} for Ho_2C_3.

III. ENERGY LEVELS AND EIGENSTATES OF Ho^{3+} IN Ho_2C_3

Ho_2C_3 has a body-centered-cubic structure ($I\bar{4}3d$) with the Ho^{3+} ions in positions of C_3 site symmetry. To model the crystal field experienced by a Ho^{3+} ion in this solid, we included 11 neighboring carbon atoms and the 12 closest Ho^{3+} neighbors (Fig. 1). The atomic positions were taken from published x-ray and neutron data for bulklike Ho_2C_3 powder,[6] and the only free parameter was the charge on the carbon atoms. In many carbide molecules[6] and solids,[7] bonding occurs between the metal atom and C_2^{n-} dimer units, and the formal charge varies with the material.[7] Previous results for Ho_2C_3 suggest that the holmium ions carry a 3+ charge, and the carbon dimers have a reduced charge because they donate electrons to a conduction band.[6] In our calculations the formal dimer charge was varied between 2− and 4−. The calculated lattice sums γ_{nm} over the near-neighbor Ho^{3+} ions shown in Fig. 1 contributed only about 10% of the total, showing that the carbon dimers dominate the crystal field of a holmium ion in Ho_2C_3.

Since the holmium ions have C_3 site symmetry, only some of the operator equivalents contribute to the crystal-field Hamiltonian:

$$H_{\text{CF}}(C_3)=B_2^0O_2^0+B_4^0O_4^0+B_6^0O_6^0+B_4^3O_4^3+B_6^3O_6^3+B_6^6O_6^6 +B_{4t}^3O_{4t}^3+B_{6t}^3O_{6t}^3+B_{6t}^6O_{6t}^6. \tag{3}$$

Here B_{nt}^m refers to the imaginary part of B_n^m, and the crystal axes were chosen to minimize the contributions from the B_{6t}^3 and B_{6t}^6 terms.

Using the free ion basis set, $|JM\rangle$, with $J=8$, the 17×17 matrix was diagonalized to determine the energy eigenvalues E_t and the eigenfunctions $|\Psi_t\rangle$:

$$|\Psi_t\rangle=\sum a_{tM}|JM\rangle. \tag{4}$$

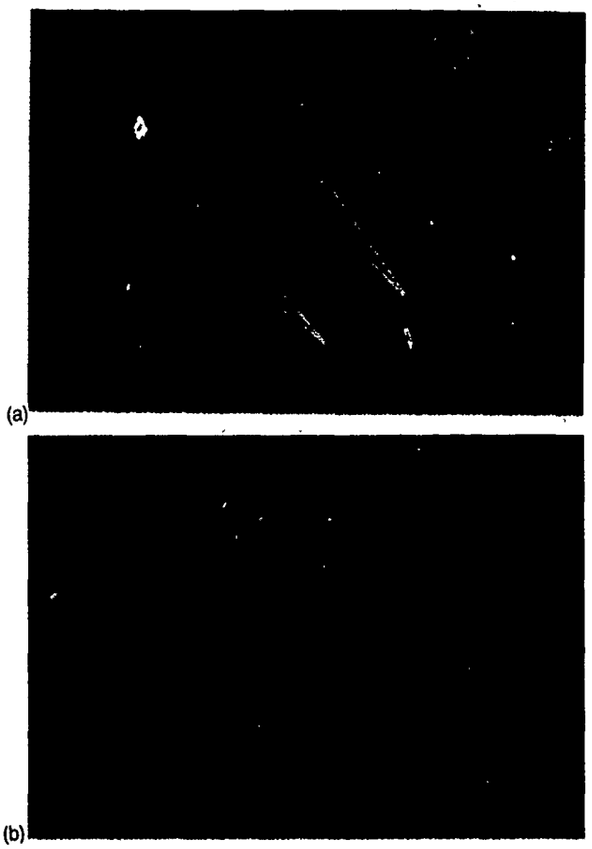

FIG. 1. (a) Ho^{3+} ion with 11 nearest-neighbor Ho^{3+} ions. (b) Ho^{3+} ion with 12 nearest-neighbor carbide ions.

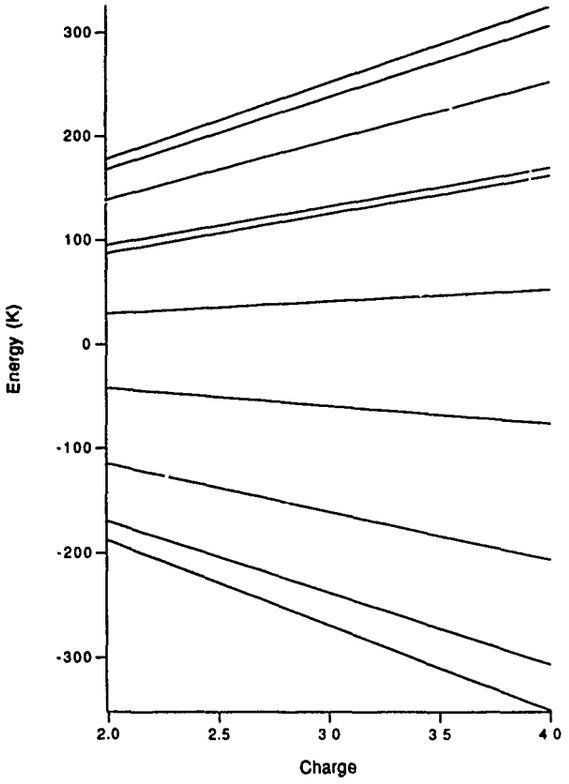

FIG. 2. Energy levels of Ho^{3+} as a function of carbon dimer charge magnitude. Energies are relative to that of a free Ho^{3+} ion. A more detailed description of the energy eigenstates for the dimer charge of -2.0 is found in Table I.

From group theory, the $J=8$ electronic ground state for a free Ho^{3+} ion should split into five $^1\Gamma_1$ states and six $^2\Gamma_2$ states when perturbed by a C_3 crystal field. As shown in Table I, the formal calculation did indeed result in six doublets and five singlet states. While the energy-level splittings varied with the formal charge on the carbon dimer, the relative ordering was the same (Fig. 2), and the makeup of the energy eigenstates was not significantly affected. The lowest doublet consisted predominantly of $M=+8$ and -8 states, and the next lowest doublet was mainly $M=+7$ and -7 states. For all formal charge values there is significant population of excited states at 300 K.

IV. MAGNETIC MOMENT OF Ho^{3+} IN Ho_2C_3

In the limit of small H/T, the paramagnetic susceptibility is given by

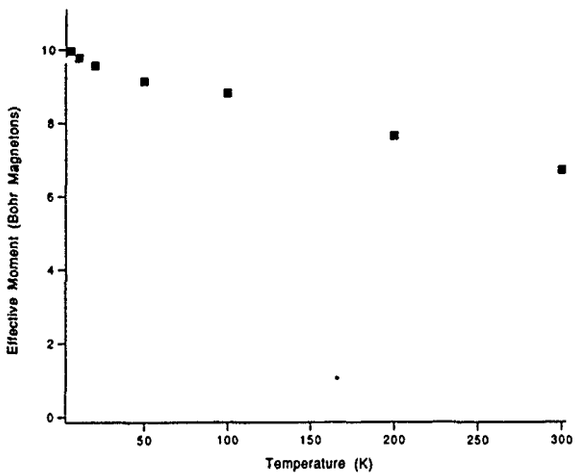

FIG. 3. Effective magnetic moment for Ho^{3+} with a carbon dimer charge of -2.0 as a function of temperature, with assumptions concerning off-diagonal elements as noted in the text.

$$\chi_{pm}=N\mu_B^2 g^2 J(J+1)/3kT=N\mu^2/3kT, \tag{5}$$

for a free rare-earth ion with ground-state angular momentum J. Here μ is the magnetic moment of the free ion. In the full quantum-mechanical treatment,[8] χ depends on the statistical averaging over the energy eigenstates. While there are several contributions,[9] the effective magnetic moment determined from the magnetization curve measured with a SQUID magnetometer is related to the low-frequency term

$$\chi=\left(\frac{N\mu_B^2 g^2}{3kT}\right) \times \frac{\sum_J \sum_M \langle JM|M^2 \exp(-E_J/kT)|JM\rangle}{\sum_J \sum_M \langle JM| \exp(-E_J/kT)|JM\rangle}. \tag{6}$$

For Ho^{3+} ions in the Ho_2C_3 crystal field, we treated only the ground electronic state multiplet, which has $J=8$. The next lowest electronic state in the free ion, $^5I_7$, lies over 5000 cm^{-1} higher in energy and is not appreciably populated in the experimental measurements.[10] With the crystal-field eigenfunctions and eigenvalues, the expression for χ is

$$\chi=\left(\frac{N\mu_B^2 g^2}{3kT}\right) \frac{\sum_i \sum_M \langle JM|a_{iM}^* a_{iM} M^2 \exp(-E_i/kT)|JM\rangle}{\sum_i \sum_M \langle JM|a_{iM}^* a_{iM} \exp(-E_i/kT)|JM\rangle},$$

$$=N\mu_{\text{eff}}^2/3kT. \tag{7}$$

The effective moment per Ho^{3+} ion, μ_{eff}, differs from the free ion moment because of the removal of the free ion degeneracy, and because the crystal-field splittings lead to a temperature-dependent moment. Figure 3 shows the temperature dependence of the moment for the case where the carbon dimer charge equals -2.0. For larger carbon dimer charge values, the temperature-dependent drop-off is less pronounced.

Earlier SQUID magnetometry measurements[2] yielded a temperature-averaged value of $\mu_{\text{eff}}=7.5\ \mu_B$. There the data were scaled as a function of H/T, and results from all temperatures were fit simultaneously.[11] Experiments are underway to study the degree of temperature dependence in order to place limits on the carbon dimer charge. Refinements in the crystal-field calculations to incorporate screening of the conduction electrons will also have an impact on the energy-level splittings, and therefore on the temperature dependence of the magnetic moment.

V. CONCLUSIONS

Crystal-field calculations were performed to determine the ground-state energy-level splittings for Ho^{3+} ions in Ho_2C_3. The energy eigenstates were used to calculate the low-frequency paramagnetic susceptibility and the effective magnetic moment. In comparison with SQUID magnetometry measurements, this calculation underestimates the reduction of the magnetic moment. However, information concerning important fitting parameters may be obtained by detailed temperature-dependent measurements of μ_{eff}.

Note added in proof: A marked increase in the magnetic moment with increasing temperature has been observed experimentally, thought the error bars for fits of the high-temperature data are quite large. When the data taken at different temperatures are scaled and fit as a group, the low-temperature contributions dominated in the determination that $\mu_{\text{eff}}=7.5\ \mu_B$.

[11] In this sample, electron diffraction has shown the presence of cubic α-Ho_2C_3. No evidence of Ho_5C_{19} has been observed. In comparing the experimental and calculated values, a factor of 1/3 should be introduced in the susceptibility formula to account for random orientations of the individual crystals.

Kramers's rate theory, broken symmetries, and magnetization reversal (invited)

Hans-Benjamin Braun
Department of Physics, Simon Fraser University, Burnaby, British Columbia V5A 1S6, Canada

The theory of thermally induced magnetization reversal in small particles is reviewed. The conventional Néel–Brown theory for uniform magnetization reversal and its derivation from Kramers's rate theory are first discussed. For sufficiently elongated particles, however, a nonuniform energy barrier ("nucleus") has lower energy than the uniform barrier and thus yields a lower coercivity. This coercivity reduction is shown to occur also for vanishing hard-axis anisotropy when the nucleus breaks the rotational symmetry around the easy axis. The prefactor of the Arrhenius factor is calculated for uniform and nonuniform barriers.

I. INTRODUCTION

Recent years have witnessed tremendous progress in the preparation of magnetic particles on the scale of a few nanometers. Such particles typically exhibit two degenerate equilibrium directions of the magnetic moment which are separated by an anisotropy barrier.

As the thermal energy k_BT approaches the barrier energy, thermal fluctuations drive the magnetization from the metastable state over the lowest-energy barrier into the adjacent anisotropy minimum. Recent experiments on a single particle[1] or lithographically produced arrays[2] of even smaller particles reveal a coercivity that is substantially smaller than that predicted by standard theories of magnetization reversal.

The most widely used theory is that by Néel[3] and Brown.[4] It is based on the picture that all spins within the grain are aligned and behave like a single large magnetic moment. The switching rate out of the metastable state is then given by the Arrhenius factor $\exp[-E_s/k_BT]$ where the barrier energy E_s is proportional to the total anisotropy energy and thus to the particle volume.

With increasing aspect ratio of the particle, this assumption of a uniform magnetization becomes questionable. A recent study[5] which includes the exchange interaction of magnetic moments along an idealized long particle with constant cross section has indeed shown that the energy exhibits a saddle point corresponding to a localized deviation ("nucleus") from the initial metastable state. This nucleus can also be viewed as a soliton-antisoliton pair.[6]

These exact results showed that several previous concepts have to be thoroughly revised: For sufficiently elongated particles, the barrier energy is proportional to the cross-sectional area of the particle rather than the particle volume. Second, the concept of an "activation volume" is misleading: Even if the nucleus represents an already reversed domain delimited by two domain walls [see Fig. 1(ii)], the barrier energy is not proportional to the volume of the reversed domain but rather equals the total energy of the delimiting domain walls. Third, it can be shown that the energy decreases monotonically from the saddle point until the magnetization is reversed. This is in contrast to a saddle point of assumed curling symmetry (where the radial component of the magnetization vanishes). Such a constraint requires the magnetization at the "backbone" in the cylinder center to remain in the initial state even if the magnetization outside this central region is reversed. This obstructs the way down from the putative saddle point of curling symmetry by an additional energy barrier of topological origin which in the case of a continuous magnetization distribution is even infinitely high. This can only be avoided by breaking the rotational symmetry of the magnetization distribution at the cylinder center. For small particle diameters, we are then led to an effectively one-dimensional model[5] that will be described below.

The purpose of this article is twofold. We start with a review of the theory of uniform magnetization reversal with particular emphasis on the difference between the rotationally symmetric case of a single easy-axis anisotropy[3,4] and the case of an additional hard-axis anisotropy.[7,8] These results have been derived by a variety of methods and unfortunately no recent review exists in the literature. Therefore, Kramers's rate theory is presented in the Appendix in a form which can be readily extended to nonuniform situations or systems of interacting particles.

In Sec. IV it is shown that in elongated particles a spatially localized deviation ("nucleus") from the metastable state provides the lowest barrier. The same nucleus also exists for vanishing hard-axis anisotropy where it breaks the rotational symmetry. This symmetry breaking gives rise to a Goldstone mode of zero energy which corresponds to an infinitesimal rotation of the saddle-point structure around the easy axis. By taking advantage of this symmetry, the statistical part of the prefactor is evaluated exactly for all values of the external field.

II. MODEL

Let us first consider an elongated particle of constant cross section $\mathcal{A}$. The energy of a one-dimensional (1D) magnetization configuration $\mathbf{M}(x,t)$ of constant magnitude $|\mathbf{M}|=M_0$ is given by

$$E=\mathcal{A}\int_{-L/2}^{L/2}dx\left\{\frac{A}{M_0^2}\left[\left(\frac{\partial M_x}{\partial x}\right)^2+\left(\frac{\partial M_y}{\partial x}\right)^2+\left(\frac{\partial M_z}{\partial x}\right)^2\right]+\frac{K_h}{M_0^2}M_z^2-\frac{K_e}{M_0^2}M_x^2-H_{\mathrm{ext}}M_x\right\}. \tag{2.1}$$

The particle length L is assumed to be considerably larger[9] than the domain-wall width $\sqrt{A/K_e}$. For particle diameters of the order of $\sqrt{A/K_e}$ or smaller, transverse fluctuations are

 0021-8979/94/76(10)/6310/6/$6.00 © 1994 American Institute of Physics

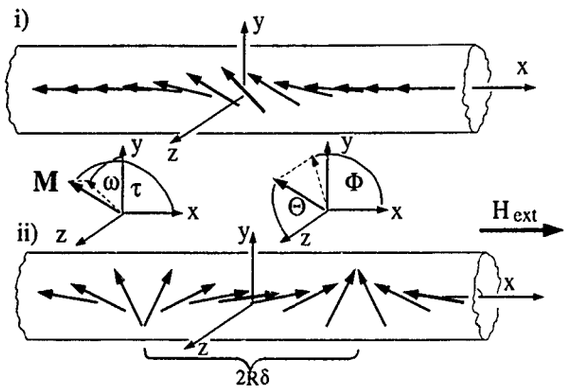

FIG. 1. The nucleus (3.2) for nonuniform magnetization reversal at (i) large external fields ($h\to 1$) and (ii) small external fields. For vanishing hard-axis anisotropy, this configuration is degenerate with all configurations that arise by a rotation around the easy axis.

suppressed and a 1D treatment is justified. The first term in the integrand of Eq. (2.1) is the exchange interaction between adjacent magnetic moments along the particle. The next two terms are effective easy and hard-axis anisotropies of strengths $K_e, K_h > 0$, respectively. They incorporate both crystalline and demagnetizing contributions.[10] For example, for an infinitely long sample of circular cross section, we have $K_e = K_{e,\mathrm{cryst}} + \pi M_0^2$, $K_h = K_{h,\mathrm{cryst}}$, where $k_{e,\mathrm{cryst}}$, $k_{h,\mathrm{cryst}}$ are crystalline anisotropy constants. The last term in Eq. (2.1) describes the interaction with an external field H_{ext} along the easy axis, which is conveniently expressed as

$$h = H_{\mathrm{ext}} M_0 / 2K_e . \tag{2.2}$$

It is appropriate to use spherical coordinates,

$$\mathbf{M}/M_0 = (\sin\theta\cos\phi, \sin\theta\sin\phi, \cos\theta),$$

where $\phi = \phi(x,t)$ and $\theta = \theta(x,t)$. The energy (2.1) then takes the form

$$E = \mathscr{A}\int_{L/2}^{L/2} dx \left\{ A\left[\left(\frac{\partial\theta}{\partial x}\right)^2 + \sin^2\theta\left(\frac{\partial\phi}{\partial x}\right)^2\right] + K_h\cos^2\theta - K_e(\sin^2\theta\cos^2\phi - 1) - H_{\mathrm{ext}}M_0(\sin\theta\cos\phi + 1)\right\}, \tag{2.3}$$

which is measured relative to the metastable state antiparallel to the external field. The magnetization is assumed to obey the Landau–Lifshitz–Gilbert equations

$$\frac{\partial\mathbf{M}}{\partial t} = -\gamma\mathbf{M}\times\mathbf{H}_{\mathrm{eff}} + \left(\frac{\alpha}{M_0}\right)\mathbf{M}\times\frac{\partial\mathbf{M}}{\partial t},$$

with $\mathbf{H}_{\mathrm{eff}} = -\delta\mathscr{E}/\delta\mathbf{M}$, which can be expressed as

$$\begin{aligned}(1+\alpha^2)\frac{M_0}{\gamma}\sin\theta\frac{\partial\phi}{\partial t} &= \frac{\delta\mathscr{E}}{\delta\theta} - \frac{\alpha}{\sin\theta}\frac{\delta\mathscr{E}}{\delta\phi},\\ (1+\alpha^2)\frac{M_0}{\gamma}\frac{\partial\theta}{\partial t} &= -\frac{1}{\sin\theta}\frac{\delta\mathscr{E}}{\delta\phi} - \alpha\frac{\delta\mathscr{E}}{\delta\theta},\end{aligned} \tag{2.4}$$

where $\mathscr{E} = E/\mathscr{A}$ is the energy per area and $\delta/\delta\phi$ denotes a functional derivative. The terms containing $\alpha > 0$ describe damping. For small values of the damping constant, the α dependence of the left-hand side (lhs) can be neglected.

The uniform configuration ($\phi_m = \pi$, $\theta_m = \pi/2$) antiparallel to the external field represents a metastable state while the state ($\phi_0 = 0$, $\theta_0 = \pi/2$) parallel to the external field is the minimum of the energy (2.1). In the following we investigate the energy barriers that separate these two states.

III. UNIFORM MAGNETIZATION REVERSAL

If the dimensions of a magnetic grain are smaller than a domain-wall width, the exchange energy dominates over demagnetizing contributions. The individual atomic magnetic moments are aligned and the system can be described by a uniform magnetization $\mathbf{M}$=const. The energy of an arbitrarily shaped particle of volume V is then given by

$$E = V[-K_e(\sin^2\theta\cos^2\phi - 1) + K_h\cos^2\theta - H_{\mathrm{ext}}M_0(\sin\theta\cos\phi + 1)]. \tag{3.1}$$

For $0 < h < 1$, the metastable state (ϕ_m, θ_m) is then separated from the stable state (ϕ_0, θ_0) by two equivalent barriers defined by

$$\cos\phi_s^{(0)} = -h, \quad \theta_s^{(0)} = \pi/2, \tag{3.2}$$

which have the energy

$$E_s^{(0)} = VK_e(1-h)^2. \tag{3.3}$$

In the vicinity of the saddle point, the energy (3.1) can be expanded to second order in the fluctuations $\varphi = \phi - \phi_s^{(0)}$, $p = \pi/2 - \theta$,

$$E \simeq E_s^{(0)} + V[-K_e(1-h^2)\varphi^2 + K_h p^2]. \tag{3.4}$$

The φ fluctuations are thus unstable while the out of easy-plane fluctuations are stable. In the vicinity of the metastable state the energy becomes

$$E \simeq V\{K_e(1-h)\varphi_m^2 + [K_e(1-h) + K_h]p_m^2\}, \tag{3.5}$$

where φ_m, θ_m are now the stable fluctuations away from the metastable point, i.e., $\varphi_m = \phi - \pi$, $p_m = \pi/2 - \theta$.

The uniform magnetization $\mathbf{M}$ obeys the equations of motion (2.4) with $\mathscr{E}$ replaced by the energy density E/V and with the functional derivatives replaced by partial derivatives. The dynamics near the saddle point is obtained by inserting Eq. (3.4) into Eq. (2.4). In particular we are interested in the motion away from the saddle point, i.e.,

$$[\varphi_+(t), p_+(t)] = e^{\lambda_+ t}(\varphi_+, p_+) \quad (\lambda_+ > 0),$$

which obeys

$$\begin{aligned}(1+\alpha^2)\frac{M_0}{2\gamma}\lambda_+\varphi_+ &= -K_h p_+ + \alpha K_e(1-h^2)\varphi_+,\\ (1+\alpha^2)\frac{M_0}{2\gamma}\lambda_+ p_+ &= -K_e(1-h^2)\varphi_+ - \alpha K_h p_+ .\end{aligned} \tag{3.6}$$

Note that the Landau–Lifshitz equation (2.4) is not consistent with the fluctuation-dissipation theorem since it lacks random forces which result from the coupling to the heat bath. Without such random forces, the magnetization would never be driven out of a metastable state. Such a term could

be added as a random field[4] to the right-hand side (rhs) of Eq. (2.4) to form a Langevin equation. However, it is only necessary to consider the stochastic dynamics near the saddle point, and we give a derivation of the corresponding Fokker–Planck equation in the Appendix.

Using the result Eq. (A11) of the Appendix, we obtain for the switching rate[7,8] out of the metastable state

$$\Gamma=\frac{\lambda_+}{\pi}\left(\frac{(K_e/K_h)(1-h)+1}{1+h}\right)^{1/2}e^{-\beta E_s^{(0)}}, \tag{3.7}$$

where we have included a factor of 2 due to the existence of the two equivalent saddle points (3.2). The escape frequency[7,8] follows from Eq. (3.6),

$$\lambda_+=\frac{\gamma/M_0}{1+\alpha^2}\{-\alpha[K_h+K_e(h^2-1)] + \sqrt{\alpha^2[K_h+K_e(1-h^2)]^2+4K_hK_e(1-h^2)}\}. \tag{3.8}$$

For weak hard-axis anisotropy, i.e., $\beta V K_h<1$ and $K_e>K_h$, the out of easy-plane fluctuations become large and the system behaves as if $K_h=0$. In this case, there is a degenerate class of energy barriers which arise from the configuration (3.2) by rotation around the easy axis. Equation (A12) then yields the switching rate[3,4]

$$\Gamma=\frac{\alpha}{1+\alpha^2}\frac{2\gamma(K_e)^{3/2}}{M_0}\left(\frac{\beta V}{\pi}\right)^{1/2}(1+h)(1-h)^2e^{-\beta E_s^{(0)}}. \tag{3.9}$$

Although Eq. (3.9) has been derived in the moderately damped regime, it is proportional to the damping constant α which is a characteristic of underdamped theories.

IV. NONUNIFORM MAGNETIZATION REVERSAL

Let us now return to the case of an elongated particle as described in Sec. II. The metastable state (ϕ_m,θ_m) along the sample and antiparallel to the external field is now separated from the stable state (ϕ_s,θ_s) by the nonuniform energy barrier (see Fig. 1),

$$\tan\frac{\phi_s}{2}=\frac{\cosh[(x-x_0)/\delta]}{\sinh R},\quad \theta_s=\frac{\pi}{2}, \tag{4.1}$$

where $\operatorname{sech}^2 R=h$ and $\delta=\sqrt{A/K_e}\coth R$. $2\delta R$ is the distance between the soliton and antisoliton constituting the nucleus (see Fig. 1). We have restricted ourselves to one of the two equivalent saddle points $\pm\phi_s$. The arbitrary position x_0 of the nucleus along the sample gives rise to a Goldstone mode of zero energy in the spin-wave spectrum. ϕ_s solves the Euler–Lagrange equations,

$$-(A/K_e)d^2\phi/dx^2+\sin\phi\cos\phi+h\sin\phi=0,$$

with the boundary condition that ϕ merges asymptotically into the metastable state. The corresponding barrier energy is

$$E_s=8\sqrt{AK_e}\mathscr{B}(\tanh R-R\operatorname{sech}^2 R), \tag{4.2}$$

where the first term is the deformation energy and the second term is the Zeeman energy of the nucleus. Equation (4.2) has three important features as follows.

(i) E_s is proportional to the sample cross-sectional area and the energy $8\sqrt{AK_e}\mathscr{B}$ of two π Bloch walls. This is in contrast to the uniform barrier energy (3.3) which is proportional to the volume. For sufficiently elongated particles, this leads to a lower coercivity than theories discussed in the previous section.

(ii) For small external fields ($R\to\infty$), where the nucleus consists of a reversed domain delimited by two domain walls, the barrier energy is twice the domain-wall energy. This shows the invalidity of the "activation volume" concept which assumes that the barrier energy equals the total anisotropy energy of the reversed domain.

(iii) The saddle point is connected to the stable state via a path of decreasing energy. Consider the sequence of configurations that arise from Eq. (4.1) if we fix δ at the value $\sqrt{A/K_e}\coth R_0$ but vary R between 0 and ∞. The energy of such configurations is

$$E=8\sqrt{AK_e}\mathscr{B}(\tanh R-R\operatorname{sech}^2 R_0),$$

which increases from 0 (for $R=0$) to E_s at $R=R_0$ and then decreases monotonically until the domain walls leave the sample and the magnetization is reversed. The way down from the saddle point is thus not obstructed by intermediate saddle points. As mentioned in Sec. I, this latter problem can arise for saddle points of curling symmetry.

We are now going to investigate the energy near the saddle point ϕ_s. Expanding Eq. (2.3) to second order in the fluctuations $\varphi(x)=\phi(x)-\phi_s(x)$ and $p(x)=\pi/2-\theta(x)$ around the saddle point, we obtain

$$E\simeq E_s+\mathscr{B}\int dx\ \varphi\mathscr{H}^{s\varphi}\varphi+\mathscr{B}\int dx\ p\mathscr{H}^{sp}p, \tag{4.3}$$

with the operators

$$\mathscr{H}^{s\varphi}=A\left[-\frac{d^2}{dx^2}+\delta^{-2}V_-\left(\frac{x}{\delta},R\right)\right], \tag{4.4}$$

$$\mathscr{H}^{sp}=A\left[-\frac{d^2}{dx^2}+\delta^{-2}V_+\left(\frac{x}{\delta},R\right)\right]+K_h. \tag{4.5}$$

The potentials are defined by

$$V_\pm(\xi,R)=1-2\operatorname{sech}^2(\xi+R)-2\operatorname{sech}^2(\xi-R) \pm 2\operatorname{sech}(\xi+R)\operatorname{sech}(\xi-R). \tag{4.6}$$

Two eigenfunctions of the eigenvalue problems $\mathscr{H}^{s\varphi,p}\chi_n^{s\varphi,p}=E_n\chi_n^{s\varphi,p}$ are exactly known: the Goldstone mode

$$\chi_1^{s\varphi}\propto\operatorname{sech}(x/\delta-R)-\operatorname{sech}(x/\delta+R)$$

of zero energy which corresponds to a translation of the nucleus, and the ground state

$$\chi_0^{sp}\propto\operatorname{sech}(x/\delta-R)+\operatorname{sech}(x/\delta+R)$$

of energy $E_0^{sp}=K_h$. Since the former eigenfunction has one node and the latter eigenfunction represents the ground state of $\mathscr{H}^{sp}$, there is exactly one eigenfunction with negative energy. This proves the instability of the nucleus. Inserting Eq. (4.3) into the Landau–Lifshitz equations (2.4), we recognize that the decay mode of the nucleus

$$[\varphi_+(x,t),p_+(x,t)]=e^{\lambda_+ t}[\varphi_+(x),p_+(x)],$$

with $\lambda_+>0$ obeys the following eigenvalue problem:

$$\begin{aligned}(1+\alpha^2)\frac{M_0}{2\gamma}\lambda_+\varphi_+&=-\mathscr{H}^{sp}p_+-\alpha\mathscr{H}^{s\varphi}\varphi_+,\\(1+\alpha^2)\frac{M_0}{2\gamma}\lambda_+p_+&=\mathscr{H}^{s\varphi}\varphi_+-\alpha\mathscr{H}^{sp}p_+.\end{aligned}\tag{4.7}$$

For the derivation of the switching rate we refer to the Appendix. For $h\to 1$, Eq. (A11) can be evaluated exactly[11] and we obtain the switching rate

$$\Gamma=\left(\frac{6}{\pi^3}\right)^{1/2}\frac{8\gamma K_e}{M_0}\frac{L}{\sqrt{A/K_h}}\sqrt{\beta\mathscr{A}\sqrt{AK_e}}(1-h)^{7/4}e^{-\beta E_s}.\tag{4.8}$$

This result is plotted in Fig. 2 which clearly illustrates the coercivity reduction compared to uniform reversal. For small K_h, i.e., $\beta\mathscr{A}\sqrt{A/K_e}K_h<1$, this result is not valid and we have to investigate an energy density with vanishing hard-axis anisotropy $K_h=0$. The energy (2.1) then exhibits rotational symmetry around the easy x axis. To account for this symmetry, it is more convenient to measure the polar angle from the external field, i.e.,

$$\mathbf{M}/M_0=(\cos\tau,\ \sin\tau\cos\omega,\ \sin\tau\sin\omega)$$

(see Fig. 1). $\tau_s(x)=\phi_s(x)$ solves the Euler–Lagrange equations in these new parameters, but it is completely degenerate with configurations that arise from Eq. (4.1) by a rotation around the easy axis by an angle $0\leq\omega_s<2\pi$ (see Fig. 1): A given saddle-point structure (τ_s,ω_s) thus breaks the rotational symmetry and there must be a corresponding (Goldstone) mode of zero energy in the spin-wave spectrum which corresponds to an infinitesimal rotation of the nucleus around the easy axis. As is shown in the Appendix, this rotation is equivalent to the ground state χ_0^{sp} of $\mathscr{H}^{sp}$ which acquires zero energy for $K_h=0$. The explicit knowledge of the rotational and the translational Goldstone mode allows the evaluation of the statistical prefactor for all values of h,[11] and we obtain from the Appendix

$$\Gamma=\frac{\tilde{\lambda}_+}{1+\alpha^2}\frac{64\gamma K_e}{\pi M_0}\beta\mathscr{A}L\frac{(1-h)^2}{h}e^{-\beta E_s},\tag{4.9}$$

where for $\alpha\gtrsim 1$, $\tilde{\lambda}_+=\alpha|E_0^{s\psi}|$ Inserted into Eq. (4.9), this vlaue for $\tilde{\lambda}_+$ also provides a good approximation of the switching rate for $\alpha\lesssim 1$. The prefactor in Eq. (4.9) remains finite since for small h,[11] we have $E_0^{s\varphi}=-2hK_e$ and for $h\to 1$, $E_0^{s\varphi}=-3(1-h)K_e$.

V. DISCUSSION

We have presented magnetization reversal rates for uniform and nonuniform magnetization reversal. It has been shown that for elongated particles, a spatially localized nucleus gives rise to a lower coercivity than a uniform barrier. This is also valid for the case of a vanishing hard-axis anisotropy as is illustrated in Fig. 2, where the switching rate is plotted as a function of the external field. The following material parameters have been used: $A=5\times10^{-7}$ erg/cm, $K_e=\pi M_0^2=7\times10^5$ erg/cm^3, $M_0=480$ Oe, $\gamma=1.5\times10^7$ Oe^{-1} s^{-1}, $T=300$ K, $K_h=K_e/5$, and $\alpha=0.05$. Note that the value of the prefactor considerably affects the value of the rate as is illustrated by the three curves for nonuniform reversal which all have the same Arrhenius factor.

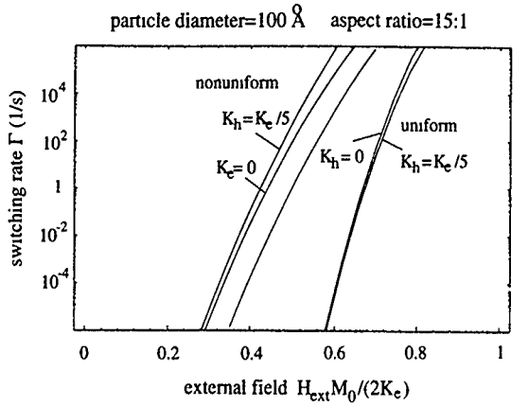

FIG. 2. Magnetization reversal rate for uniform and nonuniform reversal The dashed line is the approximation of "constant attempt frequency" $\Gamma\simeq(2\gamma K_e/M_0)\exp(-\beta E_s)$.

In view of recent experiments, one should keep in mind that the coercivity changes drastically[12] with the angle between the external field and the particle axis. A precise alignment of the particle with respect to the field is therefore extremely important.

Note that we have assumed a constant cross section of the particle. If the particle cross section is not constant, nonuniform barriers at different x_0 are no longer degenerate but they form a distribution of energy barriers. A single particle can therefore behave like an ensemble of many particles.

So far we have neglected effects that occur at the particle ends. The present treatment, however, also allows a first estimate for nucleation occurring at the particle ends. Assuming that the anisotropy persists to the very end of the particle and that the magnetization obeys open boundary conditions $d\mathbf{M}/dx(\pm L/2)=0$, the nucleus (4.1) with $x_0=-L/2$ restricted to $x>0$ describes the nucleation of a domain wall at the sample end at $x=-L/2$. The corresponding barrier energy is then half that of the nucleus $E_s/2$. In a real sample, however, the demagnetizing energy will lead to a decrease of the easy-axis anisotropy from $K_e=K_{e,\mathrm{cryst}}+\pi M_0^2$ to $K_e=K_{e,\mathrm{cryst}}$ at the sample end and thus lead to a modification of this picture. Finally, it should be noted that this behavior could be investigated experimentally by artificially pinning the sample ends by, e.g., a high-coercivity material.

APPENDIX

In this appendix we construct a Fokker–Planck equation for the magnetization dynamics and derive the corresponding switching rate. We focus on the moderately damped regime and barriers which are high compared to the thermal energy k_BT. Since the prefactor is of the order 10^{10} s^{-1}, this condition is satisfied even for large switching rates.

The present formalism which is based on work by Kramers and Langer[13] allows us to rederive the results of Zürcher[7] and Klik and Gunther[8] in a simple way. In addition, this method can be readily extended to interacting particles and nonuniform magnetization configurations.[5,11]

To simplify notation, it is convenient to use dimensionless units defined by $[x] = \sqrt{A/K_e}$, $[E/V] = 2K_e$, $[t]=(1+\alpha^2)M_0/(2\gamma K_e)$. Introducing the vectors $\psi=(\varphi,p)$, $h=(h_{s\varphi},h_{sp})$ with $h_{s\varphi}=h^2-1$, $h_{sp}=k_h/k_e$, the energy (3.4) near the saddle point reads $E\simeq E_s^{(0)}+\frac{V}{2}\Sigma_i h_i\psi_i^2$. The equations of motion linearized around the saddle point take the following form:

$$\frac{\partial\psi_i}{\partial t}=-\sum_j M_{ij}h_j\psi_j(t), \tag{A1}$$

where M is a matrix with $M_{11}=M_{22}=\alpha$, $M_{12}=-M_{21}=1$. The unstable mode $\psi_i(t) = e^{\lambda_+ t}\psi_i^+$ with $\lambda_+>0$ [Eq. (3.6)] thus obeys the equation

$$\lambda_+\psi_i^+=-\sum_j M_{ij}h_j\psi_j^+ . \tag{A2}$$

Rather than investigating the stochastic trajectories $\psi_i(t)$ that arise by adding noise terms to Eq. (A1) we now focus on the probability $\rho(\psi_i)\Pi_i\, d\psi_i$ of finding the system in a phase-space volume element $\Pi_i\, d\psi_i$ around the state ψ_i. The dynamics of this probability distribution is then governed by the Fokker–Planck equation

$$\frac{\partial\rho}{\partial t}+\sum_i \frac{\partial J_i}{\partial\psi_i}=0, \tag{A3}$$

with the probability current

$$J_i=-\sum_j M_{ij}\left(h_j\psi_j+\frac{1}{\tilde\beta}\frac{\partial}{\partial\psi_j}\right)\rho. \tag{A4}$$

Note that due to the structure of M only the diagonal part contributes to the second term in Eq. (A4). Equation (A3) can be formally derived from a Langevin equation with Gaussian white noise, but it is more instructive to consider the following heuristic motivation: (i) The coefficient of ψ_i in Eq. (A4) is constructed such that $\partial\langle\psi_i\rangle/\partial t=\langle\partial\psi_i/\partial t\rangle$. (The expectation value is defined as $\langle f\rangle=\int\Pi_i d\psi_i f\rho$); (ii) the coefficient of the derivative is determined such that the equilibrium distribution near the saddle point,

$$\rho_{eq}=Z^{-1}\exp\left[-\tilde\beta\left(e_s^{(0)}+\tfrac{1}{2}\sum_i h_i\psi_i^2\right)\right], \tag{A5}$$

is a static solution of Eq. (A3) with vanishing current, where $\tilde\beta=\beta V$ and $e_s^{(0)}=E_s^{(0)}/V$. Z is the normalization with respect to the vicinity of the metastable state.

Equation (A3) represents a continuity equation in phase space. The "leakage" of the system out of a certain region of phase space, e.g., the vicinity of the metastable state, is thus given by the flux through the boundary of this region. Due to the Boltzmann factor $\exp(-\beta E)$, this flux will be maximal around the saddle point which represents the connection of lowest energy between the metastable and the stable state. The goal of calculating the switching rate out of the metastable state thus amounts to the evaluation of the total probability current of a stationary nonequilibrium distribution through a surface near the saddle point.

Since we consider high barriers, the desired nonequilibrium probability distribution ρ will thus approach an equilibrium distribution in the vicinity of the metastable state while it has to vanish beyond the saddle point. Following Kramers, the stationary nonequilibrium distribution is assumed to factorize as follows near the saddle point:

$$\rho=\rho_{eq}F(u), \tag{A6}$$

where F depends on the single coordinate $u=\Sigma_i U_i\psi_i$ (even in the case of arbitrarily many degrees of freedom), with coefficients U_i to be determined. Inserting Eq. (A6) with Eq. (A5) into Eq. (A3) and using $\partial\rho/\partial t=0$ we obtain

$$-\sum_{ij} M_{ij}h_i\psi_i U_j\frac{dF}{du}+\frac{1}{\tilde\beta}\sum_{ij} M_{ij}U_iU_j\frac{d^2F}{du^2}=0, \tag{A7}$$

where the above boundary conditions imply $F(-\infty)=1$, $F(\infty)=0$. The consistency of the ansatz requires this to be a differential equation in u alone, and thus

$$\sum_{ij} M_{ij}h_i\psi_iU_j=\kappa u,\quad \frac{1}{\tilde\beta}\sum_{ij} M_{ij}U_iU_j=\gamma\kappa. \tag{A8}$$

First we note that $\Sigma_{ij}M_{ij}U_iU_j = \alpha\Sigma_i U_i^2$ and thus $\gamma\kappa>0$. To elucidate the meaning of κ we remark that the first equation in Eq. (A8) is solved by $U_j=h_j\psi_j^+$ and therefore $\kappa=-\lambda_+<0$. The constant γ will cancel in the final result. Equation (A7) then takes the form $-u\,dF/du+\gamma\,d^2F/du^2=0$ and the boundary conditions on F are satisfied by the solution

$$F(u)=\frac{1}{\sqrt{2\pi|\gamma|}}\int_u^\infty du\,\exp\left(-\frac{u^2}{2|\gamma|}\right). \tag{A9}$$

Inserting Eqs. (A9) and (A6) into Eq. (A4) we obtain

$$J_i=-\frac{1}{\tilde\beta}\sum_j M_{ij}U_j\rho_{eq}\frac{dF}{du}.$$

The switching rate is then given by the total probability flux through a surface near the saddle point which we choose for convenience to be $u=0$,

$$\Gamma=\int_{u=0} dS\sum_i U_iJ_i=\lambda_+\left(\frac{|\gamma|}{2\pi}\right)^{1/2}\int_{-\infty}^{\infty}\prod_i d\psi_i\,\delta(u)\rho_{eq}. \tag{A10}$$

The equilibrium probability density thus has to be evaluated near the saddle point where it is given by Eq. (A5). Using $\delta(u)=\int(dq/2\pi)\exp(iqu)$ we perform first the integration over the stable directions and then over q. The coefficient of the resulting final Gaussian integration over the unstable mode is negative although the energy decreases along this unstable direction. This follows from Eq. (A8) which implies that $\Sigma_i U_i^2/h_i=\tilde\beta\gamma<0$. Since ρ_{eq} is strongly peaked around the metastable state, we can use a Gaussian approximation and obtain $Z = \Pi_i\sqrt{2\pi/\tilde\beta h_{mi}}$ where $h_{m\varphi}=1-h$ and

$h_{mp}=1-h+K_h/K_e$ are the coefficients in a quadratic expansion of the energy (3.5). We thus finally obtain for the switching rate

$$\Gamma=\frac{\lambda_+}{2\pi}\left(\frac{\Pi_i h_{mi}}{\Pi_i|h_i|}\right)^{1/2} e^{-\tilde{\beta}e_s^{(0)}}, \tag{A11}$$

where λ_+ is the decay frequency of the nucleus and the remaining term is the ratio of the partition functions evaluated in Gaussian approximation at the saddle point and the metastable state respectively. In the derivation of Eq. (A11) it has been assumed that there is only one single saddle point. Since Eq. (3.2) defines two equivalent saddle points, Eq. (A11) has to be multiplied by a factor of 2 to yield the result (3.7).

Note that the result (A11) is completely general and can be extended to other situations with artibrarily many degrees of freedom such as interacting particles and spatially nonuniform situations.

We now focus on the situation of a vanishing hard-axis anisotropy $K_h=0$. In this case, $h_{sp}=K_h/K_e$ becomes zero and the formerly stable direction at the saddle point becomes flat. There is now a completely degenerate class of saddle points which is conveniently expressed in terms of τ and ω as in Sec. IV. The saddle point is then given as in Eq. (3.2), $\cos\tau_s^{(0)}=-h$, but as a consequence of the rotational symmetry around the easy axis the azimuthal angle $0\leqslant\omega_s^{(0)}\leqslant 2\pi$ is arbitrary.

Since the previous treatment required the existence of a stable direction at the saddle point, the derivation of the switching rate now proceeds along somewhat different lines. The difficulty arises when we try to perform the integration in Eq. (A10) over the variable $\psi_2\equiv p$ which diverges since $h_{sp}=0$. The infinite integration domain in Eq. (A10) is, however, only sensible if the Gaussian approximation of the partition function provides a sufficiently fast decay. Since this integration is related to the rotational degeneracy, it is inadequate to use an infinite integration domain. It rather has to be replaced by a finite integration over the angle $\omega_s^{(0)}$. Since a rotation around the easy axis by an angle $d\omega$ corresponds to a fluctuation $dp/\sin\tau_s^{(0)}$, the correct value for the integral is

$$\int dp_2=\sin\tau_s^{(0)}\int_0^{2\pi}d\omega_s^{(0)}=2\pi\sin\tau_s^{(0)},$$

which replaces the former term $\sqrt{2\pi/\beta h_{sp}}$ in Eq. (A11). In dimensionless units the rate becomes

$$\Gamma=\lambda_+\left(\frac{h_{m\varphi}h_{mp}}{|h_{s\varphi}|}\right)^{1/2}\left(\frac{\tilde{\beta}}{2\pi}\right)^{1/2}\sin\phi_s^{(0)}e^{-\beta E_s^{(0)}}, \tag{A12}$$

where $\phi_s^{(0)}$ is given by Eq. (3.2) and the dimensionless escape frequency $\lambda_+=\alpha(1-h^2)$ follows from Eq. (3.6).

For *nonuniform* configurations, we obtain by an adaptation of the previous method[11] the following expression of the switching rate:

$$\Gamma=\lambda_+\mathscr{L}\left(\frac{\beta\mathscr{A}}{2\pi^3}\right)^{1/2}\left(\frac{\det\mathscr{H}^{m\varphi}}{\det'|\mathscr{H}^{s\varphi}|}\right)^{1/2}\left(\frac{\det\mathscr{H}^{mp}}{\det\mathscr{H}^{sp}}\right)^{1/2}e^{-\beta E_s}, \tag{A13}$$

which is expressed in dimensionless units. Since there are two degenerate saddle points $\pm\phi_s$, a factor of 2 has been included in Eq. (A13). "det" denotes now the infinite product [see Eq. (A11)] of the eigenvalues of the fluctuation operators and the prime denotes omission of the eigenvalue $E_1^{s\varphi}=0$. $\mathscr{H}^{m\varphi}=-d^2/dx^2+1-h$, $\mathscr{H}^{mp}=\mathscr{H}^{m\varphi}+K_h/K_e$ describe fluctuations around the metastable state (ϕ_m,θ_m) and $\mathscr{L}=L\sqrt{E_s/2\mathscr{A}}\sqrt{AK_e}$ arises from the integration over the translational Goldstone mode $\chi_1^{s\varphi}$. In the limit $h\rightarrow 1$, Eq. (A13) can be evaluated analytically[11] with the result (4.8).

For vanishing hard-axis anisotropy $K_h=0$, the result (A13) fails since the ground state of $\mathscr{H}^{sp}$ acquires zero energy and needs a special treatment in the derivation of the rate formula: A rigid rotation around the easy axis by an angle $d\omega$ corresponds to the fluctuation $d\varphi(x)=0$, $dp(x)=\sin\phi_s(x)d\omega$. Since $\sin\phi_s\propto\chi_0^{sp}$, we also have $dp(x)=\chi_0^{sp}dp_o$, and the integration over the mode amplitude p_0 in the Gaussian integral in Eq. (A10) can be expressed as

$$\int dp_0=\left(\int_{-\infty}^{+\infty}dx\,\sin^2\phi_s\right)^{1/2}\int_0^{2\pi}d\omega$$

$$=4\pi(\tanh R+R\,\mathrm{sech}^2 R,$$

which replaces the factor $\sqrt{2\pi/\beta\mathscr{A}E_0^{sp}}$ that arises for $K_h\neq 0$. This fact allows an analytic evaluation of the statistical prefactor for all values of h. Using the exact results[11] for the fluctuation determinants, we obtain Eq. (4.9) after reinstating units.

Cobalt particles were prepared with the microemulsion method in the binary system of DDAB (didodecyldimethylammonium bromide)/toluene by reduction of $CoCl_2$ with $NaBH_4$. The average particle size of the as-prepared samples could be varied from 1.8 to 4.4 nm by controlling the concentration of $CoCl_2$ in the solution of DDAB in toluene. TEM studies showed that the particles were quite uniform and well isolated. The particle sizes determined from magnetic data were consistent with those measured by TEM. The coercivity of the particles at 10 K increased from 640 to 1250 Oe as particle size increased from 1.8 to 4.4 nm. The blocking temperature of the particles increased from 19 to 50 K for the same size range. The saturation magnetization σ_s at 2 K increased with decreasing particle size. The value of σ_s of the particles with average size of 1.8 nm was about 200 emu/g, which is 20% higher than the bulk value. This implies that the magnetic moment per atom is enhanced in the nanoparticle system.

I. INTRODUCTION

Nanoscale materials show novel properties that are often significantly different from the bulk due to fundamental changes in coordination, symmetry, and confinement. In magnetic materials advantage has been taken, for a considerable time, of the variation of magnetic properties of fine particles due to effects such as single domains, superparamagnetism, and surface interaction. Only recently, however, have magnetic studies proceeded into the ultrasmall regions where more fundamental changes will occur as the bulk transforms to the atomic. In this work we describe the synthesis of nanoscale metallic cobalt particles using an inversed micelle synthesis method. A consistent set of size dependent magnetic data are obtained, the most surprising of which show an enhanced, relative to the bulk, magnetic moment per Co atom.

II. EXPERIMENTAL METHODS

Cobalt particles were prepared by the microemulsion method in the binary system of DDAB/toluene.[1,2] $NaBH_4$ was used to reduce $CoCl_2$ to produce Co particles. First $CoCl_2 \cdot 6H_2O$ was dissolved in a deoxygenated 11 wt % DDAB solution in toluene at concentrations of 0.005–0.02 M. The reagent was trapped in the empty micelles and formed a blue transparent solution. Then a 10 M $NaBH_4$ aqueous solution was added on the condition of $[BH_4]:[Co^{2+}]=3:1$ and stirred. It eventually turned from blue to black and formed a stable colloid. The colloid was dried in a glove bag with all the toluene evaporated and formed a paste sample. The cobalt particles were uniformly distributed in the DDAB matrix.

The x-ray spectrum of a paste sample showed only the (111) peak of fcc cobalt. Since the concentration of cobalt in the sample is about 0.6 wt %, the other weaker peaks were in the noise.

When we studied the dependence of the spontaneous magnetization on temperature at low field for zero-field cooled samples, we found that the particles were not pure metallic cobalt when the mole ratio of water to DDAB was much larger than one. Figure 1 shows the data for two samples with the same preparation except the water content. In sample A 60 μl of 5 M $NaBH_4$, whereas in sample B 30 μl of 10 M $NaBH_4$, was added to 10 ml of 0.01 M $CoCl_2$ solution in DDAB/toluene. Sample A shows two peaks in Fig. 1, while its saturation magnetization was just 50% of that of sample B, which had only one peak in σ vs T plot. The two peaks imply two magnetic phases in sample A. In nonmicroemulsion systems we have shown[3] how water causes the borohydrate reduction to create Co_2B whereas Co is created in the absence of water. Thus we interpret the results for sample A to imply that both Co and Co_2B particles

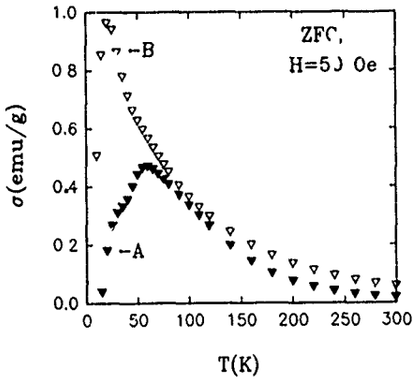

FIG. 1. Temperature dependence of the spontaneous magnetization at $H=50$ Oe for zero-field cooled samples A and B. In sample A 60 μl of 5 M $NaBH_4$, whereas in sample B 30 μl of 10 M $NaBH_4$, was added to 0.01 M $CoCl_2$ solution in DDAB/toluene The peak at 20 K in both A and B is due to Co; the peak at 60 K in A is due to Co_2B.

FIG. 2. TEM photograph of the cobalt particles with an average particle size of 3.3 nm.

were produced. On the other hand, in sample B only Co is produced. There was, of course, water present in sample B. But at low concentration (one H_2O molecule per DDAB molecule in sample B) the water must be fixed by the hydrophilic part of the DDAB and unable to participate in the Co reduction. We remark that Pileni *et al.*[4] found the oxidation states of copper metallic clusters changed with the change of water content in the micelles.

With the above results in mind, we controlled the ratio of $[H_2O]$:[DDAB] below 1.5 to make pure metallic cobalt. The particle size was varied by changing the $CoCl_2$ concentration in the DDAB/toluene system from 0.005 to 0.02 M. We have also tried to increase the particle size by increasing the reaction temperature to 50 °C, but no obvious change was observed.

III. RESULTS AND DISCUSSION

A TEM study was carried out to size the particles and study their morphology. The particle diameter changed from 1.8 to 4.4 nm as the $CoCl_2$ concentration increased from 0.005 to 0.02 M. Figure 2 is a TEM picture of one sample with an average diameter of 3.3 nm. The particles are well separated and their sizes are narrowly distributed.

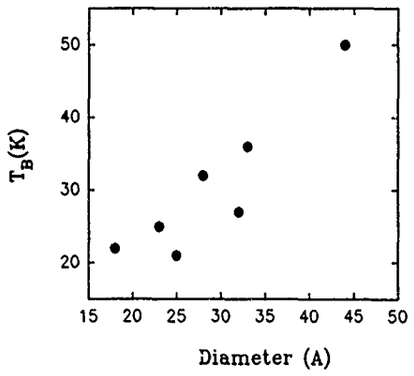

FIG. 3. The blocking temperature as a function of size for Co particles

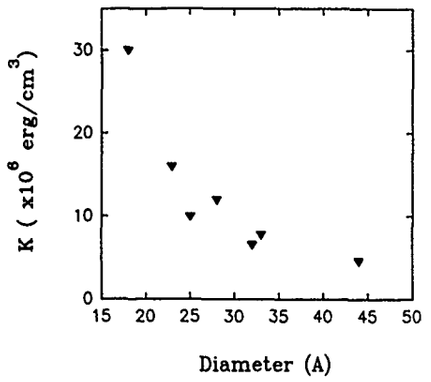

FIG. 4. Relation between the anisotropy constant and size of Co particles.

The magnetic properties were measured by a SQUID magnetometer. All the particles were in the superparamagnetic state at room temperature. The sample was cooled in zero field to 2 K, and then magnetization was measured as a function of temperature in a 50 Oe field to determine the blocking temperature. The relation between the blocking temperature and the particle size is shown in Fig. 3. The blocking temperature increased as particle size increased, which is consistent with the behavior of fine particles.

The blocking temperature should roughly satisfy the relationship

$$T_B = \frac{KV}{30k_B}, \tag{1}$$

where K is the anisotropy constant, k_B Boltzmann's constant, and V the average volume of the particle. With the knowledge of the blocking temperature and the particle size, we calculated the anisotropy constant for the Co particles as shown in Fig. 4. The calculated anisotropy is larger than the bulk value of fcc cobalt (2.7×10^6 erg/cm^3)[5,6] and increases with the decrease of particle size.

At 10 K, all the samples were in the ferromagnetic state. The coercivities of different samples are shown in Fig. 5. As particle size increased, the coercivity increased, which is the behavior of single-domain particles caused by thermal effects.

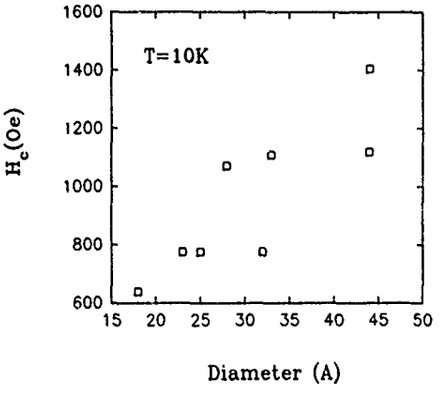

FIG. 5. Size dependence of coercivity of Co particles at 10 K

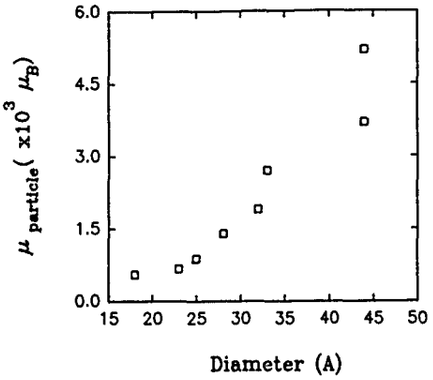

FIG. 6. Magnetic moment per particle determined from σ_s and susceptibility and for different samples at temperatures higher than T_B.

Above the blocking temperature, the magnetic anisotropy energy barrier of the single-domain particles is overcome by thermal energy and superparamagnetism occurs. The magnetic moment per particle was calculated from the susceptibility and saturation magnetization. The results are shown in Fig. 6 as a function of the TEM determined size.

All the above results are consistent with the properties of ultrafine particles. The saturation magnetization (σ_s) of the cobalt particles at 2 K (Fig. 7) showed surprising behavior. The particles were not saturated even at 5.5 T despite their large moments. To obtain σ_s we plotted σ vs $1/H$ and extrapolated to $1/H \rightarrow 0$. Figure 8 shows the relation between the saturation magnetization and the particle size. The magnetizations are larger than the bulk value of cobalt and increase with decreasing particle size. For the smallest particles, the saturation magnetization was about 200 emu/g, about 20% larger than the bulk value of fcc cobalt, which is

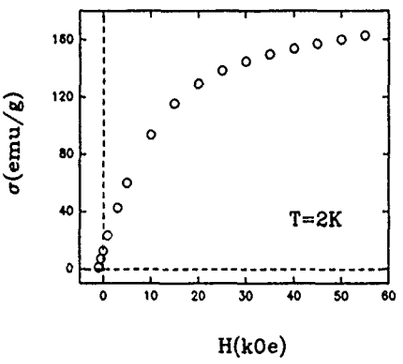

FIG. 7. Magnetization as a function of field at 2 K for a sample with the average particle size of 3.3 nm.

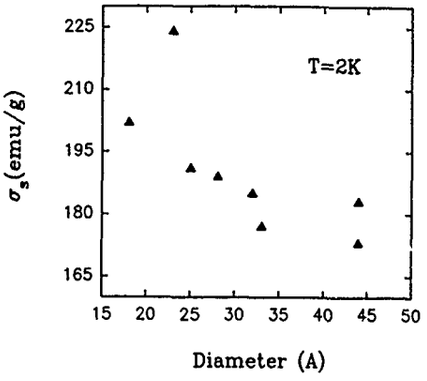

FIG. 8. Saturation magnetization of Co particles at $T=2$ K (bulk $\sigma_s=166$ emu/g).

166 emu/g.[7] An enhancement of the magnetic moment per atom in cobalt has been observed in free cobalt clusters[8] and ultrathin Co/Ag(001) films,[9] and has been predicted by theoretical calculations[10,11] this is the first time that the enhancement has been observed in supported cobalt particles.

IV. CONCLUSIONS

We have successfully made cobalt fine particles with the size varying from 1.8 to 4.4 nm. The Co particles are single-domain particles and in superparamagnetic state at room temperature. The anisotropy constants in our Co particles are larger than that of bulk material. An enhanced magnetic moment per Co atom compared to the bulk was observed. This enhancement increases with decreasing size to be ~20% greater than bulk for 1.8 nm particles. This result is consistent with theoretical calculations and experimental results in free cobalt clusters.

The structural and magnetic properties of two Fe-Co alloy particles with composition $Fe_{100-x}Co_x(x=45,65)$ were studied using x-ray diffraction, x-ray photoelectron spectroscopy, transmission electron microscopy, superconducting quantum interference device magnetometry, and Mössbauer spectroscopy. The particles were nearly spherical in shape with an average particle size around 350 Å. Particles formed long chains and showed a core/shell particle morphology. X-ray diffraction and Mössbauer studies showed the presence of bcc α-Fe-Co and $CoFe_2O_4$ phases with the former as the majority phase in $Fe_{55}Co_{45}$ and the latter the majority phase in $Fe_{35}Co_{65}$. The room-temperature coercivities of both of these samples were much higher than those in Fe particles with values exceeding 2.2 kOe. The $Fe_{35}Co_{65}$ sample showed a drastic temperature dependence of coercivity from 1.5 kOe at 300 K to 15 kOe at 10 K. The structural and magnetic data suggest a core/shell morphology with the surface oxide layer having a very important impact on both the magnitude and temperature dependence of the coercivity of the whole particle.

Previous studies on Fe, Co, and Ni particles prepared by gas evaporation have shown large coercive forces with values of 1050, 1200, and 100 Oe, respectively.[1] Transmission electron microscopy (TEM) and Mössbauer studies indicated a core-shell particle structure with a metallic core surrounded by the corresponding oxide shell. Micromagnetic calculations[2] and experimental studies[3] on passivated and unpassivated γ-Fe_2O_3 particles have shown that the thickness and magnetic state of the oxide layer affects the switching fields and hence the coercivity of the particle. In passivated Fe and Co particles the hysteresis behavior was found to be strongly dependent on the amount of surface oxidation and the magnetic interaction at the core-shell interface was claimed to be responsible for the high coercivity.[4] Previous work[5] on Fe-Co alloy particles has shown coercivities exceeding 2.5 kOe which are much higher than those of either Fe or Co particles. A similar behavior has been observed on elongated Fe-Co particles prepared by electrodeposition[6] and the high coercivity was attributed to the presence of a cobalt ferrite oxide layer on the surface of the particle.

In the present paper we try to understand the origin of the high coercivity of Fe-Co alloy particle samples by comparing their structural, microstructural, and magnetic properties.

Two Fe-Co alloy particle samples prepared by the gas evaporation method were obtained from Vacuum Metallurgical Co., Japan.

The structure of the particles was determined by x-ray diffraction (XRD) and selected area diffraction (SAD) patterns. The particle size was determined by transmission electron microscopy (TEM) and their composition was deter-

mined by energy dispersive x-ray analysis (EDAX). X-ray photoelectron spectroscopy (XPS) was used to probe and characterize the surface of the particles. The magnetic properties were measured by both a vibrating sample magnetometer (VSM) and a superconducting quantum interference device (SQUID) magnetometer. Mössbauer spectroscopy was also carried out to determine the type of the oxides present.

The two samples studied had a nominal composition $Fe_{100-x}Co_x$ with $x=45$ and 65. EDAX measurements gave the x values of 43 and 64, respectively.

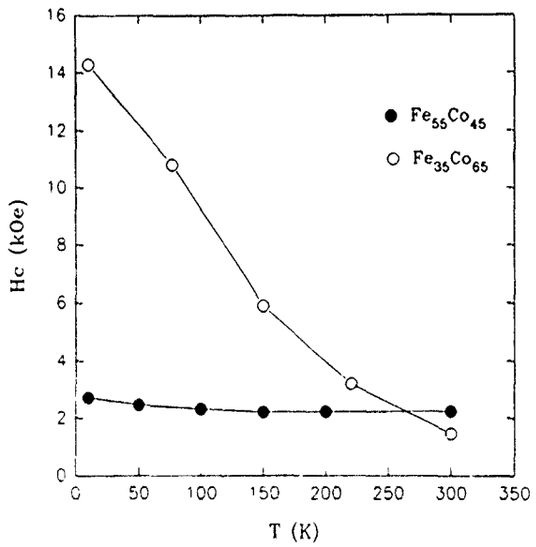

FIG 3. Temperature dependence of coercivity in the two Fe-Co samples.

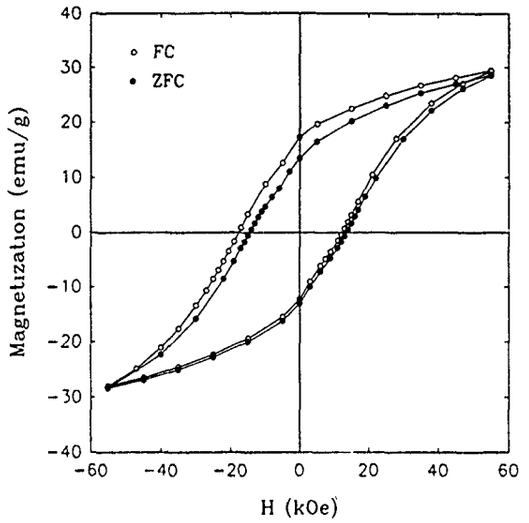

FIG. 4. Zero-field-cooled (ZFC) and field-cooled (FC) hysteresis loop in an $Fe_{35}Co_{65}$ sample.

The x-ray diffraction pattern of $Fe_{55}Co_{45}$ was dominated by bcc Fe-Co, with few extremely weak and broadened peaks corresponding to $CoFe_2O_4$ [Fig. 1(a)], while the pattern of $Fe_{35}Co_{65}$ showed strong and relatively broadened peaks corresponding to $CoFe_2O_4$ [Fig. 1(b)]. The asymmetric broadening of the $CoFe_2O_4$ peaks may be due to the small grain size and the off-stoichiometric composition of $CoFe_2O_4$. The presence of an Fe/FeCo phase could not be detected unambiguously due to the overlap of its d spacing with that of the asymmetric broadened peaks of the $CoFe_2O_4$ phase. Selected area diffraction (SAD) patterns agreed with the XRD results.

Bright-field micrographs obtained for the two samples revealed that the particles were about spherical in shape and formed a long chain-like structure. The average grain size of the two samples was about the same and ~350 Å (Fig. 2). The particles in the $Fe_{35}Co_{65}$ sample showed a very distinct contrast between the inside core area and surface shell region as shown in Fig. 2(b).

The magnetic properties of these samples were measured in the temperature range from 10 to 300 K. $Fe_{35}Co_{65}$ showed an M_s around 30 emu/g while in $Fe_{55}Co_{45}$ M_s was much

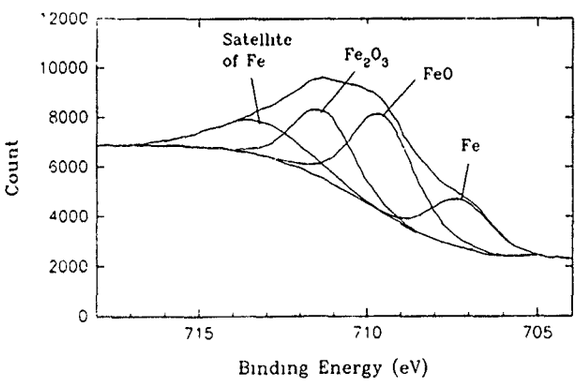

FIG. 5. XPS spectra of $Fe_{55}Co_{45}$.

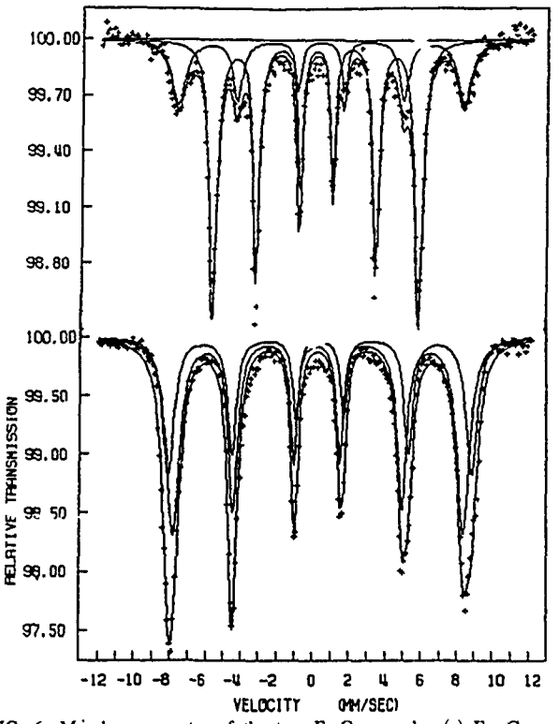

FIG. 6. Mössbauer spectra of the two Fe-Co samples (a) $Fe_{55}Co_{45}$, (b) $Fe_{35}Co_{65}$.

higher, over 170 emu/g. Such a difference in the magnetization of the two samples could be due to the presence of a large amount of $CoFe_2O_4$ in $Fe_{35}Co_{65}$ as compared to $Fe_{55}Co_{45}$, and to possible surface spin pinning in the former because of a thicker cobalt ferrite shell. The decrease in M with increasing T (10–300 K) was only about 5%. The remanence was about 0.5 in both the samples. The temperature dependence of coercivity for the two samples was quite different, as shown in Fig. 3. The coercivity of the $Fe_{35}Co_{65}$ sample was ~1.5 kOe at 300 K and increased to 15 kOe at 10 K (about 900% increase) while the coercivity of the $Fe_{55}Co_{45}$ sample was 2.2 kOe at 300 K and increased slightly to 2.7 kOe at 10 K (only 25% increase).

Field-cooled hysteresis loops on both samples showed a shift to the left (Fig. 4) with the value of the shift much larger in the $Fe_{35}Co_{65}$ sample (about 3 kOe in $Fe_{35}Co_{65}$ and 0.5 kOe in $Fe_{55}Co_{45}$ at 10 K). The shift in the field-cooled (FC) loops (H_{cool}=20 kOe) is believed to be the result of exchange interaction at the interface of a core-shell particle morphology. The larger amount of shift in $Fe_{35}Co_{65}$ is consistent with the presence of a thicker cobalt ferrite shell.

XPS is a sensitive technique to detect the type of oxides on the surface of the particles. The presence of the Fe-Co oxides was determined by deconvoluting the asymmetric broadening of the higher-energy edge of the metallic Fe and Co peaks. Figure 5 shows the spectrum of $Fe_{55}Co_{45}$ around the binding energy of Fe. These data show clearly the presence of surface oxides in both samples. Because XPS probes the surface layer, a thin Fe-O layer on the surface can result in a corresponding peak in the spectrum.

TABLE I. Mössbauer parameters δ is the isomer shift. ΔE_Q is the quadrupole splitting. H is the hyperfine field.

Sample	δ(mm/s)	ΔE_Q(mm/s)	H(kOe)	ΔH(kOe)	%	Phase
$Fe_{55}Co_{45}$	0.40	0.02	504	20	28	$(Fe,Co)_3O_4$
	0.14	−0.004	362	80	72	Fe-Co
$Fe_{35}Co_{65}$	0.37	0.018	506	15	*A*	$(Fe,Co)_3O_4$
	0.51	−0.02	529	12	*B*	

Mössbauer spectra for $Fe_{55}Co_{45}$ showed a mixture of Fe-Co alloy and cobalt ferrite while the spectrum of $Fe_{35}Co_{65}$ showed only $CoFe_2O_4$ (Fig. 6). The ratio of Fe^{3+} at the A and B site was 1.6:1 instead of 1:1, indicating an off-stoichiometric $CoFe_2O_4$. The Mössbauer parameters are listed in Table I. The fact that no FeO has been observed with Mössbauer indicates a small percentage of this oxide (<5%). This is different in XPS, where a thin FeO layer on the surface can result in a corresponding peak in the spectrum.

The XRD and Mössbauer results on the Fe-Co alloy particles indicated a core-shell particle morphology. In $Fe_{55}Co_{45}$ the core is a bcc Fe-Co alloy while the shell consists of Fe-Co oxides with $CoFe_2O_4$ as the majority oxide. In $Fe_{35}Co_{65}$ the core/shell morphology is composed of stoichiometric and off-stoichiometric $CoFe_2O_4$, respectively.

Based on the present and our previous experiments with passivated Fe particles,[4] we believe that the $CoFe_2O_4$ oxide layer plays an important role in the magnetic properties of the particles. It results in a large surface-pinning force, which impedes the rotation of magnetization near the interface layer toward the direction of the external field, and thus it leads to the high coercivity and nonsaturation effects even at 55 kOe. The anisotropy constant K_1 of $CoFe_2O_4$ is much higher than that of Fe_3O_4 (the values are 2×10^6 and -1.1×10^5 erg/cm^3 at room temperature, respectively[7]) and has a strong temperature dependence: K_1 (0 K) is almost an order of magnitude higher than K_1 (300 K).[8] This large temperature dependence of K_1 explains the drastic temperature dependence of the coercivity in $Fe_{35}Co_{65}$.

This work has been supported by NSF-CHE-9013930. The Fe-Co alloy particle samples were supplied by Dr. M. Oda of Vacuum Metallurgical Co., Japan.

The local structure and chemistry of a ferromagnetic fcc-$Fe_{50}Cu_{50}$ solid solution obtained through high-energy ball milling were measured before and after heat-treatment-induced decomposition using extended x-ray-absorption fine-structure measurements. The decomposition is first evident with the phase separation of α-Fe after a heat treatment at 523 K. Analysis of the residual fcc component revealed that the Fe atoms were predominantly surrounded by other Fe atoms, suggesting that the Fe has coalesced within the fcc structure. The Fe atoms within the fcc phase likely exist in low-spin clusters which provide an explanation for the reduced values of low-temperature magnetization previously measured in annealed samples [P. Crespo *et al.*, Phys. Rev. B **48**, 7134 (1993)].

Much research has been focused on the Fe_xCu_{1-x} system since it was shown that the miscibility of Fe in fcc-Cu can be greatly enhanced, $0 \leq x \leq 0.6$, through high-energy ball milling.[1–4] In recent work,[3,4] some of the authors have reported on the magnetic and structural properties of a ferromagnetic fcc-$Fe_{50}Cu_{50}$ solid solution processed using high-energy ball milling. Their findings indicate anomalous magnetic behavior for heat-treated samples in the intermediate stages of decomposition. Specifically, a significant decrease of the low-temperature magnetization relative to the value measured for the as-milled sample was observed in annealed samples where multiple phases are present. This behavior cannot be accounted for by a nucleation and growth decomposition where the alloy separates into pure fcc-Cu and bcc-Fe components. Alternatively, these authors have suggested a spinodal mechanism to describe the decomposition process. In an attempt to elucidate the decomposition mechanism in this material we have measured the average local structure and chemistry around the Fe and Cu sites before and after heat treatments using extended x-ray-absorption fine-structure (EXAFS) measurements.

Powder samples, having a nominal composition of $Fe_{50}Cu_{50}$, were fabricated by high-energy ball milling Fe powder with Cu foil for a period of 400 h in a Fritsch vibrating mill. X-ray-diffraction measurements of the milled powder revealed only Bragg peaks corresponding with a single fcc phase having a lattice parameter of 3.641 Å. Samples of the as-milled FeCu powders were annealed under flowing argon gas to temperatures ranging from 523 to 923 K at a rate of 20 K/min and were then allowed to cool. Details of sample processing and characterization, including results of x-ray-diffraction, Mössbauer effect, and magnetization measurements, have been reported in Ref. 4.

A portion of the as-milled and annealed powders were examined using the NRL materials analysis beamline, X23B, at the National Synchrotron Light Source (Brookhaven National Laboratory, Upton, NY). The x-ray-absorption spectra near the Fe and Cu K absorption edges were collected in conversion electron mode after attempts to employ the transmission mode failed due to our inability to grind the powder to the scale required for EXAFS measurements. In using the conversion electron technique we applied a generous amount of the powder over a still-wet coating of colloidal graphite on a substrate of commercial grade Al foil. As per this technique, the absorption spectra was measured as normalized sample current (see Ref. 5 for details of the operation and performance of the conversion electron cell used here).

Following established EXAFS analysis procedures[6] the fine structure extending from 20 to 600 eV above the absorption edges were first normalized to the edge step height and energy, then fitted with a cubic spline curve to remove a low-frequency background oscillation, and converted to photoelectron wave-vector (k) space. These data were then Fourier transformed to radial coordinates in order to obtain direct information of the structure and atomic symmetry around the Fe and Cu sites. Quantitative information of the local structure and chemistry around the Fe sites were obtained by further fitting the near-neighbor peak of the Fourier-transformed EXAFS data with empirical and theoretical standards. EXAFS data for the as-milled sample were fit using theoretical EXAFS spectra generated by the FEFF codes (ver. 3.11) developed by Rehr and co-workers.[7] Alternatively, the fitting of data collected from annealed samples, where multiple phases were present, was performed using empirical standards of bcc-Fe and fcc-FeCu (simulated using the Fe EXAFS collected from the as-milled sample). These empirical standards were chosen because the x-ray-diffraction measurements indicate that bcc-Fe precipitates from the solid solution upon heat treatment. We assume that the remaining fcc phase consists of both Fe and Cu atoms still in solution. All fits were performed in k-space using a least-squares-fitting algorithm.

Information of the local structure and chemistry around the Fe and Cu sites is contained in the Fourier transform of their respective EXAFS data. These data for the as-milled sample are presented in Fig. 1 with similar data collected

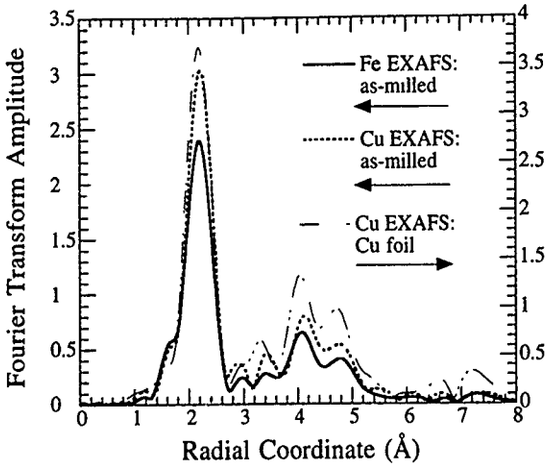

FIG. 1. Fourier-transformed Fe and Cu EXAFS from the as-milled $Fe_{50}Cu_{50}$ sample. Similar data collected from a fcc-Cu standard are shown for comparison. All data were transformed using k^2-weighting and k-ranges of 2.5–12.5 $Å^{-1}$. Electron phase-shift corrections have not been included, therefore radial distances do not correspond directly with bond lengths.

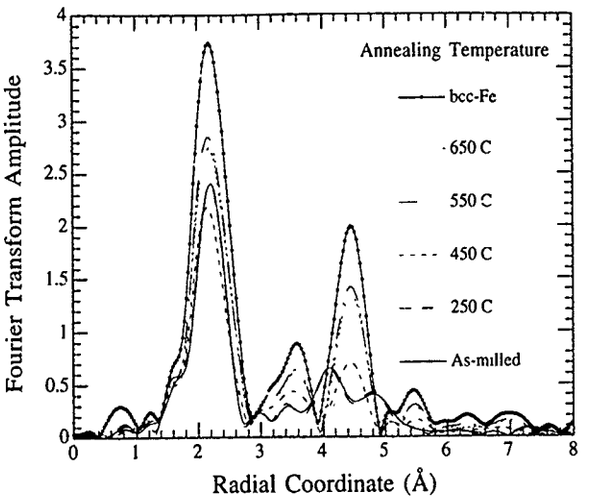

FIG. 2. Fourier-transformed Fe EXAFS data for the as-milled sample and those samples annealed at T=523, 723, 823, and 923 K. All data were transformed using k^2-weighting and k-ranges of 2.5–12.5 $Å^{-1}$. Electron phase-shift corrections have not been included, therefore radial distances do not correspond directly with bond lengths.

from a Cu foil used here to represent the fcc structure. Data corresponding with the as-milled sample are shown to resemble closely the fcc structure of the Cu standard in both the relative amplitude and radial distance of Fourier peaks appearing over the range of 1–5 Å. Slight changes in relative amplitude and distance of these Fourier peaks between the milled sample data and the fcc Cu standard can be attributed to the increased structural disorder of the milled powder and the smaller diameter of the Fe atom, respectively.

Fitting of the near-neighbor peak of the EXAFS data presented in Fig. 1 using FEFF generated EXAFS spectra indicates that the first coordination shell around both the Fe and Cu atoms consists of a mixture of Fe and Cu atoms which reflect a stoichiometry of $Fe_{48}Cu_{52}$, a result consistent within the uncertainty of the EXAFS fitting analysis with the nominal composition of the starting powder mixture. This analysis establishes that atomic level mixing has occurred around Fe and Cu sites due to the ball milling operation and indeed an fcc solid solution exists. Attempts to include a bcc component to the fit resulted in a significant deterioration of the least-squares-fitting parameter, as did attempts to simulate coherent fcc-Fe clusters within the Cu matrix. Further details of this analysis will be presented elsewhere.

Fitting of both the Fe and Cu EXAFS data found a Cu—Fe(Fe—Cu) bond of 2.60±0.02 Å, significantly larger than the sum of the Goldsmidt radii (assuming a coordination of 12), 2.55 Å. However, this result is consistent with x-ray-diffraction measurements of the as-milled powder[2] which indicate a larger lattice parameter for the solid solution, a_0=3.641 Å, than that of fcc Cu, a_0=3.615 Å. The Fe—Fe and Cu—Cu bonds are measured to be 2.53±0.01 Å. Taken together, the resulting EXAFS lattice parameter, 3.627±0.02 Å, matches within the EXAFS fitting uncertainty to the value obtained by XRD. The distorted bond distance of the Cu—Fe correlation is apparently responsible for the distorted lattice measured by XRD. However, at this time we can only speculate that the repulsion between the Fe and Cu atoms arises from an electronic interaction brought about by the filled d-band of Cu interacting with the unfilled d-band of Fe.

Figure 2 depicts the Fourier-transformed Fe EXAFS data for the as-milled and annealed samples illustrating the evolution of local structure around the Fe site as a function of heat-treatment temperature. All the data presented in Fig. 2 are shown on the same x and y axes without offset or normalization to allow for the direct comparison between samples annealed at different temperatures. The as-milled sample and the sample annealed at 523 K have nearly identical transform profiles, indicating that the local structure around the Fe atoms remains largely unchanged after this low-temperature anneal. However, the data corresponding with the sample annealed at 723 K displays significant changes in the Fourier features appearing over the r range of 3–5 Å (uncorrected for electron phase shifts). This transform illustrates features common to both bcc and fcc structures, indicating that the Fe atoms exists in both phases after this heat treatment. Evidence for the bcc phase is seen in the large peak appearing near 3.5 Å which corresponds with the cube-diagonal unit-cell site and the body-centered site of the adjacent cell. Anneals at still higher temperatures are seen to further advance the chemical and phase separation: The Fourier-transformed data for samples annealed at 823 and 923 K closely match the bcc Fe transform presented in Fig. 2 in both relative amplitude and radial distance of Fourier peaks.

Information of the local chemical environment at different stages of decomposition would be very useful in providing insight to the nature of the decomposition mechanism and in turn assist in our understanding of the magnetic properties. However, because the photoelectron backscattering amplitudes of the Cu and Fe atoms are similar, it is difficult to extract information of the local chemistry from a qualitative inspection of the data presented in Fig. 2. To this end, we have performed a quantitative fitting analysis of the near-

neighbor Fourier peak for all samples whose data appear in Fig. 2. Because the Fe atom may occupy more than one inequivalent site in these partially decomposed samples, depending upon the nature of the decomposition and the annealing temperature, it is difficult to fit the EXAFS data using only FEFF generated EXAFS spectra. This difficulty arises from the increasing number of independent variables (used in fitting) corresponding with each inequivalent site. Hence, we chose to fit these data using empirical standards of bcc-Fe and fcc-FeCu. Through this approach multiple inequivalent Fe sites in the annealed samples are simplified to two, those existing in bcc and fcc symmetries. This modeling does not take into account the variation in local chemistry around the absorbing atom. It does, however, provide a means of measuring the relative fraction of atom which occupies those sites differentiated by symmetry made possible by the differences in local atomic symmetry between the bcc and fcc structures.

The results of the fitting analysis of the annealed samples are presented graphically in Fig. 3. The inset plot illustrates the experimental Fourier-filtered Fe EXAFS data of the near-neighbor region and the best-fit calculation for the sample annealed at 723 K. The as-milled sample and the sample annealed at 523 K are measured to contain only an fcc component to the near-neighbor environment of Fe. After an anneal at 723 K, however, 30% of the sample exists in a bcc phase with 70% remaining in the fcc phase. Anneals at 823 and 923 K further advance the decomposition with a bcc atom fraction growing to 68% and 72%, respectively. The error bars presented in Fig. 3 represent a 100% increase in the goodness of fit parameter, indicating a significant deterioration relative to the best fit. The increase in error bar for samples annealed at 823 and 923 K is attributed to the gradual change in chemistry of the residual fcc phase with increasing annealing temperature. In these samples the empirical fcc-FeCu standard becomes a poor simulation of the fcc component.

The observed magnetic behavior reported in Refs. 3 and 4 cannot be explained by a simple nucleation of fcc-Cu and bcc-Fe from the as-milled fcc solid solution. The decrease of low-temperature magnetization (relative the value of the as-milled powder) with the appearance of the bcc phase suggests that a significant amount of Fe must exist in a low-spin state, either as small clusters of fcc-Fe or dilute Fe in fcc-Cu. To investigate this hypothesis, we have isolated the fcc component of a partially decomposed sample, namely the sample annealed at 723 K which was found previously to have a 30% bcc component. EXAFS modeling of the fcc component of this sample using FEFF generated theoretical EXAFS spectra indicates that the average environment of the Fe sites in this phase is dominated by Fe neighbors at a ratio of 10:1. In theory, with 30% of the Fe in the bcc phase, the fcc phase should have a composition near $Fe_{20}Cu_{80}$, if it were to remain a solid solution. If this was the case the local environment of Fe would be dominated by Cu neighbors at a ratio of 4:1. This result provides evidence that the Fe atoms in the residual fcc phase have coalesced within the Cu matrix during the heat-treatment-induced decomposition. Furthermore, it is likely that these fcc clusters of Fe are sufficiently small so as to exist in a low-spin state, thus providing an explanation for the reduced magnetization at low temperatures reported in Refs. 3 and 4.

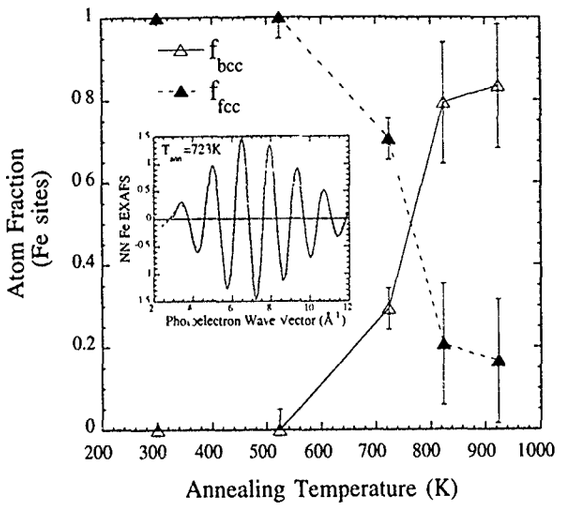

FIG. 3. Atomic fraction of Fe atoms occupying bcc and fcc sites in heat-treated samples as a function of annealing temperature. Results were derived from EXAFS fitting of the near-neighbor (NN) region of the Fourier-transformed data presented in Fig. 2 using empirical standards. The inset plot illustrates the experimental Fourier-filtered NN Fe EXAFS data for the sample annealed at 723 K and the best-fit calculation. Error bars reflect a 100% increase in the least-squares-fitting parameter. The lines connecting the data points are presented to illustrate the qualitative trend with annealing temperature.

This work, in part, has been supported by the Spanish CICYT through Projects No. Mat. 92-0491 and No. Mat. 92-0404. A. Hernando acknowledges support of the BBV Foundation. The EXAFS measurements were carried out at the National Synchrotron Light Source (Brookhaven National Laboratory, Upton, NY), which is sponsored by the U.S. Department of Energy (Division of Material Science and Division of Chemical Sciences of the Office of Basic Energy Sciences). KMK acknowledges support from the National Research Council-Naval Research Laboratory research associate program.

Structure analysis of coprecipitated $ZnFe_2O_4$ by extended x-ray-absorption fine structure

B. Jeyadevan, K. Tohji, and K. Nakatsuka
Department of Resources Engineering, Tohoku University, Aramaki, Aoba, Aoba-ku, Sendai 980, Japan

Though the anomalous antiferromagnetism of zinc ferrite was a subject of intensive studies in the past, the unusually high magnetization of coprecipitated zinc ferrite at low temperatures has drawn renewed interest among researchers. The local structures of zinc ferrites around Fe and Zn atoms are measured using extended x-ray-absorption fine structure and the results are discussed in correlation with their magnetic properties. The structure around the Zn atom was found to differ between zinc ferrite produced by ceramic and coprecipitation techniques. The position of the second-nearest neighbor of the Zn atom for coprecipitated zinc ferrite was shorter than the one produced by the ceramic method. This suggests the possible occupation of the Zn atoms in the octahedral sites and the cause for the unusually high magnetization in coprecipitated zinc ferrite. Furthermore, the intensity of the peak is weak compared to the one produced by the ceramic method. This is thought to be due to the deformation induced by the occupation of zinc ions in the octahedral sites, causing a decrease in the structural periodicity.

I. INTRODUCTION

Zinc ferrite ($ZnFe_2O_4$) is usually assumed to be a completely normal spinel with zinc ions exclusively occupied in the tetrahedral sites. This is described as an anomalous antiferromagnetic substance with a Néel temperature around 10 K. The magnetic behavior of $ZnFe_2O_4$ has drawn much interest and has been a subject of intensive studies.[1,2] To explain the anomalous behaviors, it has been suggested that small amount of Fe ions occupy tetrahedral (A) sites and the Fe(A) ions and their 12 nearest neighbors at octahedral (B) sites form a cluster. Each of the Fe (B) spins is coupled with the Fe (A) spins by AB interaction which is much stronger than the BB interaction.[3] These experiments have been carried out on polycrystalline samples prepared by the ceramic method. However, very recent research on ultrafine $ZnFe_2O_4$ prepared by the coprecipitation technique,[4] with a defect-free crystal structure,[5] has showed unusually higher magnetization.[6] Furthermore, the magnetization was found to vary with particle size and takes a maximum around 8 nm diameter.[7,8] In this paper, we report the results of structure analysis of coprecipitated $ZnFe_2O_4$ using extended x-ray-absorption fine structure (EXAFS), in search of an answer to the high magnetization observed in coprecipitated $ZnFe_2O_4$. This may solve the unresolved problem of scientific interest and provide clues to produce particles with high magnetization.

II. EXPERIMENT

A. Sample preparation and characterization

The $ZnFe_2O_4$ samples were prepared by the following procedure:

(a) Ceramic method—The powders of ZnO and Fe_2O_3 of chemical grade were mixed at a mole ratio of 1:1 in a mechanical mixer. The mixture was calcined at 1373 K for 3 h in oxidizing atmosphere and cooled slowly. Then the product was ground in a mechanical grinder for 1 h. After, it was calcined again at 1373 K for 3 h in the oxidizing atmosphere, slowly cooled to room temperature, and ground to powder again.

(b) Coprecipitation technique—The coprecipitated $ZnFe_2O_4$ was prepared by the method described in Ref. 4.

(c) Coprecipitation followed by annealing—The coprecipitated $ZnFe_2O_4$ is calcined at 1373 K for 3 h, cooled slowly, and ground to powder in a grinder.

The ferrites prepared by the above methods were examined by x-ray diffraction. The local structure was analyzed using EXAFS by measuring the absorption spectra at Fe and Zn K-edges. The sample was mixed with polythelene and pellets were made. The magnetization of these products were also measured in a vibration sample magnetometer (VSM) in the 5 K to room temperature range.

III. RESULTS AND DISCUSSION

A. Magnetization of $ZnFe_2O_4$

The magnetization temperature curves of $ZnFe_2O_4$ prepared by the methods described in the previous section was measured using VSM in the temperature range 5–293 K at 6 kOe are given in Fig. 1. As can be seen, the magnetization shows an increase with decreasing temperature and attains maximum around 20 K, in the case of $ZnFe_2O_4$ produced by the ceramic method and coprecipitation followed by annealing. But, in the case of coprecipitated $ZnFe_2O_4$, the magnetization continues to increase with decreasing temperature and the increase at 6 K is about 16× that of the value at room temperature. The x-ray-diffraction analysis confirmed that $ZnFe_2O_4$ produced by all three methods crystallized in the spinel structure and the cation distribution in the structure is believed to be the main cause for the differences in magnetic behavior among zinc ferrites prepared by different methods. The reason for higher magnetization has been suggested to be due to high concentration of magnetic clusters in coprecipitated zinc ferrite. Neutron-diffraction studies have revealed a high concentration of Fe ions in the A sites that form clusters with the Fe atoms in the B sites. It also has been reported that the $ZnO:Fe_2O_3$ ratio of coprecipitated

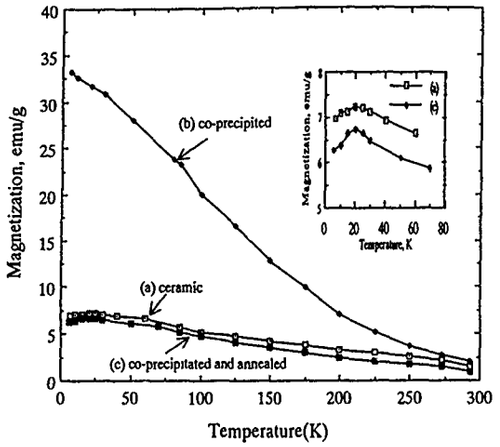

FIG. 1. Magnetization temperature curves of $ZnFe_2O_4$ produced by different methods.

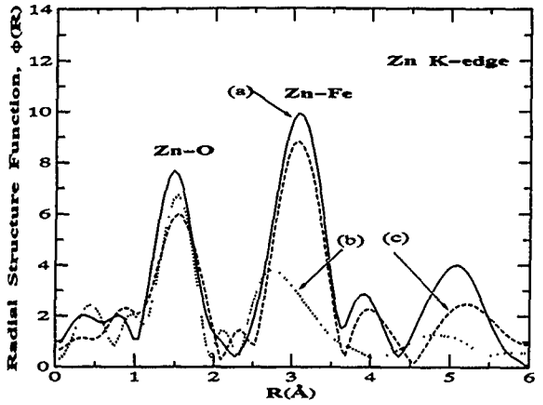

FIG. 3. Fourier transforms of $ZnFe_2O_4$ prepared by (a) the ceramic method, (b) coprecipitation, and (c) coprecipitated and annealed, at the Zn K-edge.

$ZnFe_2O_4$ is the same as that of the one produced by the ceramic method, meaning that there is no density difference among the ferrite produced by different methods. Therefore the concentration increase of Fe ions in A sites would lead to the occupation of zinc ions in the B sites. To find an explanation for the above differences, structure information of zinc ferrites is necessary.

B. EXAFS of $ZnFe_2O_4$

EXAFS is an ideal tool to investigate the local structure of matter. The local structure information, such as interatomic distances (in the case of spinel structure, this would lead to the determination of the sites occupied by the atoms), coordination number, and the kind of surrounding atoms around a selected x-ray absorbing atom could be studied.

The EXAFS spectra of $ZnFe_2O_4$ prepared by the methods described in Sec. II at the Fe K-edge are measured and the Fourier transform of the above spectra are given in Fig. 2. The two intensive peaks in the Fourier transform are centered around distances of 1.45 and 2.6 Å. In the case of $ZnFe_2O_4$, if we assume the Fe atoms to occupy exclusively

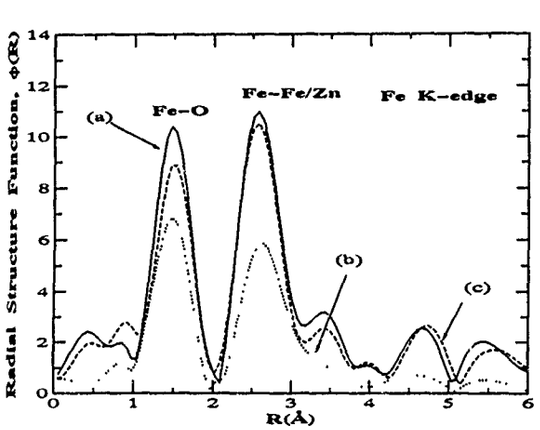

FIG. 2. Fourier transforms of $ZnFe_2O_4$ prepared by (a) the ceramic method, (b) coprecipitation, and (c) coprecipitated and annealed, at the Fe K-edge.

in the octahedral sites, the second-nearest peak is a result of the scattering from Fe-Fe atoms and Fe-Zn atoms, where Zn atoms are occupied exclusively in the A sites.

Considering the peak intensities between $ZnFe_2O_4$ samples, it could be seen that the peak intensity of coprecipitated $ZnFe_2O_4$ is weak compared to the samples produced by other methods. As far as the peak positions are concerned, the distance between the central atom and the second-nearest peak is marginally greater in the case of coprecipitated $ZnFe_2O_4$.

EXAFS spectra of $ZnFe_2O_4$ at the Zn K-edge were measured. Fourier transforms of the same are given in Fig. 3. The two intensive peaks in the Fourier transform are centered around 1.5 and 3.1 Å in the case of $ZnFe_2O_4$ produced by the ceramic method and coprecipitation followed by annealing, whereas, in the case of coprecipitated $ZnFe_2O_4$, the peaks centered around 1.6 and 2.8 Å and the intensity of the peak at 2.8 Å was very weak compared the ones produced by other methods.

The Fourier transform of the spectra at Fe and Zn K-edges for $ZnFe_2O_4$ produced by ceramic and coprecipitation methods showed considerable difference in amplitude of radial structure function. A similar observation was made by Maeyama *et al.*[9] for $ZnFe_2O_4$ of 56 and 5 nm diameters. The reduction in radial structure function, which is directly related to the coordination number, was considered due to the increase in the surface atomic layer for finer particles. The broadening of the metal-metal peak in the Zn K-edge has been considered due to the amorphous state of the sample.

In our study, if we consider the second-nearest peak in the Fourier transform of the spectrum at the Zn K-edge in all three samples, it is clear that the peak of coprecipitated $ZnFe_2O_4$ has become broader and the peak maximum lies at a distance shorter than in the other two cases. The peak broadening can be caused as a result of (a) the disordered state of the sample and (b) scattering from atoms two different distances; i.e., the peak is a result from the contribution of two different peaks. If it is true that the zinc atoms occupy only the A sites, it is not possible to get a response at shorter atomic distance than that of $ZnFe_2O_4$ produced by the ceramic method.

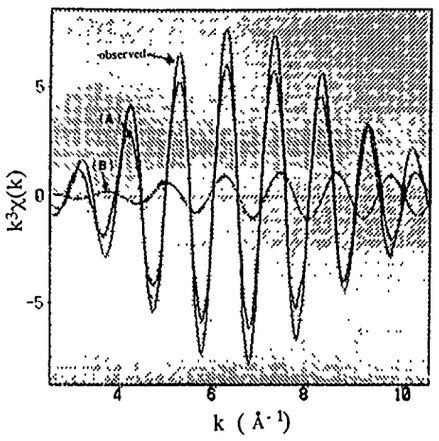

FIG. 4. The inverse Fourier transform of the second peak (Zn-Fe) in Fig. 3(a) and the contributions from shells (a) Zn(A)-Fe(B) and (b) Zn(B)-Fe(B).

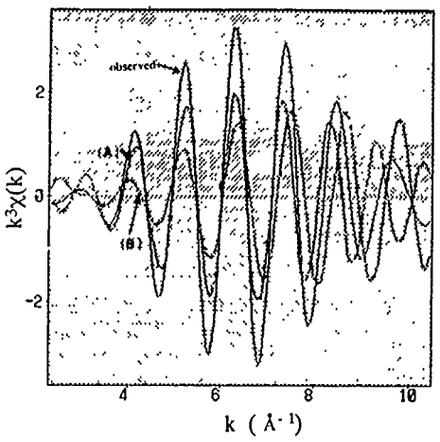

FIG. 5. The inverse Fourier transform of the second peak (Zn-Fe) in Fig. 3(b) and the contributions from shells (a) Zn(A)-Fe(B) and (b) Zn(B)-Fe(B).

Assuming that Zn atoms are occupied in both tetrahedral and octahedral sites and the main contribution of the scattering to be only from shells Zn(B)-Fe(B) at 2.98 Å and Zn(A)-Fe(B) at 3.48 Å [even though the scattering from Zn(B)-Fe(B), Zn(B)-Zn(B) at 2.98 Å and Zn(A)-Fe(B), Zn(B)-Fe(A) at 3.48 Å shells are possible], curve fitting as well as individual contributions of these scatterings were evaluated. The values of the Debye–Waller factor and mean free path were determined from the analysis of zinc ferrite prepared by the ceramic method and were used in the analysis of coprecipitated and coprecipitated and annealed zinc ferrite. The best fit obtained for the second-nearest peak in Fig. 3(a) gave a value of $R=2.7\%$. The individual contribution of the scattering from shells Zn(A)-Fe(B) and Zn(B)-Fe(B), are given in Fig. 4 and it can be seen that the scattering is contributed to almost only by shell Zn(A)-Fe(B). But, in the case of coprecipitated zinc ferrite (fit $R=2\%$), in addition to the contribution of Zn(A)-Fe(B) scattering, a considerable contribution from Zn(B)-Fe(B) is also observed and is shown in Fig. 5. Also, when the coprecipitation followed by annealing sample was analyzed, it resembled very much that produced by the ceramic method.

This suggests that the shift as well as the broadening of the peak at a shorter distance is a result of the zinc atoms occupying the octahedral sites, too. In coprecipitated zinc ferrite, this may be possible, as the cation distributions are in a metastable state as they are produced at low temperature within a short period of time. If they are brought to higher temperature, stability is achieved and the Zn ions take the most stable position in A sites. This is demonstrated in the results on coprecipitated and annealed samples. The occupation of the zinc atoms in the octahedral sites may have caused some deformation which has reduced the periodicity of the structure and may have caused the reduction in the amplitude radial structure function.

Furthermore, the occupation of zinc ions in both tetrahedral and octahedral sites may have led to a magnetization mechanism which is different to the one observed in antiferromagnetic substances, or on the other hand, the concentration increase in Fe ions in tetrahedral sites due to the occupation of zinc ions in octahedral sites may have caused an increase in the concentration of magnetic clusters formed through AB interaction and leading to magnetization increase. However, it could be said that the cation distribution in coprecipitated zinc ferrite is the cause for the higher magnetization.

IV. CONCLUSION

The results of EXAFS analysis on coprecipitated zinc ferrite have suggested that the zinc ions are occupied both in A and B sites. The resulted cation distribution is believed to have caused the increase in magnetization, and the occupation of Zn ions in the B sites is believed to have led to the deformation in the structure that reduces the periodicity of the structure, causing a decrease in radial structure function amplitude.

The magnetic anisotropy of $3d$-TM clusters is studied in the framework of a d-electron tight-binding Hamiltonian including hopping, Coulomb, and spin-orbit interactions on the same electronic level. Results for the magnetic anisotropy energy and spin-polarized DOS are given as a function of the bond length for the Fe_6 cluster. In particular it is shown that the MAE may be qualitatively related to the projections of the orbital moment along the magnetization directions, and that the "in-plane" anisotropy can be of the same order of magnitude as the "perpendicular" anisotropy. Using the same Hamiltonian, the problem of the convergence of the magnetic anisotropy energy of very thin films is revisited. By the choice of a basis which mixes spherical harmonics. it is shown that the irregular oscillations of the MAE versus the band filling disappear. For Co(111) excellent stability of the in-plane anisotropy as observed experimentally was found. Finally, the crystal-field effects are also discussed.

I. INTRODUCTION

Considerable attention has been devoted during the last years to the study of the magnetic anisotropy of low-dimensional systems. The number of papers presented during this meeting attests to the vitality of the research on thin metallic overlayers. For clusters experimental results show that the magnetic anisotropy plays an important role in the observed relaxation of the cluster magnetic moments in an external field.[1,2] However, from a theoretical point of view, very little on the magnetic anisotropy of clusters is known, contrary to the case of thin films. The purpose of this paper is to propose an unified theoretical framework able to describe the magnetic anisotropy of clusters, i.e., of systems having a finite number of inequivalent sites; the case of very thin film can be seen as a particular simple situation.

The calculations are performed in the real space by using a tight-binding Hubbard-type Hamiltonian. The magnetic anisotropy energy (MAE) is the total-energy difference for two different magnetization directions which can be chosen without restrictions. For clusters we consider directions which do not necessarily correspond to the symmetry axis of the cluster, which may result in Jahn–Teller instabilities. In analogy to magnetic thin films, we assume a *perpendicular* magnetization direction as well as one or two *in-plane* directions. In this way we can discuss not only the perpendicular but also the in-plane anisotropy. This is of considerable interest since so far very few quantitative results based on an electronic theory are known about the importance of the latter.

II. MAGNETIC ANISOTROPY OF SMALL CLUSTERS

In this work we extend a theoretical framework originally developed to describe, without spin-orbit coupling, clusters[3] and it is used with success to study low-dimensional systems[4] to include the spin-orbit interactions. This Hamiltonian includes hopping, Coulomb, and spin-orbit interactions on the same footing and can be written as

$$H=\sum_{\substack{\alpha,\beta,\sigma\\ i\neq j}} t_{ij}^{\alpha\beta}\hat{c}_{i\alpha\sigma}^{+}\hat{c}_{j\beta\sigma}+H_C+H_{\mathrm{SO}}. \tag{1}$$

Here $\hat{c}_{i\alpha\sigma}^{+}$ ($\hat{c}_{i\alpha\sigma}$) refers to the creation (annihilation) an operator of an electron with spin σ at atomic site i in the orbital α ($\alpha\equiv xy,yz,zx,x^2-y^2,3z^2-r^2$), and $t_{ij}^{\alpha\beta}$ to the hopping integrals between the orbitals α and β at sites i and j.

The Coulomb interaction H_C in the unrestricted Hartree–Fock approximation is given by

$$H_C=\sum_{i\alpha\sigma}\Delta\epsilon_{i\sigma}\hat{n}_{i\alpha\sigma}-E_{\mathrm{dc}}, \tag{2}$$

where $\Delta\epsilon_{i\sigma}=\Sigma_{\sigma'}U_{\sigma\sigma'}(\nu_{i\sigma'}-\nu_0)$ are the site and spin dependent d-level shift due to the redistribution of the spin-polarized electron density ($\hat{n}_{i\alpha\sigma}=\hat{c}_{i\alpha\sigma}^{+}\hat{c}_{i\alpha\sigma}$). $\nu_{i\sigma}=\Sigma_{\alpha}\langle\hat{n}_{i\alpha\sigma}\rangle$ refers to the average d-electron occupation at site i and spin σ and ν_0 the corresponding average d occupation in the paramagnetic solution of the bulk. The correction due to double counting is given by $E_{\mathrm{dc}}=(1/2)\,\Sigma_{i\sigma,j\sigma'}U_{\sigma\sigma'}\nu_{i\sigma}\nu_{j\sigma'}$.[3] Notice that the spin-quantization direction is taken to be parallel to the magnetization direction $\langle\mathbf{S}\rangle$. For the spin-orbit interaction H_{SO} the following single-particle, intraatomic approximation is used:

$$H_{\mathrm{SO}}=-\xi\sum_{i,\alpha\sigma,\beta\sigma'}(\mathbf{L}_i\cdot\mathbf{S}_i)_{\alpha\sigma,\beta\sigma'}\hat{c}_{i\alpha\sigma}^{+}\hat{c}_{i\beta\sigma'}. \tag{3}$$

Here $(\mathbf{L}_i\cdot\mathbf{S}_i)_{\alpha\sigma,\beta\sigma'}$ refers to the intraatomic matrix elements of $\mathbf{L}\cdot\mathbf{S}$, which couple the up- and down-spin manifolds and which depend on the relative orientation between $\langle\mathbf{S}\rangle$ and the

 0021-8979/94/76(10)/6328/3/$6.00 © 1994 American Institute of Physics

cluster structure. The spin-polarized charge distribution, and in particular the spin moments, are determined *self-consistently* by imposing the global charge-neutrality condition $\Sigma_{i\sigma}\nu_{i\sigma}=Nn_d$.

The electronic energy E_δ, from which the MAE is derived, is calculated from

$$E_\delta=\Sigma_{i\alpha\sigma}\int_{-\infty}^{\epsilon_F}\epsilon\rho_{i\alpha\sigma}(\epsilon)d\epsilon-E_{\rm dc}, \tag{4}$$

where δ refers to the magnetization direction (e.g., $\delta\equiv x,y,z$) and $\rho_{i\alpha\sigma}$ to the local density of states (DOS). The MAE is obtained from the change in the electronic energy E_δ associated with a change in the orientation of the magnetization $\langle\mathbf{S}\rangle$ with fixed position of the ions. The DOS $\rho_{i\alpha\sigma}(\epsilon)$ are computed by using the recursion method.[5] A special care must be taken in the self-consistent treatment of the Hamiltonian, in order to avoid any numerical incertitude.[6] In the case of a free-standing pure transition-metal mono- or bilayer, all sites are equivalent. For clusters it is no more the case and charge transfers occurring.

In these calculations we use parameters corresponding to Fe as given in Ref. 3 with a spin-orbit coupling constant ξ=0.05 eV.[7] Since in the clusters the value of the bond length d is somewhat uncertain, we have performed a systematical study in terms of d/d_B, where d_B is the bulk bond length.

In Fig. 1 the results obtained for the Fe_6 cluster are reported. Other clusters have been studied.[6] General trends emerge. For all studied clusters the spin moment along the magnetization direction depends very weakly on the direction of magnetization. Therefore only the results for perpendicular magnetization are reported. Clearly it is found that the variations of the MAE versus d/d_B are related to variations of the spin moment and the resulting changes in the densities of states. However, no simple rule can be given to explain these spin-flips. For very large values of d/d_B, the magnetization is saturated as expected. Before the spin-flip, the variation of the MAE and $\langle S_Z\rangle$ are continuous functions of d/d_B. This is no longer the case when a spin-flip occurs. As seen in Fig. 1 this charge redistribution can even change the sign of the MAE. For other Fe_N clusters,[6] many spin-flips can be present.

The *in-plane* anisotropy can be defined here as the difference between E_x and E_y. For Fe_6, this *in-plane* anisotropy is of the same order of magnitude as the *perpendicular* one. Similar results have been found for other Fe_N clusters.[6] The value of the MAE for this Fe cluster (around 1 meV per atom) is of the same order of magnitude as the corresponding values for very thin films. For a small value of d/d_B the perpendicular orientation is more favorable, whereas for d/d_B larger than 0.95, it is more favorable to align the magnetization along the x direction.

Assuming that interactions between unlike spins can be omitted, Bruno found within a second-order perturbation theory that the MAE is proportional to the difference of the projection of the orbital moment along the two considered magnetization directions.[7] Surprisingly, the MAE is found to follow qualitatively this simple law, especially for large values of d/d_B, where the spin moment is saturated. As already mentioned, the *in-plane* anisotropy is found to be important (more than 0.5 meV for d/d_B larger than 0.95). This result, which could seem surprising in comparison with perfect 2D film, is consistent with the large difference observed for the projection of the orbital moment along the x and y directions. The origin of these values is related to the very small size of the cluster (six atoms here). Similar behaviors have been observed for other Fe_N clusters.

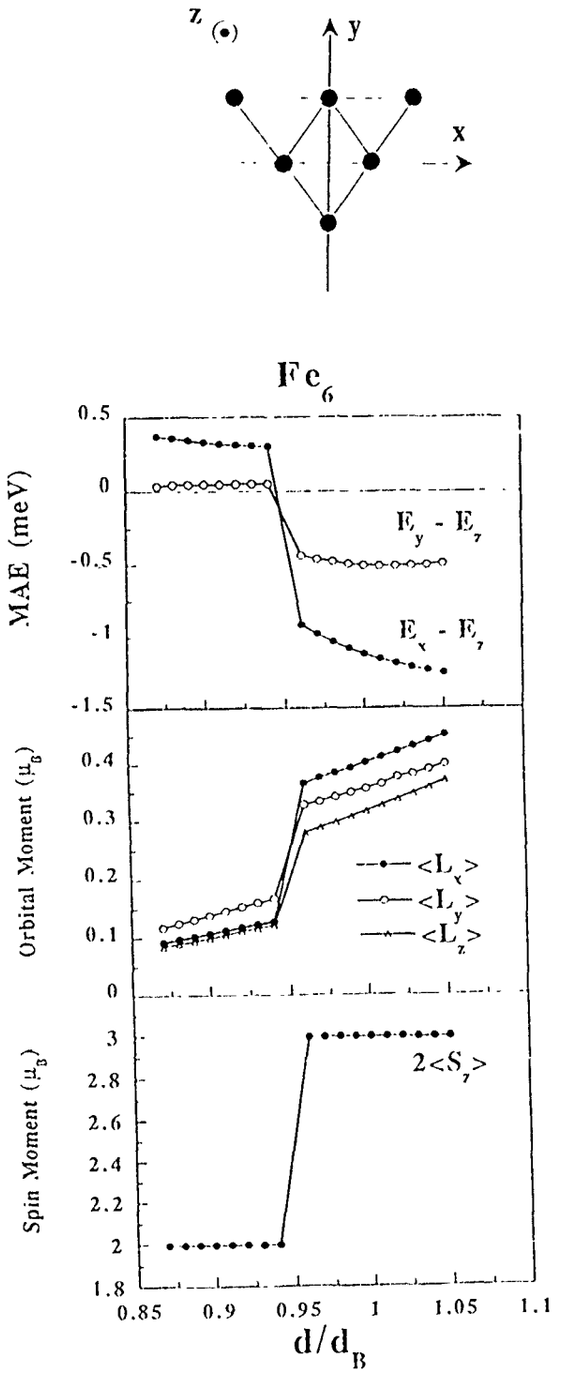

FIG. 1 The magnetic anisotropy energy per atom (meV), orbital moment, and spin moment of a Fe_6 cluster as a function of the bond length d/d_B (d_B=bulk bond length). The assumed cluster structure and the considered directions of magnetization are illustrated.

III. CONVERGENCE OF THE VERY THIN FILMS' MAGNETIC ANISOTROPY ENERGY

Some calculations for thin films or multilayers indicate that the MAE is very sensitive to band-structure details near the Fermi level and the MAE versus the band filling presents many oscillations.[8] According to other works, these oscillations are numerical artifacts.[9] In any case it is clear that the problems can be traced back to the energy-band crossing in the Brillouin zone. Recently, we have studied the MAE for transition-metal free-standing mono- and bilayers[10] by using the tight-binding Hamiltonian used in this work. A formal analysis, based on the moments theory, indicates that the MAE versus the band filling can be described by a "canonical" curve which crosses zero four times when the *d*-band occupation varies from 0 to 10.[10] In fact, the MAE curves were plagued by irregular oscillations which have been related to band crossings. Later, however, various tests on systems having little symmetry have suggested that this explanation is not valid. So we have reconsidered the problem.

In previous calculations we used, here as in the previous section, a basis of spherical harmonics (the spatial parts are eigenfunctions of the orbital moment operator without a spin-orbit interaction). We shall denote this basis as nonmixed (NM). Without spin-orbit coupling for strong ferromagnetism, the partial density of states corresponding to the minority-spin is identically zero in a large part of the majority-spin band energy region. However, when any spin-orbit interaction is considered, this partial density of states acquires a nonzero component in this region. In such a case, the method used in our previous work to get the Green's functions matrix elements is not well suitable. In order to avoid this problem, we build a mixed (M) basis where each vector contains a mix of all representations present in the original NM basis. Numerical calculations have shown that 25 levels of the continued fractions within the M basis are, at least, as precise as 150 levels within the NM basis for films. In this case the irregular oscillations disappear and one to two orders of magnitude for the computer time are gained.[11] For clusters, the NM basis is satisfactory since the finite size of the cluster allows consideration of a number of levels for the continuous fractions which is large enough to get perfect convergence.

Experimental results indicate that a free-standing Co (111) monolayer presents strong *in-plane* anisotropy.[12] Using the empirical relation between magnetic moment and exchange splitting values,[13] a value of exchange splitting of 1.9 eV is appropriate. Strong in-plane anisotropy is found. However, as it can be inferred from Fig. 2, this result is quite insensitive to the value of the exchange splitting. Moreover, introducing a crystal-field shifting does not modify significantly the magnetic anisotropy energy for the Co(111) monolayer. This stability should be related to the fact that the Co spin moment is almost satured.

In summary, a unified theoretical framework has been proposed to determine the magnetic properties of transition-metal small clusters and thin films by considering the spin-orbit coupling. The MAE has been derived. We found that in most cases the MAE can be related to the projections of the orbital moment along the considered magnetization directions. However, complete self-consistent calculations must be performed. Since a real-space method is used, this approach should provide a way to determine from the electronic structure the preferred magnetization direction of adsorbed clusters. Work is under progress.

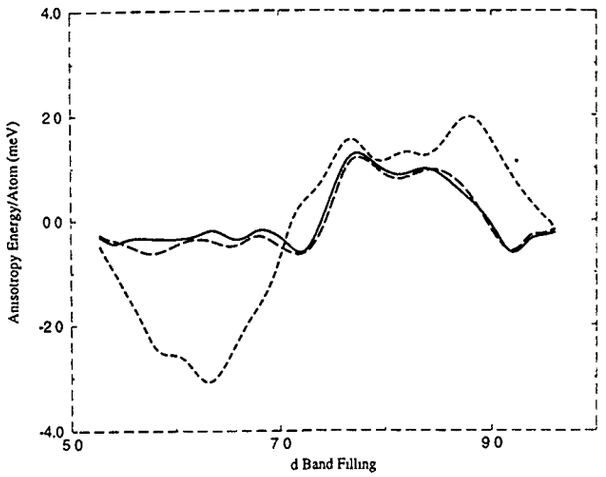

FIG. 2. Magnetic anisotropy energy per atom (meV) vs the *d*-band filling for a (111) monolayer calculated in the M basis with 25 continued fraction levels. In the full (long dashed) line, the result for the exchange splitting of 2.9 (1.9) eV is given. The dashed line corresponds to the exchange splitting of 1.9 eV and nonzero crystal-field splitting of 0.4 eV. Negative values correspond to the favorable perpendicular direction of the magnetization.

Structure and magnetic properties of $Nd_2Fe_{14}B$ fine particles produced by spark erosion (abstract)

H. Wan and A. E. Berkowitz
Center for Magnetic Recording Research, M/S 0401, University of California, San Diego, La Jolla, California 92093-0401

At present $Nd_2Fe_{14}B$ is the best permanent magnet because of its extremely high coercivity and energy product. Optimum properties of $Nd_2Fe_{14}B$ magnets can be attained by producing single domain particles, and then aligning and compacting them. Due to the high reactivity of the Nd constituent, it is challenging to produce and handle a large amount of fine particles of this material. We have prepared fine particles of $Nd_2Fe_{14}B$ by spark erosion with various dielectric media. Yield, size, size distribution, structure, and magnetic properties are discussed. The $Nd_2Fe_{14}B$ particles were made by the shaker pot spark erosion method.[1] Relaxation oscillators or a pulse generator were used to power the spark erosion. Commercial Neomax 35 was employed as the primary material. The dielectric media were liquid Ar, Ar gas, and hydrocarbons, which provided an oxygen free environment. Structure and size were studied by TEM, SEM, and x-ray diffraction. Magnetic properties were measured by VSM with temperatures in the range of 4.2–1200 K. The particles produced in these three different dielectric media had different microstructures and crystal structures. The particles made in Ar gas were pure $Nd_2Fe_{14}B$ phase. The particles made in liquid Ar were a mixture of amorphous and crystalline $Nd_2Fe_{14}B$, because the liquid Ar provided a much higher quench rate than Ar gas, which produced some amorphous $Nd_2Fe_{14}B$. Upon annealing, the amorphous particles became crystalline. The fine particles produced in hydrocarbons, such as pentane and dodecane, had more complex mixed phases, since the rare earth reacted with the hydrocarbons during the sparking process. The phases were NdC_2, α-Fe, and amorphous and crystalline $Nd_2Fe_{14}B$. The effects of power parameters, such as voltage and capacitance, on particle size were investigated. Particle sizes from 20 nm to 50 μm were obtained. We concentrated on $Nd_2Fe_{14}B$ fine particles made in liquid Ar and Ar gas. Particles were classified by centrifuging and sizes were confirmed by TEM and x-ray diffraction. The size dependence of coercivity, anisotropy, and magnetization of these $Nd_2Fe_{14}B$ particles will be discussed.

Thermal equilibrium noise with $1/f$ spectrum in a ferromagnetic alloy: Anomalous temperature dependence

S. Vitale, A. Cavalleri, M. Cerdonio, A. Maraner, and G. A. Prodi
Department of Physics, University of Trento and Centro di Fisica degli Stati Aggregati ITC-CNR, I-38050 Povo, Trento, Italy

We report on the magnetization noise in a soft ferromagnetic alloy for frequencies $f<10$ Hz, temperatures $T<4.2$ K, and excitation field amplitudes <150 μA/m. The spectra agree, without any adjustable parameter, with the fluctuation dissipation formula and the measured complex susceptibility of the material. The spectra show a $1/f$ shape coming from a frequency-independent imaginary susceptibility χ_0''. χ_0'' is found to be proportional to T above $\approx$2.5 K but tends to be independent of T below this value. After annealing the sample to relieve the internal stresses, χ_0'' is found nearly temperature independent above $\approx$2.5 K and to sharply increase by decreasing the temperature below that value. We discuss these findings in terms of the hopping of the magnetization by activation or tunneling.

I. INTRODUCTION

Thermal magnetic noise with $1/f$ power spectrum has been reported now in a variety of systems at low temperature including soft ferromagnetic alloys,[1] spin glasses,[2] and high T_c superconductors.[3] The noise originates from a frequency-independent quasiequilibrium imaginary susceptibility χ_0'' that produces, via the standard fluctuation dissipation formula, to a magnetization noise with spectrum $S_M(\omega)=(2k_BT/\mu_0)(V\chi_0''\omega)$, with T,V, and ω the temperature, the sample volume, and the angular frequency, respectively.

A frequency-independent imaginary susceptibility translates,[1] in the time domain, to a logarithmic relaxation of the magnetization after a stepwise field excitation. This is a close analogue of the phenomenon detected in relaxation experiments, and often referred to as magnetic viscosity, where instead the sample is driven far from equilibrium by large field steps. Magnetic viscosity is attributed to the existence of a collection of simple exponential relaxations with distributed time constants[4] each one due to the escape of the magnetization outside some local free energy minimum. If the escape occurs by thermal activation, the logarithmic relaxation rate is predicted[4] to be proportional to T while any nonthermal relaxation mechanism, like for instance quantum tunneling, would lead to a temperature-independent rate.

At equilibrium this picture should be rephrased[5] in terms of the hopping of the system between nearby free energy minima with distributed lifetimes. The dependence of χ_0'' on the temperature is then related both the mechanism underlying the hopping, whether thermal activation or not, and to the energy differences Δ between the minima. If the lifetime of each minimum is regulated by thermal activation and if Δ is in turn distributed from zero to a value much higher than k_BT, then (see Sec. IV) $\chi_0''\propto T$, again in analogy with relaxation experiments.

This last prediction has recently been contradicted[5] for some amorphous ferromagnetic alloys where χ_0'' has been found to be temperature independent from 4.2 K down to $T\approx100$ mK. It is tempting to think that a temperature-independent χ_0'' could occur if the hopping takes place by some dissipative tunneling mechanism.[6] This interpretation would be favored if one could observe a crossover from the observed temperature-independent regime to the temperature-dependent one due to thermal activation.

In search of a material where such a crossover is displayed within the temperature range accessible by our method, we have studied the temperature dependence of χ_0'' for a soft crystalline alloy that has already been reported[7] to show magnetic viscosity and the related thermal $1/f$ noise at 4.2 K.

II. EXPERIMENTAL METHODS

The sample studied is a strip wound toroid made of 68 turns of a $\approx$3-μm-thick ribbon of Ultraperm alloy. Ultraperm is a soft alloy of nominal composition $Fe_{12}Ni_{77}Cu_5Mo_4$. Measurements have been performed both before and after annealing the sample for 3 h at 950 °C in saturated atmosphere of hydrogen to relief stresses. The linear reversible relative permeability has been measured to be $|\mu|=180\pm10$ before the annealing and $|\mu|=210\pm10$ at 4.2 K after it.

Complex susceptibility measurements have been performed as described in detail elsewhere.[1,5,8] Here we only remind that they are based on the measurement of the complex self-inductance $L=L'i-L''$ of a superconducting transformer coupled to the sample on one side and to a commercial rf superconducting quantum interference device (SQUID) on the other hand.

The ac field amplitudes used to measure the complex susceptibility are always less than 150 μA/m and the sample behaves for such small signals as a linear device.[1,7]

The data for the phase Φ_L of the transformer inductance result from the subtraction of a proper blank measurement obtained substituting the pick-up coil coupled to the sample with a test coil with the same value of self-inductance. In the

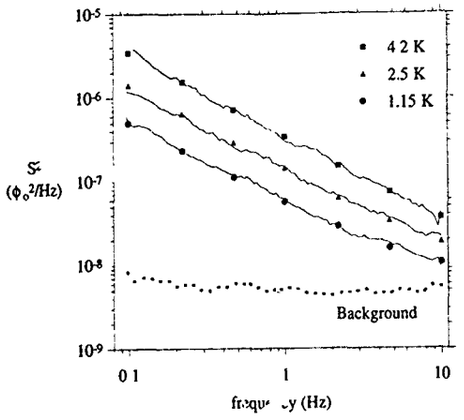

FIG. 1. Spectral noise density at the SQUID output for some different temperatures. The continuous noisy lines are the experimental spectral densities. The broken line is the SQUID background noise. The symbols represent the noise calculated from Eq. (1) using the measured values of the complex susceptibility.

0.1 Hz/10 Hz frequency range the method achieves an accuracy for Φ_L of $\approx 10^{-3}$ deg, while the modulus $|L|$ is measured with a $\approx 0.5\%$ relative accuracy. These figures translate, for the sample discussed here, to an accuracy of about 0.005 for χ'', apart from the uncertainty in the geometrical conversion factor from inductance to susceptibility (see below).

The data for L are converted to a complex susceptibility $\chi = \chi' - i\chi''$, using standard formulas for coils and transformer cores. This conversion has a relative accuracy not better than 10% but we stress that any inaccuracy in the conversion is of no consequence when calculating the thermal noise. In fact the flux noise at the SQUID output S depends on L as[8]

$$S = 2k_B T(M^2/|L|^2)(L''/\omega) + S_0, \tag{1}$$

where S_0 is the SQUID background noise and M is the mutual inductance between the SQUID and the transformer.

The spectral densities S and S_0 are measured by standard fast Fourier transform methods.[1,5]

The sample temperature was regulated by lowering the pressure above the liquid helium bath and was measured by a calibrated germanium resistor.

III. RESULTS

In Fig. 1 the spectral noise density S^2 in the presence of the sample is reported as a function of the frequency for three different temperatures. Also, in Fig. 1 the measured background noise S_0 is shown. The noisy continuous lines are the measured spectral densities while the symbols represent the noise predicted by using Eq. (1) and the measured values of L and S_0. A fit to the experimental noise spectra with a constant plus a power law gives always exponents in the range 1.00 ± 0.03.

The imaginary susceptibility χ'' of the sample between 0.1 and 10 Hz is found to be frequency independent.

The mean imaginary susceptibility between 0.1 and 10 Hz χ_0'' is reported as a function of the temperature in Fig. 2

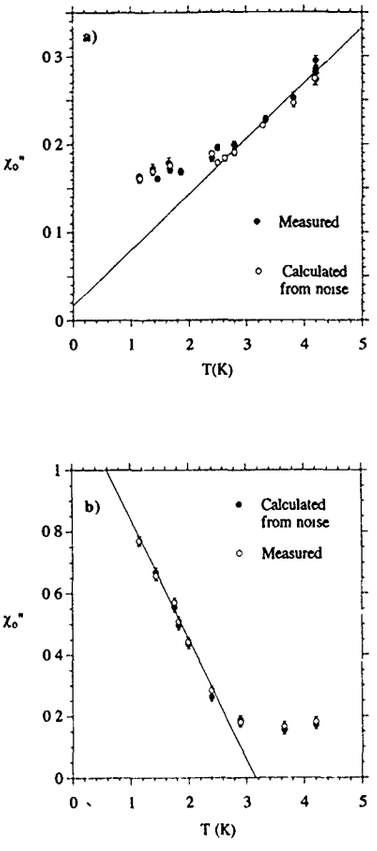

FIG. 2. The average imaginary susceptibility between 0.1 and 10 Hz χ_0'' as a function of the temperature. Closed symbols represent the values as directly measured. Open symbols are the values calculated from noise using fluctuation dissipation formula. (a) Data for the sample before the annealing. The solid line is a linear least-square fit to data above 2.5 K. (b) Data after the annealing. The solid line is a linear least-square fit to data below 2.5 K.

both for the sample before the annealing [Fig. 2(a)] and for the annealed one [Fig. 2(b)]. The values of χ_0'' as calculated from the noise by inverting Eq. (1) are also reported in Fig. 2.

Neither the data in Fig. 2(a) nor those in Fig. 2(b) can be fit to a single straight line in the whole temperature range explored, a chi square test of the linear best fit giving a probability of random occurrence not larger than 10^{-6}.

Above 2.5 K the data in Fig. 2(a) are well fitted to a simple proportionality law with a slope of 0.063 ± 0.004 K^{-1}. Below that temperature the data show a much reduced temperature dependence.

In Fig. 2(b) the data above 2.5 K are nearly temperature independent while those below 2.5 K can be fit to a straight line with a marked negative slope of -0.38 ± 0.02 K^{-1}.

The loss factor $\tan\delta = \chi''/\chi'$ in the frequency range 0.1/10 Hz, is easily calculated from the above figures to be in the range $\tan\delta \approx 5/10 \times 10^{-4}$ for both samples.

IV. DISCUSSION

The good agreement between the noise calculated from Eq. (1) and the measured one shows[1,5,8] that the sample is

acting as a linear device at thermal equilibrium. This is of no surprise as the applied field variation is less than a part in 10^5 of the coercive field of ≈ 10 A/m≈ 0.10 Oe.

If the susceptibility of the sample results from many contributions,[9] each one coming from an ordinary exponential relaxation with time constant τ, $\chi=\hat{\chi}[1+i\omega\tau]^{-1}$, a frequency-independent imaginary susceptibility is obtained by assuming that $\ln(\tau)$ is uniformly distributed between two values $\ln(\tau_1)$ and $\ln(\tau_2)$ such that the angular frequency of the measurement ω is $1/\tau_1 \ll \omega \ll 1/\tau_2$. In this case $\chi \approx \hat{\chi} \ln^{-1}(\tau_1/\tau_2)$ $[-\ln(\omega\tau_1)-i(\pi/2)]$ and $\chi_0''=i(\pi/2)$ $[\hat{\chi}/\ln(\tau_1/\tau_2)]$. Notice that the loss factor is then $\tan\delta=-\pi[2\ln(\omega\tau_1)]$. Even assuming that $\tau_1 \approx 10^{-12}$ s, a lower limit to any magnetic relaxation process, one gets $\tan\delta \approx 0.06$ at 0.1 Hz, a value much larger than the experimental one. However the above one is still a reasonable model, provided that only a fraction of the total susceptibility is contributed by the mentioned distributed relaxation mechanism.

Let us now discuss the observed dependence of χ_0'' on T within the model that assumes a collection of independent two levels systems, with distributed lifetimes and level splitting. The complex susceptibility of each system is

$$\chi=\frac{\mu_0 V m^2}{8k_BT}\cosh(\Delta/2k_BT)^{-2}\frac{1}{1+i\omega\tau}, \tag{2}$$

where m is the difference in magnetization between the two levels.

In Eq. (2) τ is given by $\tau=\tau_+/(1+e^{-\Delta/k_BT})$, where τ_+ is the mean lifetime of the upper energy level. This is given, for thermal activation, by $\tau_+=\tau_0 e^{E/k_BT}$ with E the height of the free energy barrier that prevents the escape, while it is expected to be a much slower function of the temperature for a nonthermal hopping mechanism like, for instance, quantum tunneling. As a consequence, for broadly distributed time constants, the prefactor $1/\ln(\tau_1/\tau_2)$ in χ_0'' is proportional to T for thermal activation[9] and it is expected to be instead almost temperature independent if the hopping occurs by tunneling.

A second important feature of Eq. (1) is the prefactor $\cosh(\Delta/2k_BT)^{-2}(8k_BT)^{-1}$ in the susceptibility. By introducing the two simplest hypotheses on the distributions of Δ one can calculate the two following limits: If Δ is uniformly distributed between 0 and $\Delta_{\max} \gg k_BT$ the prefactor becomes temperature independent while in the opposite limit of $\Delta_{\max} \ll k_BT$, i.e., with almost degenerate levels, it becomes proportional to $1/T$ as in a pure Curie law.

One can then predict the four following limiting temperature dependencies for χ_0'': (1) nondegenerate levels and thermal activation: $\chi_0'' \propto T$; (2) degenerate levels and thermal activation: temperature-independent χ_0''; (3) nondegenerate levels and fully nonthermal hopping: temperature-independent χ_0''; (4) degenerate levels and fully nonthermal hopping: $\chi_0'' \propto 1/T$.

Thus, if the levels are nondegenerate, a crossover from a nonthermal hopping regime to a thermal activation one would show up as a transition from a temperature-independent χ_0'' to a $\chi_0'' \propto T$ above the crossover temperature T_c. On the contrary, in the case of degenerate levels, the same crossover would appear as a transition from a $\chi_0'' \propto 1/T$ low temperature branch to a temperature-independent χ_0'' above T_c.

The data of Fig. 2 can be at least qualitatively explained if one assumes then that at $T_c \approx 2.5$ K a crossover occurs from a nonthermal to a thermal hopping regime of, e.g., a domain wall portion between two pinning sites; in addition one has also to assume that the annealing procedure, by removing the internal stresses of the material, makes the difference of the pinning energies of the two sites much less than k_BT.

It is tempting to compare the observed $T_c \approx 2.5$ K to the one predicted by theoretical models for tunneling of domain walls[6,10,11] in the bulk. These models predict that $T_c \approx (\hbar g/k_B)B_e \approx 1.3$ K$(B_e/1$ T) with g the gyromagnetic factor. B_e is an effective magnetic field that can be, for instance, the internal saturation field B_s for high anisotropy materials or $B_e \approx \sqrt{K\mu_0}$, with K the anisotropy energy density, for low anisotropy ones like that considered here. The observed crossover corresponds then to $B_e \approx 2$ T, a field much larger than the value $\sqrt{K\mu_0} \approx 0.02$ T typical of permalloys but still of the order of the internal saturation field of the sample. To ascribe the observed crossover to the model above one would then require the additive hypothesis that some local or surface anisotropy field could exceed by a large factor the average anisotropy of the material. We believe that a definitive explanation of the observations goes beyond the purport of the present data.

We report an observation of magnetostochastic resonance (MSR) in bistable magnetic systems. MSR manifests itself as a peak of a response of such a system to a periodic field as a function of the noise strength. Bi-substituted ferrite-garnet films with uniaxial anisotropy were used as simple examples of bistable systems. Noise was produced by (i) thermal fluctuations of an effective magnetic field and (ii) externally applied "noiselike" magnetic fields. The position of the peak depended dramatically on the magnitude of applied dc fields, so that dc fields of about 1 mOe in the spatial scale of 10 μm were measured. MSR applications to various tunneling phenomena such as tunneling of magnetization in small magnetic particles are discussed.

Recently, peculiarities of the response of a bistable magnetic system to a periodic magnetic field in the presence of noise have been predicted.[1] It was shown that the signal-to-noise ratio has a peak at some noise strength. This phenomenon was called magnetostochastic resonance (MSR) and turned out to be an excellent tool for investigation of various tunneling phenomena. It enables us to evaluate basic tunneling characteristics in case, e.g., of quantum magnetization tunneling and electron tunneling that depends upon magnetization. Besides, MSR provides a new method for magnetic field detection in the nanometer scale.

To model the theory in a simple system we detect MSR in a bistable ferrite-garnet film. In this article detailed description of experimental procedures is given and applications of the phenomenon to magnetic field measurements are discussed.

Let us recall main features of the magnetostochastic theory. Uniform magnetization dynamics of a bistable system is considered. An angle θ between magnetization and the easy axis is taken as the generalized coordinate of the system. The system is located in one of the minima in the absence of noise. An application of a periodic magnetic field H_{ac} (the ac field) along the easy axis changes the potential energy of the system each half of a period as shown in Figs. 1(b) and 1(c). The change of the magnetization angle θ will be referred to as a magnetization signal. In the absence of noise this change is determined by the stiffness of the potential minimum in which the system is located. The presence of noiselike magnetic fields of some origin results in magnetization changes even in the absence of the ac field. These changes are usually called noise.

In the presence of noiselike magnetic fields and the ac field the transitions between minima are possible. It means that for one-half of a period the system will move over the barrier from the higher minimum to the deeper one and for the other half of the period the system will move back, if the noise strength is sufficient enough. In this case the magnetization signal is determined by an "average" potential stiffness and is much greater than that in the absence of noise. This leads to a peak in the signal-to-noise ratio at some noise strength.[1]

The experimental setup is shown in Fig. 1. To model the phenomenon a thin easy-axis ferrite-garnet film, with high g factor, was chosen as a bistable magnetic system. An additional in-plane magnetic field H_{in} was used to lower the potential barrier between minima and to remove domains out of the sample. A periodic field H_{ac} was applied along the film's easy-axis z. The angle θ between the net magnetization of the illuminated part of the film and the easy-axis z was chosen to be the generalized coordinate of the system. The changes of the angle θ were detected by means of the Faraday effect. The magneto-optical signal (MO signal) S is given by $S = KF_0 \cos^2[\varphi + \alpha(M_z/M_0)]$, where K is a constant that describes photodiode efficiency, F_0 is the total light flux, φ is an angle between the polarizer and the analyzer, $M_z = M_0 \cos\theta$ is the z component of total magnetization M_0, and α is a Faraday rotation angle of the film. In the performed experiments the condition $\alpha M_z/M_0 \ll \varphi$ was satisfied. It means that the MO signal was simply proportional to the studied magnetization signal, which was defined in the introduction as a change of the angle θ.

It follows from the equation that the MO signal does not depend upon the size of the light spot on the film in the absence of noise. However, thermally induced noiselike magnetic fields depend upon the sample volume: the smaller the volume, the bigger the strength of the effective fields H_{eff}, which influence the uniform magnetization dynamics. It allowed us to register the film response to the ac field for

various noise strengths by changing the size of the light spot where magnetization changes were detected. For this a special lens was used. Also, an external coil powered by amplified currents from a closed diode was used as a generator of white noiselike magnetic fields H_{ext}.

The measurements were carried out in the following way. First, the amplitude of the ac field was set to zero, $H_{ac}=0$, and MO signals were measured by the photodetector and the narrow bandwidth nanovoltmeter for various sizes of the light spot on the sample. Then, the ac field was applied perpendicular to the film, see Fig. 1, and MO signals were measured in relation to the distance between the lens and the sample. The signal-to-noise ratio is the quotient of the MO signal in the presence of the ac field over the MO signal in the absence of the ac field. Using measured signals, we calculated signals-to-noise ratios for different samples and found MSR curves. Analogous procedures were used in case of externally applied noiselike magnetic fields. In this case the noise strength was varied by a change of the amplification gain of the noise generator.

In Fig. 2(a) typical MO signals in the absence of the ac field are plotted as a function of the distance between the lens and the sample. The distance of 7.7 cm corresponds to the minimal light spot size of 5 μm. As an example, the curves are presented for the sample with composition $(LuBi)_3(FeGa)_5O_{12}$ and parameters: the thickness—7 μm, the anisotropy field—1200 Oe, the domain period—22 μm, magnetization—70 G, the dimensionless Gilbert damping constant—0.16. Figure 2(a) shows MO signals in the presence of the ac field having an amplitude 0.7 Oe and a frequency 3 kHz. Using points from Figs. 2(a) and 2(b), the signal-to-noise ratio can be calculated for various noise strengths, which gave us the typical MSR curve shown in Fig. 3(a). Other films also demonstrated such dependence.

MSR curves for the case of externally applied noiselike magnetic fields were also detected. They have the same form as shown in Fig. 3.

The position of the stochastic resonance peak depends upon the frequency of the ac field. It was found that the peak position moved into the higher fluctuation strength region for a higher frequency of the ac field.

The most interesting result was obtained when an additional dc magnetic field H_{dc} was applied perpendicular to the film, see Fig. 1. Such a field removes the degeneracy of the minima of the magnetic potential and reduces the MO signals, which are measured in the presence of the ac field. The greatest MO signal in the presence of the ac field is observed when the total external field has only the in-plane component and the potential minima are degenerate. This fact was used to adjust the sample position between magnets, which were exploited to produce the in-plane field H_{in}.

The changes of MO signals due to application of the dc field were studied for various noise strengths and for various amplitudes of the dc field. In these experiments the amplitude of the ac field was chosen to be 0.2–1.0 Oe. Figure 3(b) demonstrates this change for the dc field with an amplitude of 0.2 Oe as a function of the noise strength. The change of MO signal in the presence of the ac field due to the dc magnetic field as a function of the amplitude of the dc field is shown in Fig. 4. The curves shown in Fig. 3(b) and in Fig. 4 are the same for both directions of the dc field. This fact was also used to position the sample in the external magnetic field.

It is interesting to note two important features of the change of the MO signal in the presence of ac field due to the dc fields. This change has linear dependence upon the amplitude of the dc field, see Fig. 4. In addition, the MO signals are very sensitive to the applied constant fields. For example, dc magnetic fields as small as 1 mOe were detected in our experiments. It means that MSR can be successfully used for sensor development.

Let us consider results obtained in terms of the stochastic theory[2,3] and its particular application to magnetization dynamics.[1] There are two important parameters which describe resonance: the energy barrier and the Kramers time. The energy barrier between the minima of the magnetic po-

tential of an easy-axis ferromagnetic film in the presence of an in-plane field H_{in} is given by $\Delta U = (H_a M_0 v \epsilon^2/2)$, where H_a is the anisotropy field, v is the sample volume, and $\epsilon = 1 - H_{in}/H_a$. The Kramers transition rate for the z component of magnetization in the effective potential[1] can be found as $\nu_{Kr} = (\alpha\gamma\epsilon H_a/\sqrt{2}\pi)\exp[-(H_a M_0 v \epsilon^2/2k_B T)]$, where α is the dimensionless Gilbert damping constant, γ is the gyromagnetic ratio, k_B is the Boltzmann constant, T is the temperature, and ϵ is assumed to be small. (The definition of the anisotropy field differs in factor 2 in comparison with that of Ref. 1.)

It is necessary to know the value of the in-plane field in order to calculate ΔU and ν_{Kr}. The in-plane field was produced by two magnets (ϕ 5 cm, 1800 G) mounted on movable holders, whereas the sample was placed in the region of the maximum homogeneity of the field. To evaluate the in-plane field, the response to the periodic field has been used. This response has the peculiarity at the magnitude of the in-plane field which is equal to the magnitude of the anisotropy field. It was found that the difference between the in-plane field applied in resonance experiments and the anisotropy field of the sample was smaller than 0.2–0.4 Oe for thermal "noise" magnetic fields, which was determined by the accuracy of measurements of magnets positions and the magnitude of the in-plane field. Since the anisotropy fields of studied films were of the order of 1000 Oe, it means that $\epsilon = 1 - H_{in}/H_a < 4\times10^{-4}$ in our experiments. In case of external noiselike magnetic fields $\epsilon < 3\times10^{-2}$.

It allows us to put bounds on the energy barriers and the Kramers transition rates. Taking $H_a = 1200$ Oe, $\epsilon = 3\times10^{-4}$, $M_0 = 70$ Oe, $v = 1.4\times10^{-10}$ cm^3, $\alpha = 0.16$, $\gamma = 10^8$ (Oe s)$^{-1}$, $T = 293$ K for the peak of resonance curve shown in Fig. 3(a), we find that $\Delta U < 5.2\times10^{-13}$ ergs and $\nu_{Kr} > 21$ Hz. The energy barrier and the Kramers transition rate in case of external noiselike magnetic fields were $\Delta U < 5.2\times10^{-11}$ ergs and $\nu_{Kr} > 10^{-4}$ Hz. The effective magnetic field that corresponds to the energy barrier $H_{eff} = (H_a\epsilon^2)/2$ was $H_{eff} < 10^{-4}$ Oe for thermally induced magnetic fields and $H_{ext} < 1$ Oe for the external noise. Since amplitudes of the periodic test fields were 0.03–0.7 Oe, the resonance curves were detected in the nonlinear regime, which means that the ac field made one minimum of the bistable potential disappear for each half of the period. The small value of H_{eff} required to maintain the in-plane field of the order of 1000 Oe with the accuracy better than 0.2 Oe. For this, experimental installations were mounted on a stabilized optical platform. To loosen the constraint on the stability of the in-plane field, it is necessary to detect the magnetization response in smaller volumes than those of our experiments. The promising way to solve the problem is to detect magnetization by means of the Kerr effect instead of the Faraday effect. In this case the effective depth in which magnetization is detected can be as small as wavelength of the light. It allows one to reduce the detection volume by a factor of 10. The best MSR application will be the detection of magnetization tunneling in small magnetic particles, since they inherently have small volumes.

It should be noted that samples vibrations in the external magnetic field and random magnetic fields, which contributed to the change of the in-plane field, lead to the change in basic resonance parameters (2), (3) and, hence, to the reduction of the resonance peak. Mechanical vibrations and random fields, which result in the magnetic field perpendicular to the film, contributed to the independent upon volume magnetization noise.

Finally, we would like to emphasize the important influence of the dc magnetic fields applied perpendicular to the film on the magnetization response to the ac field in the presence of noise. Such a field removes the degeneracy of the energy minima, changes the system distribution in the absence of the periodic test field, and changes the hopping rates between the energy minima. Thus, the magnetization response to the ac field depends upon the presence of small dc magnetic fields and noise. The theoretical treatment of the bistable system susceptibility to the dc field in the presence of the ac field and noise is beyond the scope of the article.

An extensive analysis of ac magnetic susceptibility measurements of single-crystal gadolinium is presented. The demagnetization-corrected c-axis data are analyzed on the basis of a power law of the form $\chi_c = At^{-\gamma}$ where t is the reduced temperature above T_c. Our results yield effective values of $T_c = 293.57$ K and $\gamma = 1.327$. The basal plane susceptibility is expressed as a parametric equation in terms of the c-axis susceptibility $\chi_{ab}^{-1} = B' + C'\chi_c^{-y/\gamma}$. The exponent y, which is related to the critical exponent associated with the specific heat α as $y = 1 - \alpha$, is determined by our analysis to be $y = 1.01(2)$. This gives a temperature scale associated with the anisotropy as $t_{\text{anis}} = 2.0 \times 10^{-3}$. These results are interpreted in the context of the effects of dipolar interactions in the critical region.

I. INTRODUCTION

The critical magnetic properties of gadolinium have recently been reported by several authors.[1–8] Although early measurements on Gd[9–12] led to certain ambiguities concerning the proper universality class for this ferromagnet, recent studies using a variety of experimental techniques have provided a consistent picture of the critical behavior which has a firm foundation on modern theoretical predictions. This behavior has been shown to be complex and to be dominated in the critical region by the presence of magnetic dipole–dipole interactions. The recent analysis of basal plane ac susceptibility by Stetter *et al.*[8] is contrary to this interpretation and these authors have suggested the Gd exhibits three-dimensional Ising behavior and that sample imperfections limit the asymptotic critical behavior. It is the purpose of the present investigation to consider the reasons for these apparent inconsistencies, to provide a new analysis of experimental results and to interpret these data in the context of recent theoretical predictions in order to provide a consistent and comprehensive understanding of the static critical magnetic behavior of gadolinium.

II. EXPERIMENTAL METHODS AND DATA ANALYSIS

A single crystal of high purity gadolinium with a resistivity ratio of $\rho(295\text{ K})/\rho(4.2\text{ K}) = 156$ was cut into the form of a cube with an edge length 0.249 ± 0.005 cm and the c-axis oriented along one of the cube edges. Further details of the sample preparation have been reported in Ref. 6. Measurements of the ac susceptibility have been performed[6,7] for two crystallographic orientations; with the c axis along the applied ac field direction and with one of the basal plane axes along the field direction.

The c-axis susceptibility in the critical region is defined for $t \to 0^+$ by the power law of the form

$$\chi_c = At^{-\gamma}, \tag{1}$$

where the reduced temperature t is defined in terms if the Curie temperature T_c as

$$t = \left| \frac{T_c - T}{T_c} \right|. \tag{2}$$

In contrast to the c-axis susceptibility which diverges as T_c is approached from above, the basal plane susceptibility remains finite and is described by

$$\chi_{ab}^{-1} = B + Ct^y, \tag{3}$$

where the exponent y is related to the critical exponent for the specific heat α by[7]

$$y = 1 - \alpha. \tag{4}$$

The susceptibilities given in the above expressions are intrinsic quantities and are independent of sample geometry. The actual measured susceptibilities are the demagnetization limited external quantities and are related to the intrinsic quantities by the demagnetization factor N as, e.g.,

$$\frac{1}{\chi_{c,\text{ext}}} = \frac{1}{\chi_{c,\text{int}}} + N \tag{5}$$

and similarly for the basal plane susceptibility. Since, in our experimental measurements the sample geometry was chosen to be cubic, the demagnetization factors for the c-axis and the basal plane susceptibility were identical. Equation (5) may be used in conjunction with Eqs. (1) and (3) to express the extrinsic quantities as

 0021-8979/94/76(10)/6338/3/$6.00 © 1994 American Institute of Physics

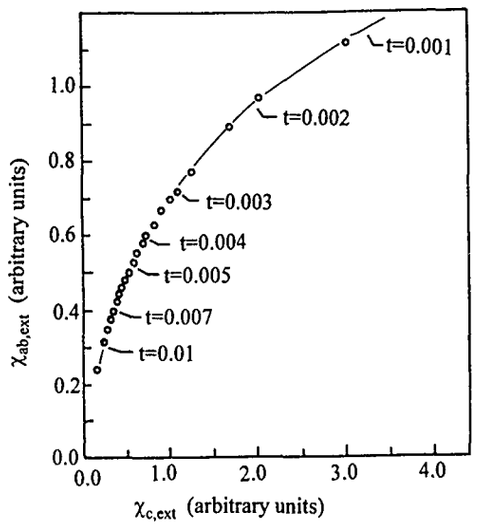

FIG. 1. Measured basal plane susceptibility as a function of measured c-axis susceptibility. Each point represents measurements of the susceptibility along the two directions at the same temperature. The reduced temperature scale as obtained from a fit to T_c for the c-axis data is indicated in the figure.

$$\chi_{c,\mathrm{ext}}^{-1}=A^{-1}t^{y}+N, \tag{6}$$

and

$$\chi_{ab,\mathrm{ext}}^{-1}=B+Ct^{y}+N. \tag{7}$$

In these expressions the coefficients A, B, and C and the exponents γ and y are fitted parameters. While the Curie temperature may be obtained by independent methods and the demagnetization factor may be estimated on the basis of geometric considerations, it is essential to determine the values of the parameters in Eqs. (6) and (7) in a consistent manner. It is clear from the form of Eq. (7) that the values of B and N cannot be determined independently from the basal plane data. It should also be noted that since $|\alpha|\ll 1$, then $y\approx 1$ and the value of C is highly correlated to the value of $B+N$. Because N is the same in Eqs. (6) and (7) it is possible to combine these two expressions and to fit the c axis and basal plane data simultaneously. Solving both expressions for t gives

$$\chi_{ab,\mathrm{ext}}^{-1}=B'+C'\left[\frac{\chi_{c,\mathrm{ext}}^{-1}-N}{N}\right]^{y/\gamma}, \tag{8}$$

where B' is given by $B+N$ and C' may be expressed in terms of C and A. This expression is valid for a given value of t and requires that experimental measurements for the c axis and basal plane orientations be made for the same values of temperature (as is the case for our measurements). This expression allows B', γ, and y to be determined in a consistent manner for both the c axis and basal plane data without the need to know T_c. Fitted values of these parameters may then be used to obtain T_c from a fit to Eq. (1) for the c-axis data.

TABLE I. Fitted parameter values for the critical susceptibility of gadolinium.

Parameter	Value	Uncertainty
A	1728	1.0
B	0.524	0.005
N	3.84	0.02
γ	1.327	0.002
y	1.01	0 01
T_c	293.57	0.02

III. RESULTS AND DISCUSSION

Measured basal plane susceptibility as a function of c-axis susceptibility measured at the same temperature is illustrated in Fig. 1. Parameters obtained from least-square fits to Eqs. (1) and (8) are given in Table I along with uncertainties based on a statistical analysis of the fits.

Although the use of a cubic sample in our studies results in a large demagnetization correction, it is precisely the use of this geometry which allows for a direct comparison of the c-axis and basal plane behavior in the critical region without the need to apply these corrections. Perhaps the ideal sample geometry in this respect would be a sphere. However, the likelihood of introducing additional defects during the machining is an important consideration in the choice of a cubic sample. The anisotropic nature of the critical behavior is readily apparent from our measurements for reduced temperatures less than about 10^{-2} and this, in itself, provides evidence to support our choice of the model based on dipolar interactions as described above for the analysis of these data. A direct measurement of the importance of the dipolar interactions may be obtained on the basis of the above treatment. A reduced temperature scale for the dipolar interactions is expressed in terms of the coefficients in Eqs. (2) and (3) as[7]

$$t_{\mathrm{anis}}=(B/A)^{1/\gamma}. \tag{9}$$

Using the values of these parameters as given in Table I, t_{anis} is found to be 2.2×10^{-3}. This corresponds to an actual temperature difference between T_{anis} and T_c of 0.65 ± 0.10 K. This is in good agreement with theoretical predictions[7,13,14] for the crossover temperature to anisotropic dipolar behavior in this system; $\Delta T=T_{\mathrm{anis}}-T_c=0.45$ K, and previous investigations involving an independent analysis of c-axis and basal plane susceptibility data.

In a comparison of recent experimental studies of Gd it is essential to consider differences in sample quality and geometry and their effects on measured magnetic properties. Of particular relevance in this respect is the relationship of the sample used in the recent study by Stetter *et al.*[8] and that used for our own investigation. Stetter *et al.*[8] have used a 300 Å film grown with the Gd basal plane parallel to the (110) surface of a tungsten substrate. It is clear from the annealing studies reported by these authors that their as-deposited films show magnetic behavior which is severely influenced by the presence of defects. Even after annealing at 870 K these authors base their data analysis on a model involving the existence of imperfections which cause a spread in Curie temperatures of 1 K. No further improvement in the sharpness of the transition was observed for

higher temperature anneals. Stetter *et al.*[8] have suggested that the behavior which we attribute to dipolar effects may actually be the result of sample imperfections as they occur on a temperature scale comparable to the T_c smearing observed in the thin-film experiment. The following evidence would seem to be against this interpretation for the following reasons:

(1) The samples used in our studies and in those of Stetter *et al.*[8] have been prepared by different methods and it would be highly coincidental if the level and type of imperfections in the two samples yielded precisely the same influence on the magnetic properties.

(2) There is no evidence on the basis of our resistivity studies of single-crystal Gd of any smearing of T_c on a reduced temperature scale of about 10^{-4} (see Ref. 5), or in the c-axis ac susceptibility data reported previously.[6,7] This is also the case for other studies of the magnetic properties of bulk Gd samples reported in the literature.[1–4]

Our own studies,[6,7] as well as those of others, e.g., Hohenemser and co-workers,[1–4] indicate that the critical temperature region of Gd exhibits complex crossover behavior over an experimentally observable range of reduced temperatures and it is not likely that measured critical properties will be asymptotic. Instead, critical exponents derived from studies of Gd should be treated as effective exponents for the particular range of reduced temperatures studied and that the values of these exponents will inevitably be dominated by anisotropic effects which result from the presence of dipolar interactions. This behavior of critical properties has been shown to result from a crossover pattern from exchange dominated Heisenberg behavior far above T_c to isotropic dipolar to anisotropic dipolar close to T_c.

The present analysis provides additional evidence for the behavior described above and indicates that, by the proper choice of sample geometry and measurement of data at proper temperature intervals, meaningful results which demonstrate the anisotropic dipolar character of gadolinium can be obtained without the need for an independent knowledge of the Curie temperature or the sample demagnetization factor.

Monte Carlo simulation of Ising models with dipole interaction

U. Nowak and A. Hucht
Theoretische Tieftemperaturphysik, Universität Duisburg, 47048 Duisburg, Germany

Recently, a new memory effect was found in the metamagnetic domain structure of the diluted Ising antiferromagnet $Fe_xMg_{1-x}Cl_2$ by domain imaging with Faraday contrast. Essential for this effect is the dipole interaction. We use a Monte Carlo method to simulate the low-temperature behavior of diluted Ising antiferromagnets in an external magnetic field. The metamagnetic domain structure occurring due to the dipole interaction is investigated by graphical representation. In the model considered, the antiferromagnetic state is stable for an external magnetic field smaller than a lower boundary B_{c1} while for fields larger than an upper boundary B_{c2} the system is in the saturated paramagnetic phase, where the spins are ferromagnetically polarized. For magnetic fields in between these two boundaries a mixed phase occurs consisting of ferromagnetic domains in an antiferromagnetic background. The position of these ferromagnetic domains is stored in the system: after a cycle in which the field is first removed and afterwards applied again the domains reappear at their original positions. The reason for this effect can be found in the frozen antiferromagnetic domain state which occurs after removing the field at those areas which have been ferromagnetic in the mixed phase.

The three-dimensional Ising model with an antiferromagnetic exchange interaction undergoes a first-order phase transition from an antiferromagnetic to a paramagnetic saturated phase for low temperatures during an increase of the homogeneous external magnetic field. Because of demagnetizing field effects in experimental systems like $FeCl_2$ there occurs a mixed phase for external fields $B_{c1} \leq B \leq B_{c2}$.[1] In theoretical considerations the existence of a mixed phase is often neglected since dipole interactions have to be considered in order to investigate the mixed phase. Especially in Monte Carlo simulations, the dipole interaction can hardly be taken into account for lattices large enough to investigate domain structures due to its long-range nature: for each spin flip the number of operations to calculate the change in energy scales with the number of spins in the system. However, we used a specially adjusted algorithm to do these calculations efficiently. The details of our method will be published elsewhere.

In this paper, we perform simulations in order to get a deeper understanding of a new memory effect that was found recently in the mixed-phase domain structure of the diluted Ising antiferromagnet $Fe_xMg_{1-x}Cl_2$ by domain imaging with Faraday contrast.[2] The position and shape of paramagnetic saturated domains which grow within the antiferromagnetic state while the field is increasing, is stored in the sense that the domains reappear even after a cycle in which the field is first removed and afterwards again applied. Essential for an investigation of this effect is obviously the dipole interaction, since it is this long-range interaction which is responsible for the occurrence of a mixed phase.

The diluted Ising antiferromagnet in an external magnetic field (DAFF) is an ideal system to study random field behavior theoretically as well as experimentally since it is believed to be in the same universality class as the random field Ising model (RFIM).[3] A well-known feature of the DAFF is the formation of a domain state with extremely long relaxation times (for an overview see Ref. 4). This domain state is frozen even for zero field and it is obtained by either cooling the system in an external field from the paramagnetic high-temperature phase or by decreasing the field correspondingly. The mechanisms which are responsible for the hysteretic properties of the DAFF have been investigated experimentally,[5,6] theoretically,[7] and in computer simulations.[8–11] In the following, we will show that the understanding of the hysteretic behavior of the DAFF is essential for an understanding of the memory effect.

The Hamiltonian of an Ising model with dipole interaction in units of the coupling constant reads

$$H = \sum_{\langle i,j \rangle} \epsilon_i \epsilon_j \sigma_i \sigma_j - B \sum_i \epsilon_i \sigma_i + d \sum_{i,j} \frac{\epsilon_i \epsilon_j \sigma_i \sigma_j}{r_{i,j}^3} (1 - 3 \cos^2 \theta_{i,j})$$

where $\sigma_i = \pm 1$ are the spins and the $\epsilon_i = 0,1$ represent the dilution $p = 5\%$. In the first sum $\langle i,j \rangle$ means all combinations of spins which are nearest neighbors. The exchange interaction favoring antiferromagnetic alignment of spins is set equal to one. The second sum represents the interaction with the external magnetic field B. The third sum is over all combinations of spins and d represents the strength of the dipole interaction ($d = 0.5$ in this case). $r_{i,j}$ is the distance between two spins on sites i and j and θ is the angle between the z axis (the direction of the external field) and the distance vector $\mathbf{r}$. In order to simplify the model we restrict ourselves to a two-dimensional system with open boundary conditions representing one plane of the experimental system. As we will see the qualitative behavior of the experimental system is well described by our model as far as the domain structure is concerned, which is responsible for the memory effect.

We use an antiferromagnetic long-range ordered system as the initial spin configuration. The simulation is done at very low temperature, $T = 0.1$. The system builds up a saturated-domain state for a field of $B = 2.65$ which is within the mixed phase, then we investigate the development of this domain state during a field cycle to zero field, $B = 0$, and

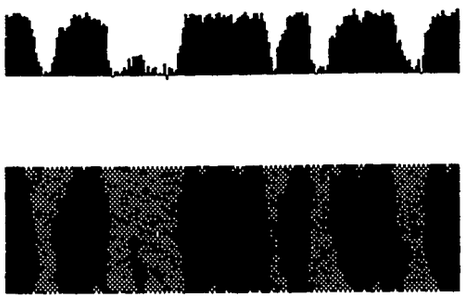

FIG. 1. Spin configuration and column magnetization of the simulated system as explained in the text: a metamagnetic domain configuration in the mixed phase.

then back to the mixed phase, $B=2.65$. The time that is needed to equilibrate the system is a few hundreds of Monte Carlo steps per spin.

The system has a size of 190×50 ($x\times z$), i.e., 190 columns and 50 rows. The figures show spin configurations of the simulated system as well as the mean magnetization of the columns of the system. The external magnetic field is aligned with the easy axis of the spins, the z direction. Each site of the two-dimensional square lattice is represented by a square, the vacancies of the system are shown as black, upspins as grey and downspins as white squares. The mixed phase (Fig. 1) consists of antiferromagnetic domains (checkerboardlike) and paramagnetic saturated (ferromagnetic) domains (grey, "spinup"). In the latter domains the spins are aligned with the field. The domains have the form of stripes. This follows directly from the nature of the dipole interaction which favors those spins to order ferromagnetically which are on lattice sites placed along the direction of the easy axis leading to the development of ferromagnetically ordered columns. Also shown in the upper part of Fig. 1 is the column magnetization, i.e., the mean magnetization of each column of the system. This quantity corresponds to the Faraday contrast that is observed in experiments. Since the domains are striped there is a sharp contrast between antiferromagnetic domains (magnetization$\approx$0) and paramagnetic saturated domains (magnetization$\approx$1/per spin).

Lowering the field to zero the saturated domains vanish (Fig. 2) and the magnetization decreases to nearly zero. However, an accurate analysis of this zero-field spin configuration shows that it is not completely antiferromagnetically long-range ordered. Instead, those regions of the system

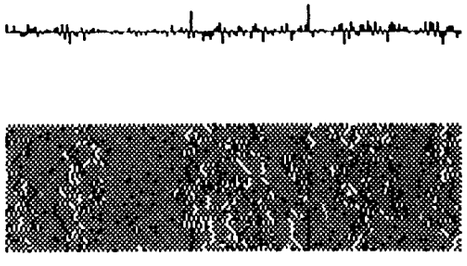

FIG. 2 Spin configuration and column magnetization of the simulated system an antiferromagnetic domain configuration after removing the field.

FIG. 3. Spin configuration and column magnetization of the simulated system: the metamagnetic domain configuration after applying the field again.

which have been paramagnetic saturated in the field now consist of an antiferromagnetic domain structure corresponding to the domain state of a DAFF after field decreasing. Why does this happen?

In a field-decreasing procedure the antiferromagnetic–paramagnetic phase boundary is crossed in a direction from the paramagnetic to the antiferromagnetic phase. In this case, due to the unconventional dynamics of the DAFF which follows from random-field pinning, the system cannot develop a long-range ordered state. Instead, it freezes in an antiferromagnetic domain state. This effect is the reason for the unconventional structure of the system after removing the external field. In regions of the system which have been paramagnetic saturated in the mixed phase, a frozen antiferromagnetic domain state develops while in the regions of the system which have been antiferromagnetic nothing changes, the long-range order persists. The nonexponential dynamics of antiferromagnetic domains in a DAFF after removing the external field has been investigated earlier (see Ref. 12; and references therein). The domains are frozen and remain practically constant on time scales accessible for observation. Note that due to the existence of antiferromagnetic domains and domain walls, respectively, there is a finite column magnetization. This magnetization is small compared to the magnetization of a saturated domain but it is larger than the magnetization of an antiferromagnetic column which is also not exactly zero due to fluctuations of the vacancy distribution in our finite system.

After applying the magnetic field again, once more a configuration of striped antiferromagnetic domains arises (Fig. 3). Comparing this configuration with the original domain configuration (Fig. 1) one finds that the original domain configuration is nearly reproduced, at least in that sense that paramagnetic saturated domains grow first at those places which have been paramagnetic saturated before. This is the memory effect. Its origin is the antiferromagnetic domain configuration of the system after removing the field (Fig. 2). The regions which consist of an antiferromagnetic domain state are less stable than the long-range ordered regions since the first contain domain walls. These regions are the first in which saturated domains during an increase of the external field occur, restoring the original metamagnetic domain configuration.

Here we report a detailed study providing complete H-T phase diagrams for both $NdRu_2Si_2$ and $TbRu_2Si_2$ intermetallic compounds, based on high resolution SQUID magnetization measurements, in the temperature range 2–300 K and in applied magnetic fields up to 5 T, using c-axis magnetically oriented powders. For $NdRu_2Si_2$, our results are in good agreement with recent neutron diffraction work under applied magnetic fields, confirming the appearance of an intermediate (temperature and field) ferrimagnetic phase responsible for the two-step metamagnetic process observed in the temperature range 16–22.5 K. Our isofield magnetization curves provide unambiguous evidence on the decomposition of this ferrimagnetic phase into ferromagnetic and antiferromagnetic components. Furthermore, at low temperatures and low fields, we observe, in this compound, the presence of thermal irreversibility effects. For $TbRu_2Si_2$, we present an experimental account, on its H-T phase diagram, which shows striking differences with respect to that of $NdRu_2Si_2$. In particular, the ferrimagnetic phase, which sets in at 50 K, persists down to the lowest temperature. In addition, we observe reentrant ferrimagnetism in this compound (ferri-ferro-ferri) under applied fields in the range 28–31 kOe.

I. INTRODUCTION

The ternary intermetallic compounds $NdRu_2Si_2$ and $TbRu_2Si_2$ crystallize in the tetragonal $ThCr_2Si_2$-type crystal structure, with magnetic moments only at the rare-earth sites. Due to their strong crystal field magnetic anisotropy, they behave as uniaxial materials, with the moments always directed along the tetragonal c axis.

The first neutron diffraction measurements on these compounds, at zero magnetic field, have shown interesting sequences of magnetic phases at low temperatures, specially in the case of $NdRu_2Si_2$.[1]

At the Néel point, T_N=23.5 K, $NdRu_2Si_2$ undergoes a second-order phase transition from the paramagnetic state into a pure sinusoidal amplitude modulated phase, with modulation vector [0.13, 0.13, 0]. As temperature decreases below approximately 16 K, the growth of higher-order harmonics takes place and the structure squares up, reducing its entropy. This process is completed at $T_C \approx 8$ K, at which the system becomes partially ferromagnetic (FE), through a second-order phase transition. Below this temperature, the coexistence of both the FE and square-wave modulated phases was observed.

At zero field, $TbRu_2Si_2$ orders below T_N=55 K, through a first-order phase transition, in a [0.23, 0, 0] modulated phase which squares up at low temperatures.

The application of a magnetic field along the tetragonal c axis induces the appearance of new phases through the inversion of moments at those sites where the internal field is small. At intermediate fields, similar ferrimagnetic (FI) phases stabilize in both compounds. In $NdRu_2Si_2$, a FI phase consisting of a FE component and antiferromagnetic (AF) modulations [0.13, 0.13, 0] and [0.26, 0, 0] in the temperature range 16 K$<T<$23 K, for magnetic fields from 5.5 to 8 kOe, has been reported.[2] In $TbRu_2Si_2$, a FI structure with a FE component and [0.23, 0, 0], [0.23, 0.23, 0] AF modulations has been observed at 4.2 K.[3]

The aim of our present work was to determine the complete magnetic phase diagram of both compounds through SQUID magnetization measurements. These measurements were performed in powder samples whose grains were magnetically oriented. The original samples were prepared as described in Ref. 1.

A. $NdRu_2Si_2$

Typical isothermal magnetization curves of $NdRu_2Si_2$, are presented in Fig. 1. We see that for magnetic fields in the range 5 kOe $<H<$8.5 kOe a FI phase stabilizes from 22.5 K down to 16 K, the temperature at which the zero-field AF phase starts squaring-up.[1] Below 16 K, a single-step AF–FE magnetization process is observed. This suggests that the metamagnetic transition to the FI phase is only possible when the nearly pure sinusoidal amplitude modulated structure is the starting phase at zero field.

According to Ref. 2, this FI phase has a complex structure consisting of a FE and two AF components, [0.13, 0.13, 0] and [0.26, 0, 0]. Such decomposition of the FI phase is consistent with our isofield magnetization curves (see Fig. 2). Indeed, the usual AF cusplike behavior of the magnetization near T_N persists for fields up to ~8.5 kOe. Starting at ~5 kOe and up to ~8.5 kOe, the shape of the isofield magnetization curves can be viewed as a superposition of an AF (cusplike) contribution which is partially masked by an increasingly important FE one. Above ~8.5 kOe, no AF behavior is seen to exist and the system behaves as a typical ferromagnet.

At low fields ($H<$1 kOe), as temperature decreases below 10 K, the magnetization increases in a FE-like way, reaching a maximum around 5 K. Besides, it shows thermal

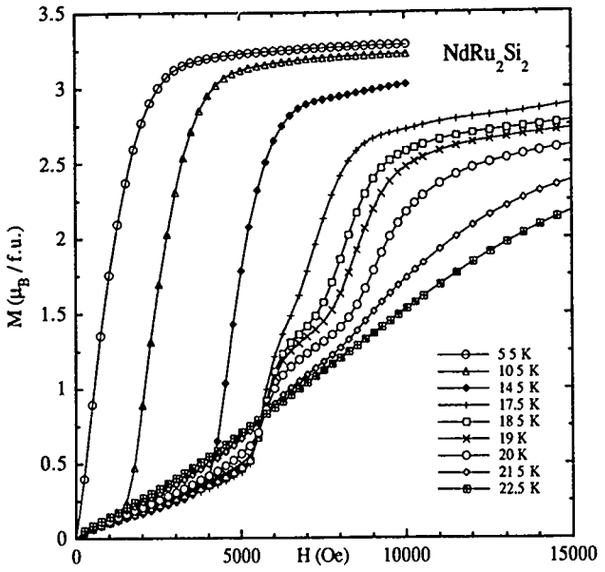

FIG 1. Isothermal magnetization curves of $NdRu_2Si_2$ at several temperatures.

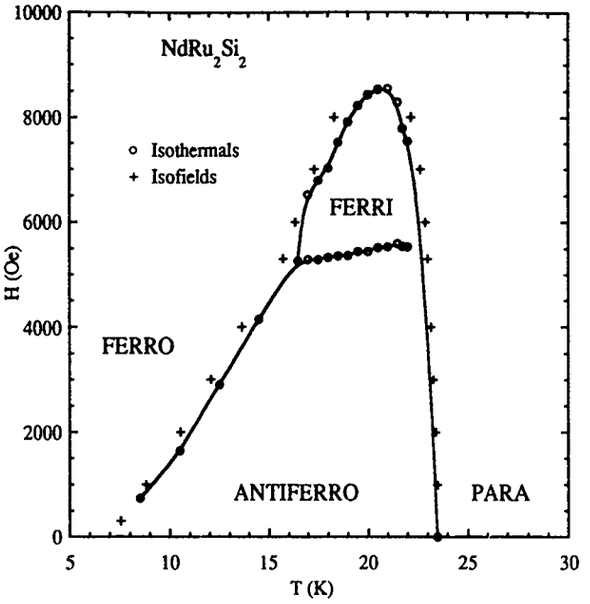

FIG. 3. H-T magnetic phase diagram of $NdRu_2Si_2$.

irreversibility effects, such as the difference between the zero field cooled (ZFC) and field cooled (FC) measurements. Such magnetic behavior may be the result of the competition between FE and AF phases which were reported to coexist in this region.[1]

The magnetic phase diagram (Fig. 3) was completed with both isothermal and isofield results. We notice that the phase line separating the AF and FI regions is not horizontal, as in Ref. 2. All other features of our phase diagram are in good agreement with Ref. 2.

B. $TbRu_2Si_2$

A clear two-step metamagnetic process is observed, characterized by two critical fields, H_{c1} and H_{c2}, which persists from the lowest temperature up to about 50 K, i.e., in almost all the ordered temperature range (see Fig. 4). We also observed the existence of magnetic hysteresis above H_{c1}. At this field, the magnetization jumps to an intermediate FI plateau with approximately half the saturation moment, jumping again at H_{c2} towards saturation. The intermediate phase in the range $H_{c1}<H<H_{c2}$ has been identified at 4.2 K

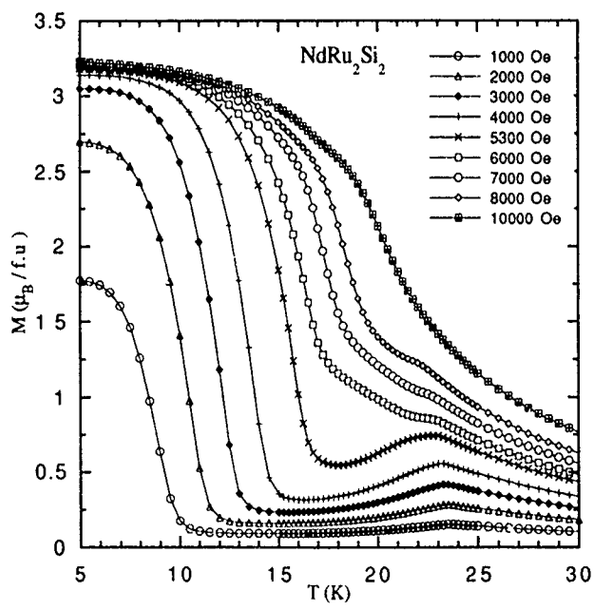

FIG 2 Isofield magnetization curves of $NdRu_2Si_2$ at several applied magnetic fields.

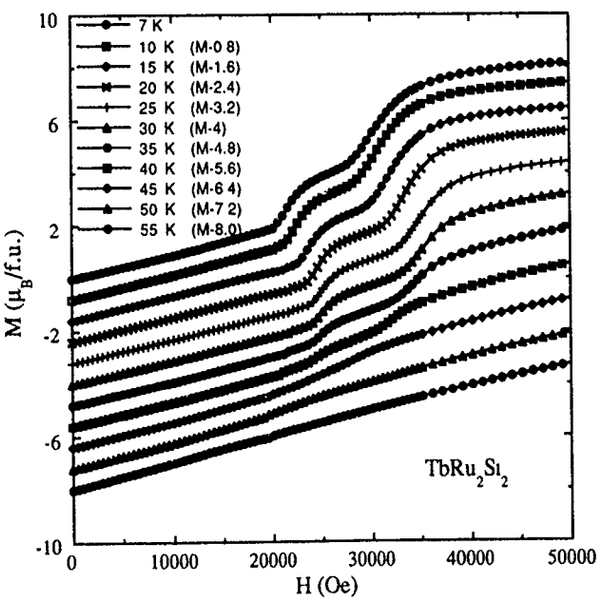

FIG. 4. Isothermal magnetization curves of $TbRu_2Si_2$ at several temperatures.

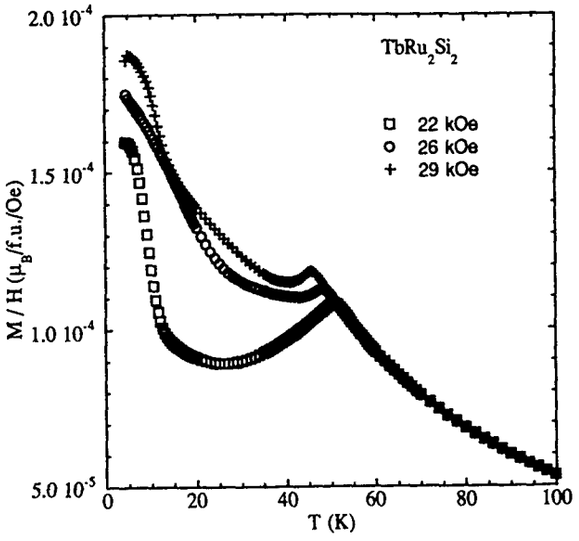

FIG. 6. Isofield M/H curves of $TbRu_2Si_2$ at several applied magnetic fields.

by neutron diffraction[3] as a complex two-dimensional modulated structure with a FE component and AF modulations [0.23, 0, 0], [0.23, 0.23, 0].

The observed regular increase of the magnetization below H_{c1}, characteristic of the development of a FE component, is attributed to the growing of higher-order harmonics in the AF [0.23, 0, 0] structure as H approaches H_{c1}.[3] The sudden enhancement of this FE component is made possible only at H_{c1} where an additional [0.23, 0.23, 0] modulation sets in.

The obtained H-T phase diagram (see Fig. 5) is divided into three main ordered regions: AF for $H<H_{c1}$ and $T<T_N$; FI resulting from the superposition of two-dimensional AF modulations and a FE component, for $H_{c1}<H<H_{c2}$ and $T<50$ K; FE for $H>H_{c2}$. As shown in Fig. 5, this compound exhibits reentrant ferrimagnetism (FI–FE–FI) under applied fields in the range 28–31 kOe and the FI phase is seen to persist down to the lowest temperature. The isofield curves near this field range also illustrate this phenomenon (see Fig. 6). For a field well within the FI region, e.g., $H=26$ kOe, and after the initial cusplike AF behavior just below T_N, the magnetization increases regularly with decreasing temperature. However, for a field intercepting both FE and FI regions, e.g., $H=29$ kOe, a noticeable change in slope takes place as temperature crosses the transition from the FI to the FE phases, at about 15 K. The magnetization reaches a maximum at a lower temperature which coincides with the transition from the FE back to the FI region. At $H=22$ kOe, the AF region is seen to extend over a wider temperature range.

II. CONCLUSION

The H-T phase diagrams of $NdRu_2Si_2$ and $TbRu_2Si_2$ were obtained from SQUID magnetization measurements on powder samples.

While in $NdRu_2Si_2$, the high field FI phase exists only for intermediate temperatures, in the case of $TbRu_2Si_2$ the FI phase persists down to the lowest temperature and behaves as a reentrant phase for 28 kOe$<H<$31 kOe.

A common feature of both diagrams lies in the fact that the respective intermediate FI phases set in through the appearance of an additional AF modulation. In the resulting FI structure, a larger number of magnetic moments is expected to detect a reduced exchange field and thus flip in a smaller applied field.[4]

The modified variational cumulant expansion (VCE) method valid for the whole temperature range and for arbitrary fields is developed to study the critical properties of the general q-state Potts model used to stimulate various magnetic systems. The series expansion is generated directly in terms of the Potts Hamiltonian. The free energy and the internal energy are calculated up to the third-order cumulant terms for the d-dimensional hypercubic q-state Potts model. The expression for the critical temperature T_c is derived in a closed form which allows to determine T_c up to arbitrary order cumulant terms. The modified VCE method eliminates the unphysical first-order phase transition at the mean-field critical point in the internal energy of the Potts model which plagues the conventional VCE method.

As a generalization of the Ising model to more than two components, the Potts model has become a subject of intense theoretical studies. In the absence of an exact solution for the general q-state Potts model, series expansions remain one of the most powerful tools in the theoretical studies of this model.[1] However, the critical behavior of the Potts model has been studied by generating series expansions only in the limiting cases of low and high temperatures.[1] In this paper, a modified variational cumulant expansion (VCE) method is developed to study the critical properties of the general q-state Potts model in the whole temperature range. This modified VCE expansion is generated directly in terms of the Potts Hamiltonian. The expressions for the free energy and the internal energy for the d-dimensional hypercubic q-state Potts model are obtained up to the third-order cumulant terms valid for the whole temperature range. A procedure is developed to eliminate the unphysical first-order phase transition at the mean-field critical temperature for the corrections higher than the first order, which plagues the VCE method.[2] This procedure is tested for the Potts model with second- ($q=2$, $d=2$) and first- ($q=4$, $d=3$) order phase transitions.

The Hamiltonian of the general Potts model can be expressed as[1]

$$H=-J\sum_{\langle i,j\rangle}\delta(\sigma_i,\sigma_j)-H\sum_i\delta(\sigma_i,0), \tag{1}$$

where $\sigma_i=0,1,2,...,q-1$ specifies the spin states at the site i, J stands for the coupling constant, and H is the external field. In applying the VCE method[2] one first introduces a trial Hamiltonian $H_0(\xi_i)$ with variational parameters ξ_i and expands the free energy of the Hamiltonian H of a real system as a series of cumulants averaged over $\exp(-H_0/kT)$. The first-order expression for the free energy is minimized to determine the variational parameters, which are then substituted back into the free energy expansion or higher-order cumulants. The action for the system is defined as $S=-H/kT$. Our trial action $S_0=-H_0/kT$ is chosen as follows

$$S_0=\sum_i\sum_{k=0}^{q-1}\xi_k\delta(\sigma_i,k) \tag{2}$$

where $\xi_k=1+(q-1)\cdot s$ for $k=0$ and $\xi_k=1-s$ for $k=1,2,...,q-1$. Here s is the variational parameter which serves as the order parameter of the system. The asymmetric state ξ_i ($i=0$) is chosen to account for the symmetry breaking below the critical temperature $T_c(H)$ ($s=0$). When $T>T_c(H)$, symmetry should be retained, i.e., $\xi_k=$const, ($k=0,1,2,...,q$), which implies that $s=0$. The VCE of the free energy up to the order m can be expressed as[2]

$$W_m=W_0-\sum_{n=1}^{m}\frac{1}{n!}\langle(S-S_0)^n\rangle_c \tag{3}$$

where W_0 is the free energy of the corresponding trial system, the symbol $\langle...\rangle_c$ denotes the cumulant average of the considered quantity over the Boltzmann weight $\exp(S_0)$. The order parameter s is determined as a function of J/kT by minimizing the first-order free energy with respect to s.

The free energy and the internal energy are calculated up to the third order in the cumulant terms. The results of calculations within the VCE method of the internal energy of the Potts model with a second-order phase transition ($q=2$, $d=2$) are plotted in Fig. 1. It follows from Fig. 1 that the first-order internal energy is continuous as it should be, while the second- and third-order internal energies have discontinuities which occur at the mean-field critical point [$kT_c(1)/J=2$]. As it follows from the comparison with the exact results, this is the unphysical phase transition which plagues the VCE method.[2]

The central issue for the VCE method is how to determine the variational parameters (s for the present case). Within the VCE method the value of the order parameter is calculated only to the first order.[2] This is actually the pure variational result which gives the mean-field results when the trial action is chosen in the mean-field form.[3] Thus, the ex-

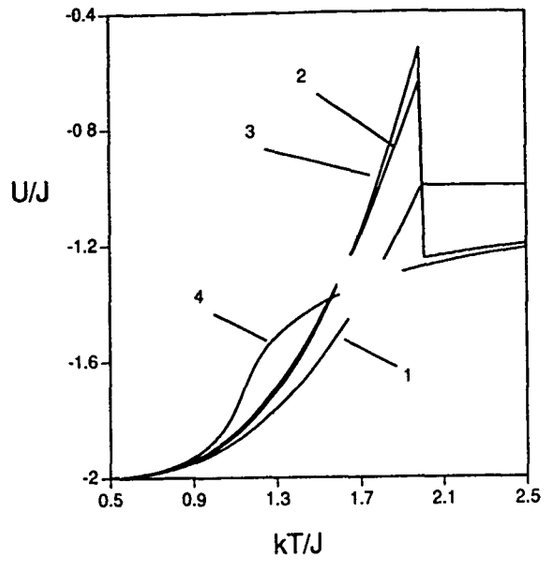

FIG. 1. VCE results for internal energy vs temperature for the $q=2$ and $d=2$ Potts model. The curves 1, 2, and 3 are the internal energy calculated up to first-, second-, and third-order cumulant terms, respectively. Curve 4 is the exact result.

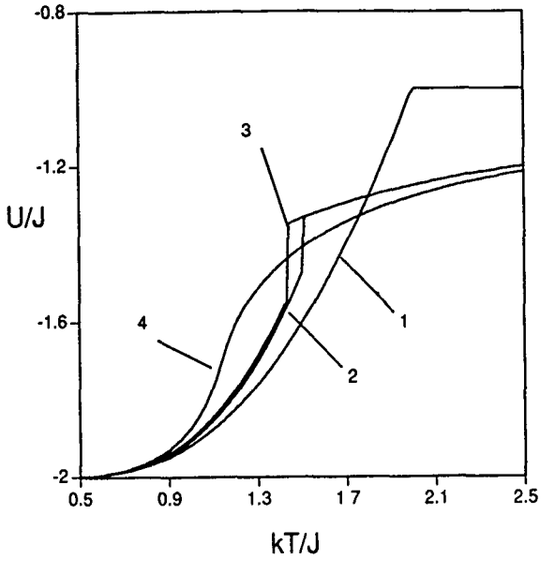

FIG. 2. Modified VCE results for internal energy vs temperature for the $q=2$ and $d=2$ Potts model. Curves 1, 2, and 3 are the internal energy calculated up to first-, second-, and third-order cumulant terms, respectively. The exact result is curve 4.

pansions with the order higher than one would carry the features of the first-order expansion. This leads to the appearance of the unphysical phase transition at the mean-field critical point.

To eliminate the unphysical phase transition we use a procedure based on some conjectures for the location of the true critical temperature $T_c(m)$ for the mth order VCE. From the general symmetry consideration, the order parameter s should take value zero when $T>T_c(m)$ for the mth order expansion. It is therefore reasonable to expect that the values $s=0$ corresponds to the global extremum (not necessarily the global minimum) of $W_m(T,s)$ for $T>T_c(m)$ and that $s=0$ remains to be the solution as temperature decreases until it reaches the critical temperature when this solution becomes "unstable," and then s changes to another solution which becomes "stable." These considerations lead to the following two equations which determine the critical temperature $T_c(m)$ and critical order parameter s_c

$$W_m(T_c,0)=W_m(T_c,s_c)$$
$$\frac{\delta}{\delta s}[W_m(T,s)]|_{s=s_c}=0, \tag{4}$$

with

$$\left.\frac{\delta^2 W_m(T,s)}{\delta s^2}\right|_{s=0}\times\left.\frac{\delta^2 W_m(T,s)}{\delta s^2}\right|_{s=s_c}\geq 0. \tag{5}$$

For systems with the second-order phase transition $s_c=0$ and the equality (5) holds. The order parameter $s(T,m)$ within this approach is determined by

$$s(T,m)=\begin{cases}0 & \text{for } T>T_c(m)\\ s(T,1) & \text{for } T<T_c(m)\end{cases} \tag{6}$$

The internal energy of the Potts model with the second-order ($q=2$, $d=2$) phase transitions is recalculated by means of the modified VCE method up to the third order in the cumulant terms and the results are plotted in Fig. 2. As it follows from Fig. 2, the unphysical phase transition at the mean-field critical point has been eliminated and the overall features have been much improved although the higher-order internal energies still have discontinuities, which are shifted to $T_c(s,m)$ and are strongly reduced. The results of calculations of the internal energy of the Potts model with the first-order ($q=4$,

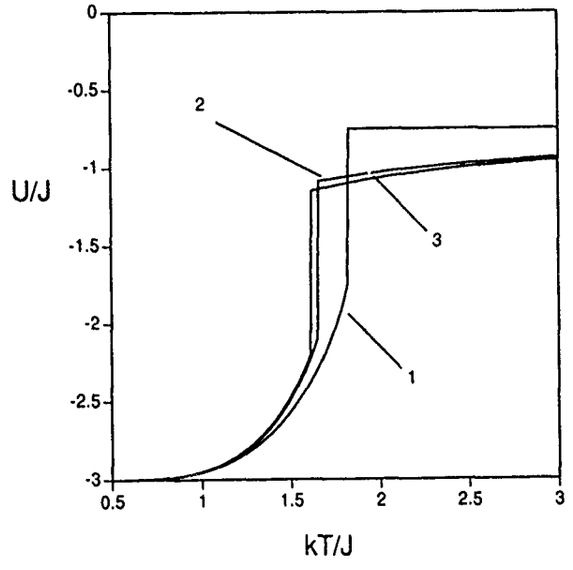

FIG. 3. Modified VCE result for internal energy vs temperature for the $q=4$ and $d=3$ Potts model Curves 1, 2, and 3 are the internal energy calculated up to first-, second-, and third-order cumulant terms, respectively.

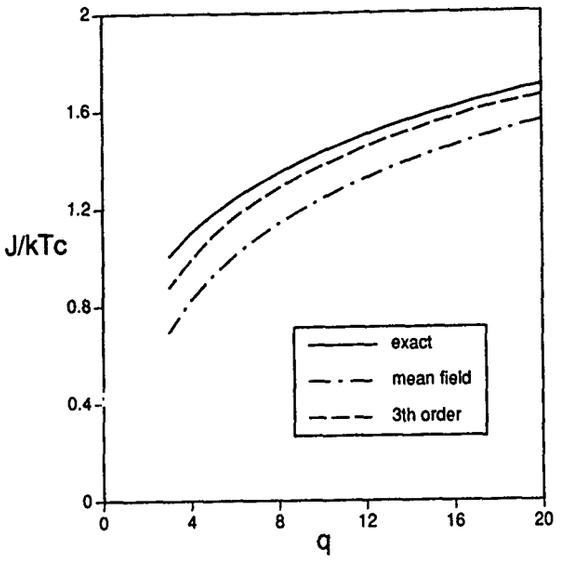

FIG. 4. Inverse of the critical temperature vs q for the $d=2$ Potts model.

$d=3$) phase transition are presented in Fig. 3. It follows from Fig. 3, that the discontinuity in the internal energy, which is a characteristic feature of the first-order phase transition, is present to all orders. As a test of our conjecture on the definition of the critical temperature, which is crucial for the modified VCE method, we calculated the first- and third-order critical temperatures for the two-dimensional Potts model with q varying from 3 to 20. The results of the calculation together with the exact ones are presented in Fig. 4. As it follows from Fig. 4 the results of calculations converge to the exact one, thus supporting our conjecture.

In summary, we have developed the modified VCE method valid for the whole temperature range to study critical behavior of the general q-state Potts model. The free energy and the internal energy for the d-dimensional hypercubic q-state Potts model are calculated up to the third-order cumulant terms. It is shown that by analyzing the cumulant expansions the expression for the critical temperature T_c is derived in a closed form which allows to determine T_c up to arbitrary orders. It is found that the first-order cumulant term gives results which coincide with the mean-field results as expected. The modified VCE method eliminates the unphysical first-order phase transition at the mean-field critical temperature in the internal energy of the Potts model which plagues the conventional VCE method. Calculation of T_c for q varying from 3 to 20 shows that the results obtained up to the first- and third-order cumulant terms converge toward the exact results.

Phase transition in a system of interacting triads

H. T. Diep and D. Loison
Groupe de Physique Statistique, Université de Cergy-Pontoise 49, Avenue des Genottes, B.P. 8428, 95806 Cergy-Pontoise Cedex, France

The present work is motivated by the controversy on the nature of the phase transition on the Heisenberg stacked triangular antiferromagnet (STA). In particular, the renormalization group with $4-\epsilon$ expansion suggests a new universality class, while the renormalization group with $2+\epsilon$ expansion using a nonlinear σ (NLS) model shows that the transition, if not mean-field tricritical or first order, is of the known $O(4)$ universality class. In order to verify this conjecture, we study here an equivalent system obtained from the STA by imposing the local rigidity as has been used in the NLS model. The results show that none of the scenarios predicted by the NLS model is found. The critical exponent $\nu=0.48\pm0.05$ is quite different from the original STA without local rigidity, indicating that the local rigidity changes the nature of the transition. It is also different from that of $O(4)$. It means that successive transformations used to buildup the NLS model from the original STA may lead to the $O(4)$ universality class.

I. INTRODUCTION

Phase transitions in frustrated spin systems have been extensively investigated during the last decade.[1] In particular, the nature of the phase transition in the stacked triangular antiferromagnets (STA) with Heisenberg spins interacting via nearest-neighbor (nn) bonds has been widely studied. This system belongs to a general family of periodically canted spin systems known as helimagnets. Recent extensive Monte Carlo (MC) simulations which are more precise than early MC works[2] have shown that the transition in STA is of second order with the critical exponents quite different from those of known universality classes.[3–5] The body-centered tetragonal helimagnet has also shown almost the same critical exponents.[6] Using a renormalization group (RG) technique in a $4-\epsilon$ perturbative expansion, Kawamura[7] has suggested a new universality class for that transition. However, by using a RG technique for a nonlinear σ (NLS) model with a $2+\epsilon$ expansion, Azaria *et al.*[8–10] showed that the transition, if not of first order or mean-field tricritical, is of second order with the known $O(4)$ universality class. This situation is embarrassing since the RG technique with $2+\epsilon$ and $4-\epsilon$ expansions usually yields the same result in three dimensions for nonfrustrated systems. Furthermore, it is clear that none of the scenarios predicted by Azaria *et al.* was verified by the above-mentioned independent MC simulations of the Heisenberg STA.[3–5]

The purpose of this paper is to find out the reason of the disagreement between the $2+\epsilon$ and the MC results. To this end, we study by the histogram MC simulation technique,[11,12] the approximated system used in the NLS model[8–10] and to compare the MC results with those performed on the original STA.[3–5] The approximated system, as seen in Sec. II, is in fact, obtained from the STA by neglecting local fluctuations while keeping the symmetry of the original Hamiltonian.

Section II is devoted to the description of our model and method. Results are shown and discussed in Sec. III. Concluding remarks are given in Sec. IV.

II. MODEL AND METHOD

Let us consider the STA with nn interaction. The ground state (GS) is characterized by a planar spin configuration where the three spins on each triangle form a 120° structure with either left or right chirality. Thus, the GS degeneracy is twofold in addition to the global rotation. The Hamiltonian is given by

$$H=J\sum_{ij}\mathbf{S}_i.\mathbf{S}_j \tag{1}$$

where S_i denotes the classical Heisenberg spin of unit length at the ith site, $J(>0)$ is the interaction between two nn spins, and the sum runs over all nn pairs. The Hamiltonian (1) has been used in previous MC simulations[3–5] which all give the same critical exponents within statistical errors: $\nu=0.59\pm0.01$, $\beta=0.28\pm0.02$, $\gamma=1.25\pm0.03$, and $\alpha=0.40\pm0.01$.

Following Azaria *et al.*[10] we take the continuum limit at each triangle by putting the three spins at its center. In doing so for all triangles, we generate a new superlattice [see Fig. 1(a)]. In the NLS model, the local rigidity was assumed, i.e., the sum of the three spins on each triangle is set to zero.[8–10,13] The resulting model is a system of triads each of which is defined by the three orthogonal unit vectors $\mathbf{e}_i(x)(i=1,2,3)$ which replace the spins at the center of the xth triangle in Fig. 1(a). The original spins at the xth triangle are obtained by a linear combination of $\mathbf{e}_i(x)(i=1,2,3)$. The system of triads is shown in Fig. 1(b). Note that the third vectors $\mathbf{e}_3(x)$ which are perpendicular to the figure sheet are not shown for clarity. Since there is no more frustration by geometry, one can take indifferently ferromagnetic or antiferromagnetic interaction between nn triads with the following Hamiltonian

$$H_t=-\sum_{xy}\sum_{i=1,2,3}K_i(x,y)\mathbf{e}_i(x).\mathbf{e}_i(y), \tag{2}$$

where $K_i(x,y)$ is the interaction between the two ith unit vectors sitting at the nn, xth, and yth, triads. The original STA is now transformed into a triad system which is defined on a simple cubic lattice. Strictly speaking, the STA corre-

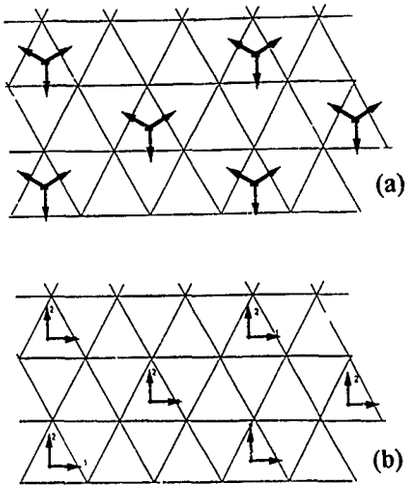

FIG. 1. (a) The continuum limit of the ground state of the STA is taken by putting the spins on each triangle at its center (b) system of triads which is equivalent to the Heisenberg STA with local rigidity. The third unit vectors perpendicular to the figure sheet are not shown.

sponds to the case where the interactions between one of the unit vectors, say $\mathbf{e}_3(x)$, are zero.[10] We will consider in this paper not only this case but also the symmetric case where all $K_t(x,y)$ are equal. Since the interactions in (1) are site independent, all interactions for the triad system are also site independent, i.e., $K_t(x,y)=K_t$.

Before showing our results, let us emphasize that the model considered in this paper is equivalent to the Heisenberg model on the STA *only within the so-called local rigidity condition.*

The method used here is the histogram MC technique which has been recently developed by Ferrenberg and Swendsen to study phase transitions.[11,12] The reader is referred to these papers for details. In our simulations, we use a simple cubic lattice of linear size $L=10,12,14,16,18,20$ sites with periodic boundary conditions. In general, we discarded 500 000 MC steps per triad for equilibrating and calculated the energy histogram as well as other physical quantities over 1–2 M MC steps. We first estimate roughly the transition temperature T_0 at each size and calculate at T_0 the energy histogram as well as the following quantities:

$$\langle C\rangle=\frac{(\langle E^2\rangle-\langle E\rangle^2)}{Nk_BT^2}, \tag{3}$$

$$\langle \chi\rangle=\frac{N(\langle O^2\rangle-\langle O\rangle^2)}{k_BT}, \tag{4}$$

$$\langle (O)'\rangle=\langle OE\rangle-\langle O\rangle\langle E\rangle, \tag{5}$$

$$\langle (O^2)'\rangle=\langle O^2E\rangle-\langle O\rangle^2\langle E\rangle, \tag{6}$$

$$\langle (\ln O)'\rangle=\frac{\langle OE\rangle}{\langle O\rangle}-\langle E\rangle, \tag{7}$$

$$\langle (\ln O^2)'\rangle=\frac{\langle O^2E\rangle}{\langle O^2\rangle}-\langle E\rangle, \tag{8}$$

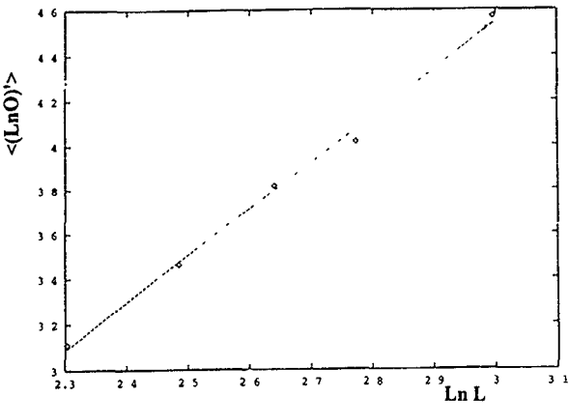

FIG. 2. $\langle(\ln O)'\rangle$ vs $\ln L$. The slope is $1/\nu=2.08$.

$$\langle V\rangle=1-\frac{\langle E^4\rangle}{3\langle E^2\rangle^2}, \tag{9}$$

$$\langle U\rangle=1-\frac{\langle O^4\rangle}{3\langle O^2\rangle^2}, \tag{10}$$

$$\langle (U)'\rangle=\langle UE\rangle-\langle U\rangle\langle E\rangle, \tag{11}$$

where E is the internal energy of the system, T the temperature, O the order parameter, C the specific heat per site, χ the magnetic susceptibility per site, U the fourth-order cumulant, V the fourth-order energy cumulant, $\langle ...\rangle$ means the thermal average, and the prime denotes the derivative with respect to $\beta=1/(k_BT)$. Using the energy histogram at T_0, one can calculate physical quantities at neighboring temperatures, and thus the transition temperature at each size is known with precision.[11,12]

III. RESULT

Let us show the results for the two following cases.

A. $K_1=K_2=K$, $K_3=0$

The system in this case is equivalent to the STA with local rigidity. The transition is found of second order. Using the finite size scaling for the maxima of $\langle C\rangle$, $\langle\chi\rangle$, $\langle(\ln O)'\rangle$, etc.[11,12] we obtained the critical temperature for the infinite system which is $T_c(\infty)=1.5325\pm0.0020$. The exponent ν can be obtained from the inverse of the slope of $\langle(\ln O)'\rangle$ [and $\langle(\ln O^2)'\rangle$] versus $\ln L$. This is shown in Fig. 2 where $\nu=0.48\pm0.05$. The critical exponents γ and β are obtained by plotting $\ln\langle O\rangle$ and $(\ln\langle\chi\rangle)$ vs $\ln L$, respectively (not shown here). They are $\beta=0.22\pm0.04$ and $\gamma=1.15\pm0.07$. These exponents are completely different from those of the original STA (without local rigidity) (see values of exponents given in the preceding section). They are also different from those of the $O(4)$ universality class which are $\nu=0.74$, $\beta=0.39$, $\gamma=1.47$.

There are two things we learn from these results: (i) the local rigidity changes the nature of the phase transition; (ii) when one starts with the local rigidity, one does not find the scenarios predicted by the NLS model in $2+\epsilon$ expansion.[10] It means that the subsequent approximations used in the theoretical calculation,[10] for instance, the continuum limit performed at some steps, may alter the nature of the transition

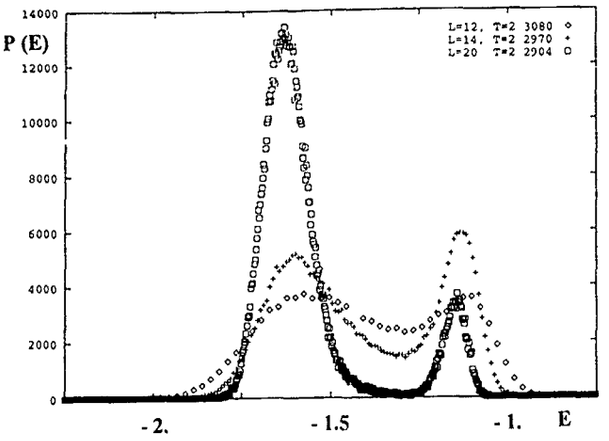

FIG. 3. Energy histogram $P(E)$ for $L=12$ at $T=2.3080$ (diamonds), for $L=14$ at $T=2.2970$ (crosses), and for $L=20$ at $T=2.2904$ (squares). Bimodal distribution characteristic of first-order transition is seen. E is internal energy per unit vector $\mathbf{e}_i(x)(i=1,2,3)$

found by MC simulation for the discrete lattice system. We believe that the continuum limit used in the NLS model excludes possible topological defects which can change the transition nature.

B. $K_1=K_2=K_3=K$

In this case, we find a strong first-order transition. This is unexpected since the symmetry of the Hamiltonian is invariant with respect to the previous case. We show in Fig. 3 the energy histogram $P(E)$ performed for several lattice sizes at the transition temperature of each size. The bimodal distribution characteristic of a first-order transition is seen. The two maxima, which are separated by a continuum for small sizes, show a real discontinuity between them for $L=20$. Note that for $L=20$ the two maxima do not have the same height because the temperature at which the simulation was performed is not precisely the transition temperature. Another signature of the first order is the fact that the energy cumulant $\langle V\rangle$ does not tend to 2/3 at the transition for increasing size as it should be in a second-order transition. Instead, it decreases with increasing size to reach the value of 0.628 for $L=20$. The maxima of $\langle C\rangle$ and $\langle\chi\rangle$ vary as L^3, providing another evidence of the first-order character. Details will be shown elsewhere.

At this stage, it is interesting to note that there should be a critical value of K_3 between 0 and 1 where the transition undergoes a crossover from second to first order. The determination of this tricritical point is left for a future study.

IV. CONCLUSION

Here we have studied a system of interacting triads which is equivalent to the STA if one neglects local fluctuations by imposing a local rigidity on all triangles. In the case which is equivalent to the Heisenberg STA ($K_1=K_2=K$, $K_3=0$), we do not find the same critical exponents as those found for the STA. It means that the local rigidity changes the nature of the transition. The obtained critical exponents are, in addition, different from those of $O(4)$ found in the NLS calculation. We think that during the successive transformations of the initial STA to build the NLS model,[10] some ingredients may have been lost, though the system symmetry is preserved. In the case where $K_1=K_2=K_3=K$, we find that the transition is unexpectedly of first order, though the symmetry of the system does not change with respect to the case where $K_1=K_2=K$, $K_3=0$. We hope that this work will stimulate further theoretical investigations on the nature of phase transition in helimagnets.

Critical behavior of the random Potts model

B. M. Khasanov, S. I. Belov, and D. A. Tayurskii
Physics Department, Kazan State University, Kazan 420 008, Russia

The phase transition in the continual random n-component Potts model is studied by the renormalization group method. It is shown that for the three-dimensional model and $n=3$ the phase transition is to be of the first order. In the case $n=2$ which corresponds to the random Ising model the stable fixed point exists as early as in the one-loop approximation of renormalization group equations.

In the Potts model each lattice site can be in one of n possible states. The energy of interaction between neighboring sites is equal to ϵ_0 for the sites being in the same states and to $\epsilon_1 > \epsilon_0$ in the opposite case. The Landay theory predicts the first-order phase transition due to the third-order vertex in the Hamiltonian of continual Potts model with tensor order parameter. On the other hand, it was shown in Refs. 1 and 2 that the strong fluctuations can lead to continuous transition in pure Potts model.

The static point defects which do not cause the matrix ordering in their localization lead to the local change of the effective Hamiltonian constants. One of the most simple defects is the defectlike "random temperature," but there are a number of situations where coupling constants may vary in a random way. In general, the third- and the fourth-order random potentials should be included in the reduced Hamiltonian. In this paper, we shall consider the critical behavior of continuous analogy of the random lattice Potts model and take into account local changes of all effective parameters in Hamiltonian.

Earlier it was shown that for the random P-model (the system with symmetric nonsingular and traceless tensor order parameter) its critical behavior was experimentally undistinguishable from pure model. The reason for it is that the stable fixed points of renormalization group equations in random and pure systems are located very closely to each other.[3]

For the model we consider the Hamiltonian has the form:[4]

$$\mathbf{H}=\frac{1}{2!}\int_{\mathbf{q}_1\mathbf{q}_2}\nu_2(\mathbf{q}_1\mathbf{q}_2)Q_{\alpha\beta}(\mathbf{q}_1)Q_{\alpha\beta}(\mathbf{q}_2)+\frac{1}{3!}\int_{\mathbf{q}_1\mathbf{q}_2\mathbf{q}_3}\nu_3(\mathbf{q}_1\mathbf{q}_2\mathbf{q}_3)Q_{\alpha\beta}(\mathbf{q}_1)Q_{\beta\gamma}(\mathbf{q}_2)Q_{\alpha\gamma}(\mathbf{q}_3)$$
$$+\frac{1}{4!}\int_{\mathbf{q}_1\mathbf{q}_2\mathbf{q}_3\mathbf{q}_4}\nu_4(\mathbf{q}_1\mathbf{q}_2\mathbf{q}_3\mathbf{q}_4)Q_{\alpha\beta}(\mathbf{q}_1)Q_{\alpha\beta}(\mathbf{q}_2)Q_{\gamma\delta}(\mathbf{q}_3)Q_{\gamma\delta}(\mathbf{q}_4)+\frac{1}{4!}\int_{\mathbf{q}_1\mathbf{q}_2\mathbf{q}_3\mathbf{q}_4}\nu_4'(\mathbf{q}_1\mathbf{q}_2\mathbf{q}_3\mathbf{q}_4)$$
$$\times Q_{\alpha\beta}(\mathbf{q}_1)Q_{\beta\gamma}(\mathbf{q}_2)Q_{\gamma\delta}(\mathbf{q}_3)Q_{\delta\alpha}(\mathbf{q}_4). \tag{1}$$

Here $Q_{\alpha\beta}(\mathbf{q})$ is the Fourier transform of symmetric, diagonal, and traceless tensor of rank n, $\int_q=\int d^d\mathbf{q}/(2\pi)^d$. ν_2,ν_3,ν_4 are the random fields for which we suppose the translational invariance of all averages and the absence of the long-range correlations. The average value of ν is transformed according to the full space group of the system without impurities and can be obtained by the averaging over a probability distribution of fields ν in the Hamiltonian

$$\langle\nu_2(\mathbf{q}_1\mathbf{q}_2)\rangle=(r+q_1^2)\,\delta(\mathbf{q}_1+\mathbf{q}_2),$$
$$\langle\nu_2(\mathbf{q}_1\mathbf{q}_2\mathbf{q}_3)\rangle=B\,\delta(\mathbf{q}_1+\mathbf{q}_2+\mathbf{q}_3),$$
$$\langle\nu_4(\mathbf{q}_1\mathbf{q}_2\mathbf{q}_3\mathbf{q}_4)\rangle=C\,\delta(\mathbf{q}_1+\mathbf{q}_2+\mathbf{q}_3+\mathbf{q}_4),$$
$$\langle\nu_4'(\mathbf{q}_1\mathbf{q}_2\mathbf{q}_3\mathbf{q}_4)\rangle=U\,\delta(\mathbf{q}_1+\mathbf{q}_2+\mathbf{q}_3+\mathbf{q}_4). \tag{2}$$

The renormalization group transformation change also averages $\langle\delta\nu\delta\nu\rangle$ as well as parameters B, C, and U. Here $\delta\nu$ denotes the deviation from the translation invariance $\nu=\nu+\delta\nu$. In the three-dimensional space it is necessary to consider the following cumulants:

$$\langle\delta\nu_i(\mathbf{q}_1\mathbf{q}_2)\,\delta\nu_j(\mathbf{q}_3\mathbf{q}_4)\rangle=\Delta_{ij}(\mathbf{q}_1+\mathbf{q}_2+\mathbf{q}_3+\mathbf{q}_4),$$
$$\Delta_{ij}\in(\Delta_{rr},\Delta_{BB},\Delta_{rB},\Delta_{rC},\Delta_{rU}). \tag{3}$$

The functions $B(T)\equiv\Gamma_3$ and $C(T)=\Gamma_4^i$ (i is a number of the fourth-order invariant) are the irreducible vertices at zero momentum for the Hamiltonian (1). Besides those vertices there are a number of effective impurity vertices: the vertex Δ_{rr} has the same dimension as Γ_4, the vertex Δ_{rB} is equivalent to the fifth-order invariant in the Hamiltonian, and vertices $\Delta_{BB},\Delta_{rC},\Delta_{rU}$ are equivalent to the sixth-order invariant. For the continuous transition all vertices depend on correlation radius κ by means of the power law

$$\Gamma_k\propto g_k\kappa^{2k-d(k-2)-k\eta/2}, \tag{4}$$

where η is the Fisher critical exponent. One can obtain the Gell-Mann-Low-like equations for dimensionless invariant charges $g_k\in(B,C,U,\Delta_{ij})$

$$\frac{\partial g_k}{\partial t}=\Psi_k(g). \tag{5}$$

Δ_{rC}	0	0	0	0	−0.008	−0.03	0.0007	−0.31	0

where $t=\ln \kappa^2$. For arbitrary n there are eight such equations. For $n=3$ the two fourth-order invariants in (1) are connected by means of equality $TrQ^4=(TrQ^2)^2/2$. In this case the number of equations is reduced to six, but they are still rather complicated. The numerical solution gives the fixed points with positive B^2 and C that is summarized in Table I.

The first three fixed points with $\Delta=0$ earlier obtained in Ref. 1, describe the critical behavior of the Potts model without impurities. The fixed point A_+ is the saddle point while the stable point A_- is the stable focus. The Hamiltonian flow of renormalization group equations that is going through the fixed point A_+ divides the phase diagram into two parts. Flows from the one part are going to the line 01 of the Fig. 1 on which the first-order phase transition occurs, and flows from another—to the fixed point A_-, where the second-order phase transition takes place. For the random Potts model the only one stable fixed point is the A'_-. In the real physical system the cumulants Δ_{rr} and Δ_{BB} are by definition a positive definite quantities. The flow lines make it impossible for a point that starts in the region with $\Delta_{ii}>0$ to flow after renormalization into the region with $\Delta_{ii}<0$ (Fig. 2). Thus, the fixed point A'_- is inaccessible to physical systems. Hence, the phase transition in the random three component Potts model described by the Hamiltonian (1) is the phase transition of the first order. It is important to note that the fixed point A_- of the pure system is unstable with respect only to Δ_{BB} and Δ_{rC}. All given fixed points in Table I are in the region of values B^2 and C that is stable about condensate separation. Presently, results for the continual model are correlated with the lattice model mentioned at the beginning are discussed. By means of functional integration, the lattice model may be presented as a field theory with a nonpolinomial interaction potential in which all bare constants are connected. It is not obvious that the expansion up to the fourth-order invariants in (1) is sufficient to describe the phase transition in a lattice model. However, if that is the case then Hamiltonian (1) will correspond to the lattice model only with the definite correlations between the bare parameters in (1). After that the critical behavior of a lattice model will described only by the same phase flow of renormalization group equations. Probably, this flow line will go near the fixed point A_- or A'_1. In this case, one can obtain the critical exponent of susceptibility γ from equation

$$1-\gamma^{-1}=\frac{n+1}{3}C-\frac{3(n-2)}{2n}B^2-2\Delta_{rr}, \tag{6}$$

Therefore $\gamma=1.3$. If the flow line passes near A_+ or A'_+, then $\gamma=0.6$. In order to investigate the critical properties for $n>3$ one has to solve eight equations like (5). This problem is rather complicated in comparison with the three-component system. Therefore, we will discuss only impurities of "random temperature" type, i.e., $\Delta_{rr}\neq 0$. In this regime the unstable fixed point for $n=4$ and the stable fixed point for $n\geq 5$ with B^2, $U>0$, and $C,\Delta_{rr}<0$ could be obtained. There are not stable fixed points in the physical region with $B^2,\Delta_{rr}>0$.

If we take $B=0$ in the Hamiltonian (1) and consider the limit $n\to\infty$ (in this case, the condition $TrQ=0$ becomes irrelevant), then the stable unphysical fixed point with $U=1/12$, $C=1/(4n)$, $\Delta_{rr}=-1/48$, and the stable fixed point $U=1/6$, $C=1/(2n)$, $\Delta_{rr}=0$ appear. The latest point describes the critical properties of the spherical model with cubic anisotropy. Calculating the exponent γ for it

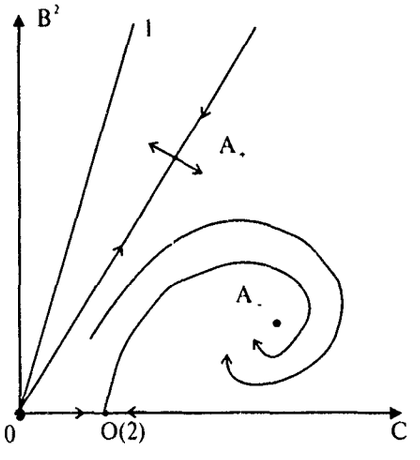

FIG. 1 Flow diagram for pure model, $n=3$.

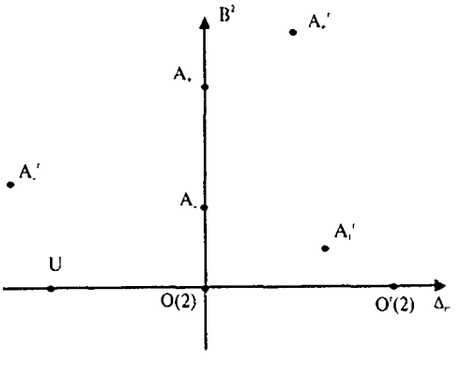

FIG 2. The fixed points on the (B^2,Δ_{rr}) plane for $n=3$.

$$1-\gamma^{-1}=\frac{n}{3}C+U,$$

we have $\gamma=3/2$. In the three-loop approximation the stable fixed point is equal to $nC=0.480$, $U=0.176$, $\Delta_{rr}=0$, and $\gamma=1.43$. It happens that in the zero order to $1/n$ the renormalization group equation for vertex U and the critical exponent η depend only on U, so the value of η for the spherical model with cubic anisotropy is equal to η of the Ising model. The same results were obtained in Ref. 5 where the perturbation theory on vertex C was used. Note that if one can take only $C\neq 0$ in the Hamiltonian (1) (spherical model) then the well-known result in three-dimensional space $\gamma=2$ follows. The limit of large n considered here is of consequence with the statement that for $n\to\infty$ and $d>2$ the interaction of fluctuations C disappears while the value nC remains finite and the expansion over $1/n$ can be effective.

The case $n=2$ that corresponds to the Ising model is the subject of special interest. Here, the third-order vertex B does not influence the critical behavior, and corresponding to it, charge g_3 drops out of Eqs. (5). This circumstance follows from the symmetry of the Potts model for $n=2$. Besides, here as well as for $n=3$, there is only one fourth-order invariant in (1), so the total number of variables is reduced to three: C and two cumulants Δ_{rr} and Δ_{rC}. If $\Delta_{rC}=0$, Eqs. (5) are degenerated in the one-loop approximation and do not have nontrivial solutions. There is no degeneracy in the two-loop approximation, but at the same time the fixed point describing the critical behavior in the pure Ising model is absent. The pure and random fixed points appear only in the three-loop approximation.[6] Assuming that $\Delta_{rC}\neq 0$, one can get nontrivial random stable fixed point even in the one-loop approximation: $C=0.390$, $\Delta_{rr}=0.051$, $\Delta_{rC}=-0.002$. Using (6) it is easy to find susceptibility exponent γ. Other critical exponents are expressed through γ and η with the help of the scaling relation laws. One can use two approaches in order to find the value of γ in the three-dimensional renormalization perturbation theory: (i) to substitute into (6) the fixed point coordinates and to reverse the obtained value; (ii) on the first inverse Eq. (6) and to expand γ as a series of C and Δ_{rr}, then the fixed point coordinates into obtained expressions are substituted. As a result, we find for γ and the heat capacity exponent α the following values, calculated in the following ways, respectively: $\gamma=1.4$, $\alpha=-0.1$, and $\gamma=1.29$, $\alpha=0.07$. Higher-order terms of perturbation theory (it is necessary to consider the three-loop approximation) lead to the small increase of γ and can essentially change the value of α. Even in the one-loop approximation, two ways of calculations give the opposite signs of α. Hence, the obtained results do not allow to estimate reliably estimate the value of the random exponent α. It is a very reasonable possibility that this cannot also be made in the three-loop approximation as it was shown in Ref. 6 for the "random temperature" impurities. Using Harris' arguments[7] it is possible to show that two different kinds of the disorder variables Δ_{rr} and Δ_{rC} do not change the statement[6] that critical exponent α must be negative.

The work of B.Kh. was supported, in part, by a Sloan Foundation Grant awarded by the American Physical Society and the work of D.T. was supported, in part, by a Soros Grant awarded by the International Science Foundation.

Influence of exchange bond disorder on the magnetic properties of $(Pd_{1-x}Fe_x)_{95}Mn_5$ near T_c

Z. Wang, X. Qi, H. P. Kunkel, and Gwyn Williams
Department of Physics, University of Manitoba, Winnipeg, Manitoba R3T 2N2, Canada

A summary of a detailed study of the field and temperature dependent ac susceptibility of a series of ternary $(Pd_{1-x}Fe_x)_{95}Mn_5$ alloys near the ferromagnetic ordering temperature T_c is presented. By following the behavior of the crossover line (a line of maxima in the field dependent susceptibility *above* T_c, the maxima moving upwards in temperature but decreasing in amplitude with increasing field) it is possible to catalog the influence of exchange bond disorder on aspects of the critical behavior. These ternary systems are not soft ferromagnets and thus asymptotic critical exponents are difficult to estimate using this technique. Nevertheless, effective exponents (i.e., obtained away from the critical point) clearly reflect the presence of significant variance in the distribution of exchange bonds.

I. INTRODUCTION

$(Pd_{1-x}Fe_x)$ $(0.01 \leqslant x < 0.25)$ is a well-known ferromagnet[1] and $Pd_{95}Mn_5$ is a spin glass.[2] In the frequently referenced approach[3] in which the exchange bond distribution that exists in such metallic systems is approximated by a Gaussian, the mean value of this distribution thus exceeds its variance in the former system, while in the latter this inequality is reversed.

Binary $Pd_{1-x}Fe_x$ ($x \simeq 0.014$–0.016) is a nearly ideal example of a soft ferromagnet.[1] Internal fields as low as $H_i \simeq 1$ Oe are capable of revealing structures normally associated with critical fluctuations at a second-order phase transition, and a detailed analysis of this structure yields critical exponents[1] ($\gamma = 1.36 \pm 0.03$, $\beta = 0.39(5) \pm 0.015$, $\delta = 4.5 \pm 0.15$) close to the values predicted by the isotropic, three-dimensional Heisenberg model[4] using renormalization group techniques ($\gamma = 1.386$, $\beta = 0.365$, $\delta = 4.8$). Binary $Pd_{1-x}Mn_x$ ($x \geqslant 0.05$) is a spin glass, characterized by a divergence in the nonlinear susceptibility[5,6] (the associated exponents having been most recently reported[6] as $\gamma = 2.0 \pm 0.2$, $\beta = 0.9 \pm 0.15$, $\delta \simeq 3$). Ternary $(Pd_{1-x}Fe_x)_{95}Mn_5$ ($x = 0.0035$) remains[7,8] as one possible example of a system exhibiting sequential phase transitions following detailed studies,[8] viz. near $T_c \simeq 9$ K the field- and temperature-dependent susceptibility exhibits features associated with critical fluctuations near a second order paramagnetic to ferromagnetic transition (but with some indication of the influence of variance in the exchange bond distribution), while at lower temperature, $T_{SG} \simeq 4.1$ K, the nonlinear response displays a marked (but *not* divergent) anomaly.

Here we present a summary of comparable measurements on ternary $(Pd_{1-x}Fe_x)_{95}Mn_5$. At rather higher Fe concentrations ($x \simeq 0.016$–0.022), these samples have correspondingly higher ferromagnetic ordering temperatures, and the "reentrant" transition is also suppressed. For this reason we have focused attention on the detailed behavior of the field- and temperature-dependent response near T_c, and on the influence exerted on this response by the exchange disorder expected in such systems.

II. EXPERIMENTAL DETAILS

Samples were prepared individually in an argon arc furnace from high purity starting materials using a well-established sequence of inverting, remelting, cold rolling, and annealing steps,[1,9] to ensure homogeneity. Field- and temperature-dependent ac susceptibility data were collected continuously using a previously described[1] phase-locked susceptometer on samples of typical dimensions (17×2×0.1) mm;[3] both the ac excitation field (50 m Oe rms at 2.4 kHz) and static biasing fields up to 1 k Oe were applied along the largest specimen dimension. The data were corrected for background and demagnetizing effects, as described previously.[1]

III. RESULTS AND DISCUSSION

Figure 1 reproduces the zero-field susceptibility in binary Pd-1.6 at. % Fe [Fig. 1(a)], and in ternary $(Pd_{1-x}Fe_x)_{95}Mn_5$ ($x = 0.0035$ [Fig. 1(c)] and 0.016 [Fig.

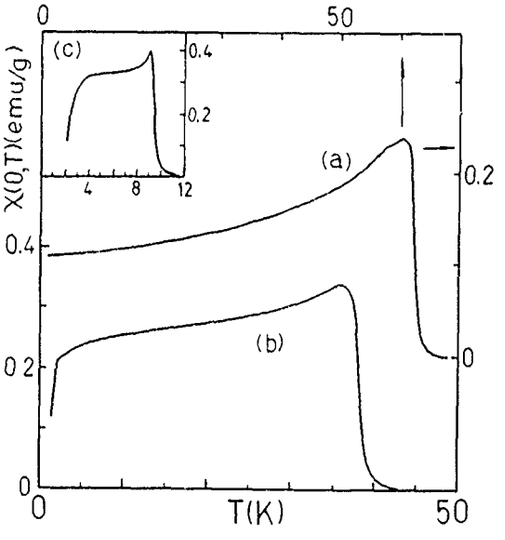

FIG 1. The zero-field susceptibility $\chi(0,T)$ (in emu/g) plotted against temperature (in K) for (a) Pd + 1.6 at. % Fe, (b) (Pd + 1.6 at. % Fe)$_{95}$Mn$_5$, and (c) (Pd + 0 35 at. % Fe)$_{95}$Mn$_5$.

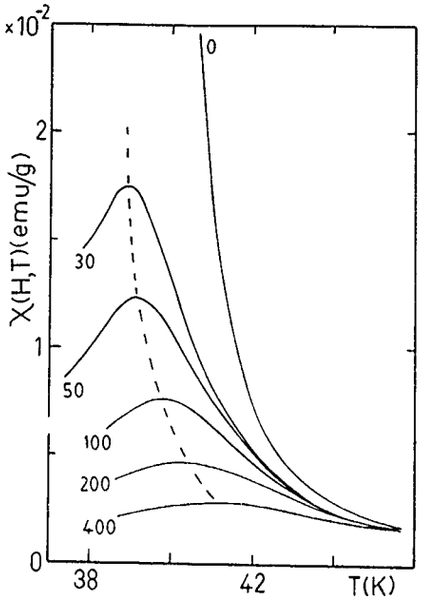

FIG. 2. The susceptibility $\chi(H,T)$ (in emu/g) plotted against temperature T (in K) for (Pd+1.6 at. % Fe)$_{95}$Mn$_5$; the numbers marked against each curve are the estimated, superimposed (internal) fields H_i (in Oe). The dashed line represents the crossover line.

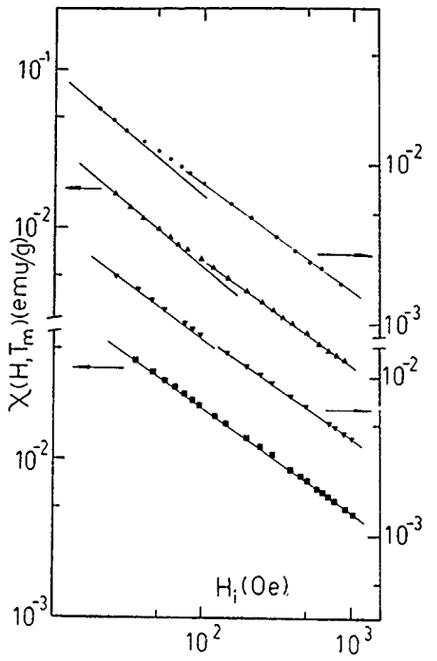

FIG. 3. The *peak* susceptibility $\chi(H,T_m)$ (in emu/g), taken from data similar to that shown in Fig 2, plotted against the internal field H_i (in Oe) on a double logarithmic scale for $(Pd_{1-x}Fe_x)_{95}Mn_5$, with $x=1.6$ at. % Fe (●), 1.8 at. % Fe (▲), 2.0 at. % Fe (▼) and 2.2 at % Fe (■). The lines drawn yield the $\delta^*(H)$ values listed in Table I.

1(b)]), so that the general features of the behavior of these systems can be compared and contrasted. While the characteristic structure usually associated with reentrant behavior is evident in Fig. 1(c), the lower (reentrant) transition is suppressed in both binary and ternary samples with higher Fe concentration. Nevertheless, as is clear from a comparison of Figs. 1(a) and 1(b), the ferromagnetic ordering temperature T_c is lowered by the addition of Mn. Figure 2 details the influence of superimposed static biasing fields on Fig. 1(b) near 40 K; such fields suppress the principal (Hopkinson) maximum enabling a secondary peak structure to be observed. These latter peaks decrease in amplitude and move upwards in temperature as the applied field increases; they are a characteristic signature[1,10] of critical fluctuations at a second-order paramagnetic to ferromagnetic transition, and their locus defines the crossover line.[10,11] In terms of the usual[12] scaling law expression for the field (h) and temperature (t) dependent susceptibility $\chi(h,t)$

$$\chi(h,t)=t^{-\gamma}F\left(\frac{h}{t^{\gamma+\beta}}\right)=h^{(1/\delta)-1}G\left(\frac{h}{t^{\gamma+\beta}}\right), \tag{1}$$

[with $h\sim H_i/T_c$ and $t=(T-T_c)/T_c$ in the usual notation], the temperature T_m of these critical (secondary) peaks varies with fields as [1,10]

$$t_m=(T_m-T_c)/T_c\propto\left(\frac{H_i}{T_c}\right)^{1/(\gamma+\beta)}, \tag{2}$$

while the critical peak amplitude $\chi(h,t_m)$ behaves as

$$\chi(h,t_m)\propto h^{1/\delta-1}. \tag{3}$$

Equations (2) and (3) along with the more conventional dependence of the zero-field susceptibility on (reduced) temperature above T_c, viz:

$$\chi(0,t)\propto t^{-\gamma}, \tag{4}$$

have provided the basis for a detailed analysis of the critical behavior in a variety of systems.[1,10]

Here, however, two factors conspire to preclude such a detailed analysis; (a) fields in excess of $H_i\simeq 15$ Oe are required initially to resolve critical peak structure, and (b), even when these peaks are resolved they are considerably broader than those in the corresponding binary $Pd_{1-x}Fe_x$ samples. The influence of point (a) can be seen in Fig. 3 which tests Eq. (3) via a double logarithmic plot of the peak susceptibility $\chi(H,T_m)$ (evident in Fig. 2) against internal field (H_i); in the case of the 1.6 and 1.8 at. % Fe samples the line drawn at *low* field corresponds to the 3D-Heisenberg model value of $\delta=4.8$ while the higher field slope yields an *effective* exponent $\delta^*(H)\sim 3$ (the mean-field value). This fall in the effective exponent $\delta^*(H)$ with increasing field is well cataloged[1,10] in systems with exchange bond disorder. The field dependence of the effective exponent $\delta^*(H)$ is not so evident in the 2.0 and 2.2 at. % Fe specimens as even larger fields H_0 (listed in Table I) are required to resolve critical peak structure in them.

Figure 4 tests the predictions of Eq. (2) and also illustrates the difficulties introduced as a result of point (b) above. Briefly, in the most favorable cases,[1,10] t_m can be plotted against H_i on a double logarithmic scale, the slope of which yields the crossover exponent $(\gamma+\beta)$. Here the diffuse nature of the critical peaks renders this procedure inappropriate since T_m (and hence t_m) cannot be established with sufficient accuracy. The best that can be done is a linear plot of the peak temperature T_m against $(H_i)^{0.57}$ ($[\gamma+\beta]^{-1}=0.57$

for Heisenberg model exponents), which indicates that these data are generally consistent with such model exponents within the rather appreciable scatter evident here. The intercept from such plots yields the T_c estimates listed in Table I.

Further effects of exchange bond disorder are provided in Fig. 5 where, rather than to test Eq. (4) directly, the effective Kouvel–Fisher susceptibility exponent[13]

$$\gamma^*(t)=d\ \ln[\chi(0,t)]/d\ \ln(t) \tag{5}$$

is plotted against t for the 2.0 at. % Fe sample. The nonmonotonic variation of this effective exponent with temperature—specifically the peak in $\gamma^*(t)$ *above* T_c near

$t\simeq 0.16$—is well documented in systems with bond disorder,[1,10,14] confirming the conclusions drawn from the data shown in Fig. 3.

IV. SUMMARY

A detailed study of the field- and temperature-dependent ac susceptibility near the ferromagnetic ordering temperature T_c in $(Pd_{1-x}Fe_x)_{95}Mn_5$ indicates a significant suppression in the value for T_c following the addition of Mn. Within the framework of an S–K like model,[3] this represents a marked reduction of the mean value/second moment ratio for the exchange bond distribution. The field and temperature dependence of the effective exponents $\delta^*(H)$ and $\gamma^*(t)$ indicate that this distribution retains a substantial width/second moment although the width cannot exceed the mean value as the reentrant transition is suppressed.

In the series of ordered DO_3 solid solutions $Fe_{3-x}Mn_xSi$, field-induced transitions have previously been found to occur for antiferromagnetic alloys with values of x near 1.70. The present work has determined a region of composition in which antiferromagnetism is the low-field, low-temperature state and gives the variation of the critical field as a function of temperature and composition. The critical field decreases approximately quadratically with temperature and rises to beyond 6 T in the range of composition from $1.6 \leqslant x \leqslant 1.8$. Neutron diffraction indicates that the antiferromagnetic axis is shifted from the [111] direction and that in a 5 T field the antiferromagnetic component of the scattering is reduced considerably from that in zero field. However, no corresponding increase in ferromagnetic component is observed within experimental error and Arrott plots suggest the high-field state is still largely antiferromagnetic.

I. INTRODUCTION

Fe_3Si and Mn_3Si are known to form solid solutions with the DO_3 ordered structure. The substitution of Mn for Fe in forming the series $Fe_{3-x}Mn_xSi$ results in a selective site occupation which has been fully described in earlier papers.[1,2] The present paper is concerned with the magnetic properties of the compounds in the compositional range $1.6 \leqslant x \leqslant 1.8$. These properties derive from the occupation of the A and C sites by Mn atoms, the B site being already fully occupied.[1] Magnetization studies show that the zero field magnetization $\sigma_{0,T}$ for these compounds decreases below a "reorientation temperature" T_R (~65 K) to give a smaller saturation magnetization $\sigma_{0,0}$. The previous work has shown that $\sigma_{0,0}$ is zero at $x = 1.70$ beyond which antiferromagnetism is the low temperature, low-field state. The present work stems from the observation[2] that for the alloys with $x = 1.70$ and 1.75 a field-induced transition from antiferromagnetism to another magnetic state occurs at temperatures below T_R. We have extended this work considerably to determine the alloy compositions for which this transition occurs (i.e., for which antiferromagnetism is the low-temperature, low-field state) and the variation of the critical fields as a function of temperature and composition. We have also attempted to determine the high field magnetic state of the compounds by comparing the neutron diffraction patterns in zero field and in a field of 5 T as a function of temperature, as well as examining the Arrott plots.

II. EXPERIMENTAL DETAILS

The material used for this investigation was prepared in an identical manner to that employed in the earlier examinations.[1,2] The new material consisted of alloys with x having values of 1.60, 1.625, 1.65, and 1.80. X-ray examination of the alloys indicated all to be single phase alloys. The quenched samples in powder form were examined in field up to 12 T using the Manchester and Salford Vibrating Sample Magnetometer facility over the temperature range 2–300 K. Data acquisition is by microprocessor control in which at a given temperature the field is swept automatically from 0 to 12 T and back to 0 within about 20 min. The critical field was taken to be that at which the differential susceptibility $d\sigma/dH$ was a maximum. Neutron diffraction measurements as a function of field and temperature were obtained at the HFIR Reactor, Oak Ridge National Laboratory using a wavelength of 1.42 Å. 24 h isothermal scans were normally employed with the field applied vertically, perpendicular to the scattering vector. Rietveld plots were obtained above the magnetic ordering temperatures allowing the site occupations and compositions to be refined.

III. RESULTS

The determination of the composition at which $\sigma_{0,0}$ becomes zero was made more difficult by the observation that for $x = 1.60$ and 1.625 the low-temperature properties of the alloys (in common with those of alloys having smaller values of x (Ref. 1) are dependent on previous magnetic field history. Since a demagnetizing facility was not available magnetization measurements at each temperature were obtained only after cooling in zero field from the paramagnetic state. Following this procedure it was established that $\sigma_{0,0}$ is zero for $x = 1.60$ and 1.625, although as indicated in the inset to Fig. 1, a magnetic measurement produces a large remanent moment in these cases which is associated with the transition fields being very small. Such effects are not observed for $x > 1.65$. A typical field transition is shown in Fig. 1 for the alloy with $x = 1.80$. The transition occurs over a wide range of field and is accompanied by considerable hysteresis at the lowest temperatures suggesting a first-order phase transition and possibly a large magnetostrictive effect. It is possible therefore to define two critical fields. At the lowest temperatures the difference between these two fields is often large, of the order of 1 T. At low fields the magnetization increases linearly with field as expected for an antiferromagnetic material but above the transition the observed curvature suggests an unsaturated state. The variation of the mean critical fields with temperature and composition is illustrated in Fig. 2 where a quadratic decrease with increasing temperature is seen (the results for $x = 1.75$ are included for comparative purposes). The solid lines are a fit to $H^* = (1 - T^{*2})$ where

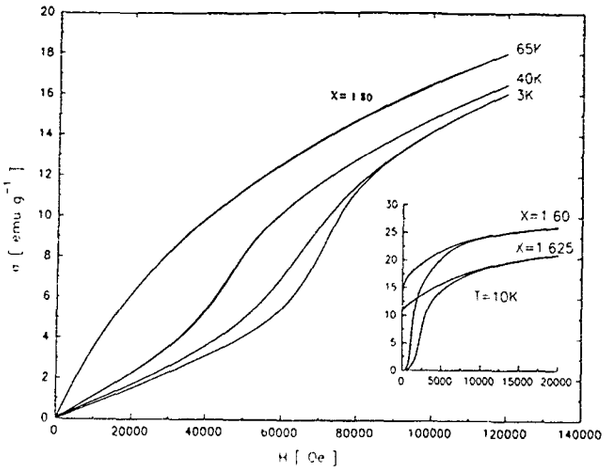

FIG. 1. Typical variation of magnetization with applied field at several temperatures below T_R for $Fe_{1.20}Mn_{1.80}Si$ Inset: low field data at low temperatures for $x=1.60$ and $x=1.625$.

the asterisks indicate reduced critical fields and temperatures, i.e., $H^*=H_c(T)/H_c(0)$ and $T^* =T/T_R$. Arrott plots were obtained both above and below T_R. Figure 3(a) shows that for $x=1.8$ above T_R the intercept on the H/σ axis approaches the origin as the temperature falls towards the ordering temperature. Information on the high-field state below T_R is provided by the Arrott plots shown in Fig. 3(b) for which the intercept on the H/σ axis retreats away from the origin as the temperature continues to fall. This behavior has recently been shown to be characteristic of an antiferromagnetic state[3] and will be discussed below. The situation for the other alloys is complicated by the appearance of a ferromagnetic region in a narrow temperature range above T_R. This is also reflected in the Arrott plots of those materials. Table I gives the approximate values of T_R and T_C versus x.

Neutron diffraction was carried out on the alloy with $x=1.65$ at the following temperatures and fields: 130 K and zero field in the paramagnetic regime; 80 K and zero field in

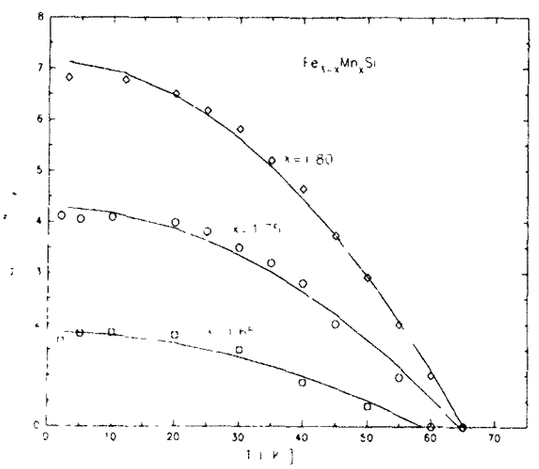

FIG. 2. Mean transition field vs temperature for the alloys discussed in this paper. Data for $x=1.75$ is included from Ref. 2 for comparative purposes. The solid lines are fits to the data using $H_C(T)/H_C(0)=[1-(T/T_R)^2]$.

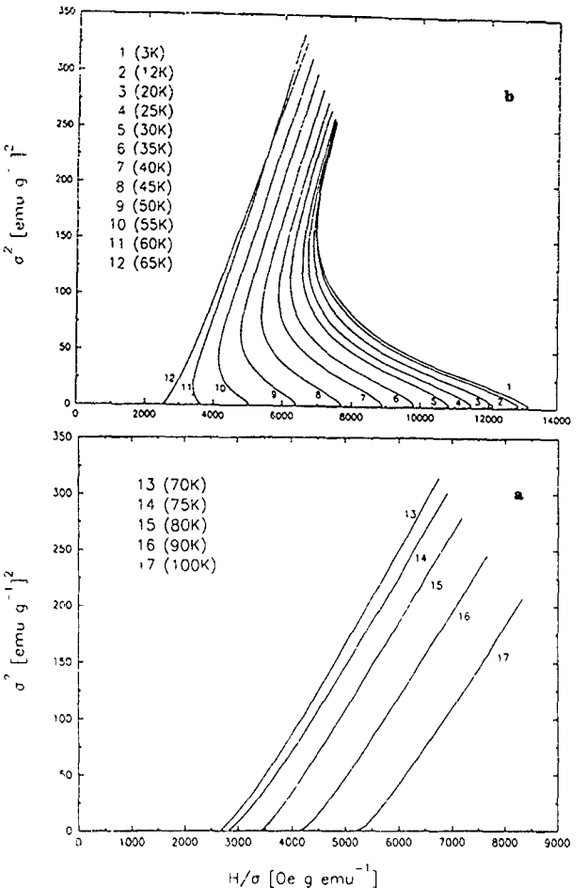

FIG. 3. Arrott plots for $Fe_{1.20}Mn_{1.80}Si$ (a) above T_R and (b) below T_R.

a regime where the alloy is weakly ferromagnetic; 4.2 K and zero field where the alloy is antiferromagnetic; 4.2 K and 5 T at which field the transition to another magnetic phase has occurred. For the results from the paramagnetic regime (130 K) the composition and site occupations were refined by a Rietveld plot which included parameters taking into account a small preferred orientation. The refined composition corresponded to $x=1.64$ and the following site occupation: (A) (0.32 Mn+0.68 Fe), (B) Mn, (C) as (A), and (D) Si. Figure 4(a) shows the results in zero field at 4.2 K and this is compared with the equivalent results in a field of 5 T in Fig. 4(b). The very small peaks in Fig. 4 were not observed at 130 K and indicate the antiferromagnetic order.

IV. DISCUSSION

The remarkable feature of Fig. 3 is the observation that below T_R the Arrott plot intercepts on the H/σ axis retract from the origin. It has recently been shown using the Landau theory of phase transitions[3] that such behavior is characteristic of systems with coupled antiferromagnetic and ferromagnetic components with $T_N<T_C$ and theoretical curves similar to those in Fig. 3 have been obtained. It is possible that the high-field state remains predominantly antiferro- (or ferri-) magnetic and that further transitions at even higher fields might be expected. The magnetization and neutron diffraction data have previously been shown to be consistent with a model in which in the zero field the Mn moments on alternate B sites ($\sim 2\ \mu_B$ independent of x in this range of x) are canted at opposing angles to the magnetic axis and it is assumed that at T_R these moments "flip" to become parallel to the moments on A and C sites. In the composition range considered here the previous neutron diffraction data has indicated that the moments on A and C sites are practically zero so that the BB antiferromagnetic interactions dominate and indeed become stronger as x increases beyond 1.5. The neutron diffraction results in Fig. 4 show that the intensities of the superlattice peaks in zero field are much reduced by the application of a 5 T field. Since the applied field is perpendicular to the scattering vector one might expect that any reduction in the antiferromagnetic alignment would correspond to the appearance of a ferromagnetic component and that this would be reflected in an increase in the scattering at the nuclear peaks. The structure factors for the latter are such that one would expect the (111) line, which contains only the contribution from the B site, to be most sensitive to an increase in ferromagnetic alignment but within experimental error the intensity remains the same. Table II gives the effect of field on the intensities of the superlattice lines showing, in general, a reduction to some 57% of the zero-field value. The application of a magnetic field alters the basic antiferromagnetic arrangement but it seems likely that the resultant state is another unsaturated one. To explain the observations this state must be such as to contribute only very small ferromagnetic components to the scattering.

Clearly further work on this most interesting region of concentration is required and further neutron diffraction and μSR investigations are planned.

Critical behavior of the two-dimensional easy-plane ferromagnet

Alessandro Cuccoli, Valerio Tognetti, and Paola Verrucchi
Dipartimento di Fisica dell'Università di Firenze, Largo E. Fermi 2, I-50125 Firenze, Italy

Ruggero Vaia
Istituto di Elettronica Quantistica del Consiglio Nazionale delle Ricerche, Via Panciatichi 56/30, I-50127 Firenze, Italy

The critical behavior of 2D magnetic easy-plane systems has mainly been studied by the classical XY model. However, the z components of the spins have to be considered in order to describe real systems, and their fluctuations cannot positively be neglected when quantum effects are to be included, quantum spins being intrinsically three-component objects. Therefore, Monte Carlo simulations are performed for the Heisenberg ferromagnet with easy-plane anisotropy (XXZ model) on a two-dimensional square lattice with a twofold aim: first, to obtain accurate quantitative results about the critical behavior of the classical model, showing the relevant role played by the out-of-plane fluctuations; second, to open the way for approaching the quantum thermodynamics by means of the effective Hamiltonian method that reduces the quantum thermodynamics of the XXZ ferromagnet to the investigation of an effective classical model with temperature-dependent renormalized interaction parameters. Specific heat, magnetic susceptibility, and correlation length are calculated in the critical region for lattice sizes up to 128×128. These quantities preserve the Kosterlitz–Thouless behavior of the XY model. For the transition temperature of the classical $XX0$ model we obtain the estimate $k_B T_c/(J\tilde{S}^2)=0.69\pm0.01$.

The two-dimensional XXZ model is described by the Hamiltonian

$$\hat{\mathcal{H}}=-\frac{1}{2}J\sum_{i,d}[(\hat{S}_i^x\hat{S}_{i+d}^x+\hat{S}_i^y\hat{S}_{i+d}^y)+\lambda\hat{S}_i^z\hat{S}_{i+d}^z]. \tag{1}$$

The index $i\equiv(i_1,i_2)$ labels the sites of a two-dimensional Bravais lattice, and $d\equiv(d_1,d_2)$ represents the displacements of the z nearest-neighbors of each site. The easy-plane anisotropy is represented by the dimensionless parameter $\lambda(|\lambda|<1)$. For $\lambda=0$ the above Hamiltonian describes the $XX0$ model (also called "quantum XY model").

In this paper, we are mainly concerned with the classical counterpart of Eq. (1). For our purposes it is sufficient to take the spins in Eq. (1) as classical vectors of length $\tilde{S}$, i.e., $\hat{S}_i\to\tilde{S}\mathbf{s}_i$ with the classical vectors $\mathbf{s}_i$ varying onto the unit sphere $|\mathbf{s}_i|=1$. The natural energy scale is then $\epsilon=J\tilde{S}^2$, so we define a dimensionless reduced temperature $t=k_BT/\epsilon$. The classical XXZ Hamiltonian reads

$$\mathcal{H}=-\frac{\epsilon}{2}\sum_{i,d}[(s_i^x s_{i+d}^x+s_i^y s_{i+d}^y)+\lambda s_i^z s_{i+d}^z]. \tag{2}$$

This system belongs[1] to the universality class of the planar (or XY) model (i.e., $s_i^z\equiv0$), that is characterized by the Berezinskii-Kosterlitz-Thouless[2] (BKT) phase transition at $t_c\simeq0.89$.[3,4] The transition is driven by the unbinding of vortex pairs,[5] and its peculiar characteristics are that for $t<t_c$ the correlation function $\langle\mathbf{s}_i\cdot\mathbf{s}_j\rangle$ displays a power law decay, $\sim|\mathbf{i}-\mathbf{j}|^{-\eta(t)}$, whereas for $t>t_c$ its behavior is exponential. Moreover, the susceptibility and the correlation length have an exponential divergence for $t\to t_c^+$, although long-range order is also absent in the low-temperature phase, i.e., $\langle\mathbf{s}_i\rangle=0$ at any T.

In the case of the XXZ model the out-of-plane components s_i^z of the spins can fluctuate and give a $t_c(\lambda)$ lower than the value for the XY model. In the isotropic limit $\lambda\to1$ the transition disappears logarithmically,[1] $t_c\sim[-\ln(1-\lambda)]^{-1}$.

Kawabata and Bishop[6,7] performed pioneering Monte Carlo (MC) simulations of the classical XXZ model, and obtained estimates of the transition temperature confirming the theoretical asymptotic dependence of $t_c(\lambda)$. Their result in the $XX0$ limit is $t_c(\lambda=0)=0.78\pm0.03$.

As the first step to approach the quantum model by means of the effective Hamiltonian,[8] we have reconsidered the classical $XX0$ model producing accurate thermodynamic data and giving a quantitative description of the relevant quantities in the transition region. We present here MC results for the $XX0$ model, i.e., for $\lambda=0$. The MC sample consists of a square lattice of $L\times L$ classical spins, with periodic boundary conditions, and we considered lattices with $L=32$, 64, 128. The simulations were based on single spin moves, using a combination of the Metropolis and the overrelaxed algorithm.[4] The former consists in rotating a single spin at random, and accepting the resulting configuration after the Metropolis test; the maximum amplitude of the move is such that 45%–55% of the trial moves are accepted. The overrelaxed algorithm[4] is a reflection of the in-plane component of one single spin with respect to the in-plane component of the resultant of its nearest neighbors; this move leaves the energy unchanged and is always accepted. The advantage is in the reduction of the MC critical slowing down, in spite of the fact that this algorithm is local. One MC step is defined as N_O overrelaxed sequential sweeps through the two sublattices whose sites $\mathbf{i}\equiv(i_1,i_2)$ have even and odd i_1+i_2, plus N_M Metropolis random sweeps (i.e., L^2 randomly chosen spins are moved). For each run the system has been equilibrated for 1000 steps with $N_O=0$ and $N_M=2$, i.e., 2000 Metropolis steps have been employed in order to take the system in a typical equilibrium configuration before accumulating data. After a preliminary series of test runs we

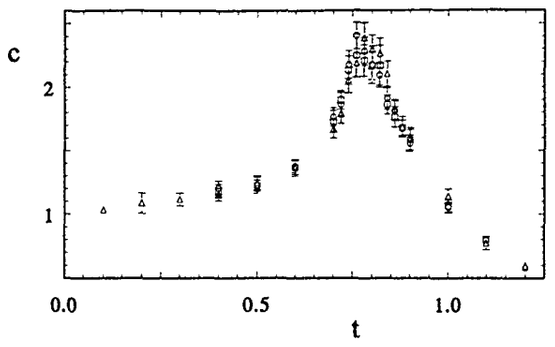

FIG. 1. Specific heat per site c vs reduced temperature $t=k_BT/\epsilon$. MC data for $L=32$ (triangles), 64 (squares), and 128 (circles).

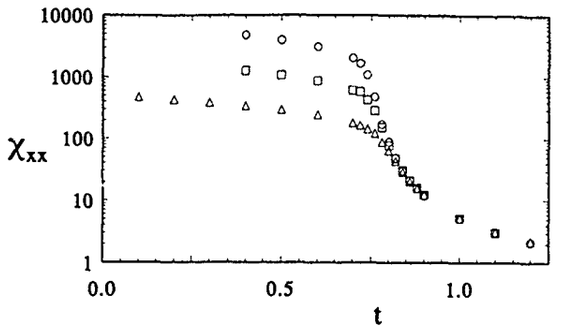

FIG. 2. The in-plane magnetic susceptibility χ_{xx} vs temperature. MC data for $L=32$ (triangles), 64 (squares), and 128 (circles).

observed that the initial configuration chosen (spins aligned along one axis, or random) does not affect the subsequently accumulated averages, within the statistical uncertainty, at all the temperatures we used. The averages were accumulated for 10 000 steps with $N_O=4$ and $N_M=2$. For each quantity with measured values Q_i at the ith MC step, the average is calculated as $Q=\langle Q_i\rangle$ and in order to account for MC correlation effects its variance σ_Q is multiplied by 2τ, where the *decorrelation* MC time τ is defined by the fit $\langle Q_{i+n}Q_i\rangle-\langle Q_i^2\rangle\sim e^{-n/\tau}$. For all quantities τ turns out to be less than 10 for $t>t_c$, and increases by one order of magnitude for $t\ll t_c$.

We have calculated the internal energy per spin $u=L^{-2}\langle\mathscr{H}\rangle$, the specific heat per spin

$$c=L^{-2}(k_BT)^{-2}\langle(\mathscr{H}-\langle\mathscr{H}\rangle)^2\rangle, \tag{3}$$

the magnetization $m^\mu=\langle s_i^\mu\rangle$ ($\mu=x,y,z$), the spin-row correlation function

$$C^{\mu\mu}(r)=\langle S_i^\mu S_{i+r}^\mu\rangle, \tag{4}$$

where $S_{i_2}^\mu\equiv\Sigma_{i_1}s_{i_1i_2}^\mu$, and the in-plane **k**-dependent susceptibility

$$\chi_k^{\mu\mu}=L^{-2}\left\langle\left|\sum_i s_i^\mu e^{ik\cdot i}\right|^2\right\rangle, \tag{5}$$

which for $k=0$ gives the magnetic susceptibility $\chi_{\mu\mu}$. The correlation length ξ_μ has been obtained in two ways: by means of an exponential fit of the spin-row correlation function (accounting for periodicity, the fitting function is $\cosh[(L/2-r)/\xi_\mu]$) and by an Ornstein–Zernicke fit of $\chi_k^{\mu\mu}\sim(k^2+\xi_\mu^{-2})^{-1}$, using the lowest six irreducible values of k. The two determinations coincide within the MC uncertainty.

The results for the specific heat $c(t)$ depend weakly on the lattice size L, as it appears from Fig. 1, and do not give rise to divergencies. The temperature dependence of the specific heat shows a peak around $t=0.78$, similar to the one observed in the planar model[3,4] at a temperature $t\simeq 1.15t_c$; then, if the similarity would be quantitatively correct, the BKT transition temperature of the $XX0$ model should be expected to be around $t_c\simeq 0.7$.

The finite-size saturation at low temperatures is apparent in the data we obtained for the in-plane susceptibility $\chi_{xx}(t)$, and the in-plane correlation length $\xi_x(t)$ (Figs. 2 and 3). Indeed, when ξ_x is comparable with L, L becomes the dominant length scale of the system, and the first consequence is that the measured ξ_x is linear in L, i.e., ξ_x/L is independent of L (see Fig. 3). At the same time, these figures show that the data at temperatures where $\xi_x(t)$ are smaller than $\sim L/3$ are unaffected by finite-size effects, and can be taken as reliable estimates of the infinite lattice values. For the 128 $\times$128 lattice this happens for temperatures larger than $\sim$0.75.

As for the direct estimate of the critical temperature, we have made use of BKT fits with the trial function

$$f(t;a,b,t_c)=ae^{b(t-t_c)^{-\nu}},\quad(\nu\equiv 1/2). \tag{6}$$

Also, the power-law fit, typical of second-order phase transitions,

$$g(t;a,\nu,t_c)=a(t-t_c)^\nu \tag{7}$$

has been considered for comparison. In Table I we report the results for t_c obtained from weighted fits to the data points for $t\geq 0.76$ and those for $t\geq 0.78$, respectively. The second case is reported in Fig. 4. The BKT form (6) appears to be superior, both because it displays a more favorable $\chi^2/_{\mathrm{DOF}}$ with respect to the power law, and because there is agree-

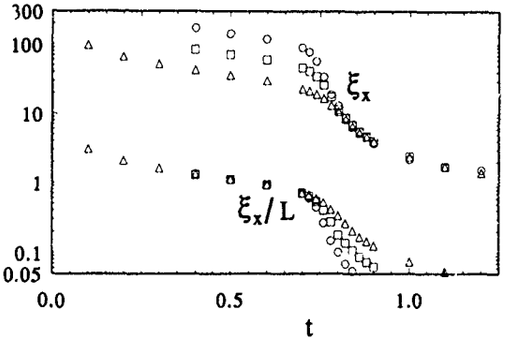

FIG. 3. The in-plane correlation length ξ_x vs temperature. The data points for ξ_x/L show the onset of finite-size scaling when $\xi_x\sim L$ MC data for $L=32$ (triangles), 64 (squares), and 128 (circles)

TABLE I. Results for the critical temperature t_c from weighted fits to the in-plane susceptibility $\chi_{xx}(t)$ and correlation length $\xi_x(t)$. MC data for the 128×128 lattice. Data sets for $t \geq 0.76$ and for $t \geq 0.78$, with power law and BKT fitting functions following Eqs. (7) and (6) in the text. $\chi^2/_{DOF}$ represents the sum of the squared deviations from the fit divided by the number of degrees of freedom (DOF).

Data	Fit	t_c	$\chi^2/_{DOF}$
χ_{xx}	power	0.742±0.003	3.86
$t \geq 0.76$	BKT	0.694±0.002	0 45
χ_{xx}	power	0.752±0.003	2.10
$t \geq 0.78$	BKT	0.697±0.003	0.43
ξ_x	power	0.721±0.004	3.10
$t \geq 0.76$	BKT	0.681±0.005	2.02
ξ_x	power	0.727±0.008	3.24
$t \geq 0.78$	BKT	0.679±0.011	2.29

ment among the values obtained for t_c, whereas those for the power law are not in agreement. At present, we are computing more accurate data for giving a final answer about the BKT character of the transition, and determining the critical exponent ν, that here is kept fixed to the BKT value $\nu=0.5$. The results for t_c obtained through $\chi_{xx}(t)$ are more accurate since $\chi_{xx}(t)$ is a direct product of the MC simulations. Therefore, at present there is good evidence that the classical $XX0$ model undergoes a BKT transition at $t_c=0.69\pm0.01$. This value turns out to be much lower than the one (0.78) estimated by Kawabata and Bishop.[7] In our opinion their

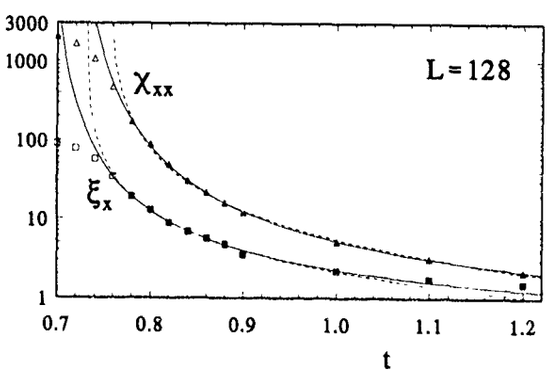

FIG. 4. MC data at $L=128$ for the magnetic susceptibility χ_{xx} and the correlation length ξ_x vs temperature. The solid and dashed curves report the best fits obtained using Eqs. (6) and (7), respectively (see also Table I), with the data at $t \geq 0.78$ (data with open symbols are excluded from the fit).

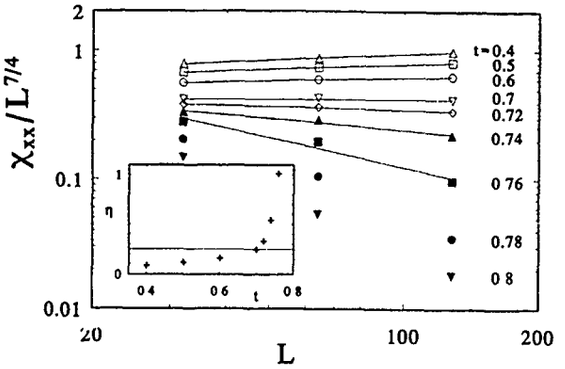

FIG. 5. MC data for $\chi_{xx}/L^{7/4}$ vs L, at different temperatures. Below t_c a linear behavior with positive slope $1/4-\eta(t)$ is displayed as expected for a BKT system. The inset shows the corresponding values of $\eta(t)$.

determination suffered from the poorer statistics ($N_O=0$, $N_M=1$, 6000 steps) and the smaller lattice size ($L=40$). In addition, they have extrapolated t_c by looking for the crossover where the correlation function ceases to be exponential. Since the crossover is strongly dominated by finite-size effects, they got an overestimated t_c.

For $t \leq t_c$ the susceptibility satisfies the finite-size scaling relation $\chi_{xx} \sim L^{2-\eta(t)}$, where the exponent $\eta(t)$ increases with t and should reach the BKT critical value $\eta(t_c)=1/4$. Therefore, in Fig. 5 we report a log–log plot of the dependence of $\chi_{xx}/L^{7/4}$ on L in such a way that the dependence at $t \leq t_c$ is linear with a slope that at the critical temperature decreases to $1/4-\eta(t_c)=0$. Even though at each t there are only three data points, it is possible to roughly estimate $\eta(t)$ by taking the linear fits shown in Fig. 5. As reported in the inset, $\eta(t)$ behaves in the expected way; the critical value, $\eta=0.25$, is indeed reached at about $t \simeq 0.7$, consistent with the above estimate of t_c.

The effective magnetic permeability of composite materials containing fine iron particles of 1–2 μm size is investigated theoretically and experimentally. This permeability is considered due to both the ferromagnetic properties of iron and the generation of eddy currents by an alternating magnetic field. An analytical result shows that as the percolation threshold is approached, the skin effect in large conducting clusters dominates, suppressing the ferromagnetic behavior for any value of frequency. As a result of this, the effective permeability tends to become zero near the percolation threshold, having a "v" form anomaly. The experimental data for frequencies of 6–10 GHz where the skin depth is of the order of a particle size, clearly exhibit a sharp decrease near the percolation threshold in the real part of the effective magnetic permeability. We believe this is the first observation of a possible magnetic anomaly in a percolating system.

I. INTRODUCTION

The study of composite materials has been the subject of considerable interest in recent years because of their possible technological applications. The mixture of metal and insulator particles with the concentration of metal particles p close to the percolation threshold p_c at which the system first exhibits a nonzero conductivity has a number of anomalies in electrophysical properties. For example, the dielectric constant and the inductance of percolating materials become infinite on approaching p_c.[1–3] In Refs. 4–6 it has been reported on a divergence in the limit $p \to p_c$ ($p < p_c$) for the imaginary part of the magnetic permeability associated with eddy currents induced in the system by an alternating magnetic field. These investigations have ignored the effects of the inductive interactions of currents, however, these effects are of predominant importance near p_c and allowance for them removes the divergence of the magnetic permeability[7] which tends to become zero at $p \to p_c$.

In the present paper, we investigate both theoretically and experimentally the effective magnetic permeability $\mu_{\text{eff}} = \mu'_{\text{eff}} + i\mu''_{\text{eff}}$ of a percolating system composed of fine iron particles. The eddy current contribution to μ_{eff} becomes dominant near p_c even if the skin effect in a single particle is weak. The reason for this is related to the appearance of large conducting clusters in the vicinity of the percolation threshold. The induced magnetic moments of those clusters substantially suppress the ferromagnetic properties, resulting in a sharp drop in μ_{eff} at $p \to p_c$. We observed this behavior in a mixture with iron inclusions of 1–2 μm size in the frequency region of 6–10 GHz.

II. EFFECTIVE MAGNETIC PERMEABILITY OF COMPOSITE MATERIAL

The proximity of a composite system to the percolation threshold is characterized by the value of the correlation length ξ which defines the typical magnitude of fluctuations. Near the percolation threshold ξ varies with concentration as $|(p_c - p)/p_c|^{-\nu}$, with $\nu = 0.88$,[8] tending towards infinity at $p \to p_c$. The composite material placed in an electromagnetic field can be described by the effective magnetic permeability, μ_{eff}, and the dielectric constant, ϵ_{eff}, if the wavelength of this field λ is smaller than the correlation length ξ. The most general analytical approach for calculating μ_{eff} and ϵ_{eff} is to use the effective medium approximation,[9–11] in which the influence of all the other particles on a selected one reduces to the replacement of the environment by some effective medium with μ_{eff} and ϵ_{eff}. The effective magnetic permeability μ_{eff} of an n-component percolating system can be found from the following equation[11]

$$\sum_{j}^{n} p_j \alpha_j(\mu_{\text{eff}}) = 0, \tag{1}$$

where p_j, $\alpha_j(\mu_{\text{eff}})$ are the concentration and the magnetic polarizability of the j-th component. For a magnetic particle of a spherical shape the polarizability is of the form

$$\alpha_m(\mu_{\text{eff}}) = 3(\mu_m - \mu_{\text{eff}})/4\pi(2\mu_{\text{eff}} + \mu_m) \tag{2}$$

$$\mu_m = \mu[2\, f(ka)]/[1 - f(ka)], \quad k = (1+i)/\delta$$

$$f(x) = 1/x^2 - \cot(x)/x, \quad \delta = c(2\pi\sigma\omega\mu)^{-1/2}, \tag{3}$$

where μ_m substitutes for the magnetic permeability μ in the case of a conducting particle if the skin effect is essential ($\delta < a$), a is the particle size and σ is its conductivity.

To extend Eq. (1) for the case of a cluster structure which exists near p_c, the averaged magnetic polarizability of clusters α_{cl} due to eddy currents has to be included in Eq. (1). Each cluster represents a set of doubly connected regions having a scale-invariant drop structure. It is assumed that, relative to the alternating magnetic field, a doubly connected cluster is equivalent to a contour of size identical to the characteristic size l of this cluster,[7] then the averaged polarizability can be written in the form

 0021-8979/94/76(10)/6365/3/$6.00 © 1994 American Institute of Physics

$$\langle \alpha_{cl} \rangle = \int_a^{\xi} \tilde{\alpha}_{cl}(l, \mu_{\text{eff}}) F(l) dl, \tag{4}$$

$$F = B_1 l^{-3} \begin{cases} 1/l, & p < p_c \\ 1/l + B_2 \delta(l-\xi), & p > p_c \end{cases}$$

where $F(l)$ is the size distribution of doubly connected clusters and $\tilde{\alpha}_{cl}$ is the total polarizability of doubly connected clusters. B_1 and B_2 are certain normalization constants independent of ξ. The additional term $\propto \delta(l-\xi) l^{-3}$ appearing in $F(l)$ above the percolation threshold is attributed to a regular conducting structure. By analogy to a contour placed in a medium with the magnetic permeability μ_{eff}, the parameter $\tilde{\alpha}_{cl}(l)$ can be written in the form

$$\tilde{\alpha}_{cl} = -A \mu_{\text{eff}} l^3 / Z, \quad Z = \mu_{\text{eff}} \ln l/a + Z_{cl};$$

$$Z_{cl} = \mu_m/4 + i(\delta_m/a)^2, \quad \delta_m \gg a,$$

where A is a correction factor independent of both μ_{eff} and l.

For a binary mixture with a nonmagnetic dielectric matrix, effective medium Eq. (1) which accounts for all kinds of polarizabilities (2) and (4) reduces to the form

$$\mu_{\text{eff}} = 1 + 3p\mu_{\text{eff}}(\mu_m - 1)/(2\mu_{\text{eff}} + \mu_m) - \mu_{\text{eff}} B_1 \int_a^{\xi} \frac{(l^{-1} + B_2 \theta(p) \delta(l-\zeta)) dl}{\mu_{\text{eff}} \ln (l/a) + Z_{cl}}, \tag{5}$$

where $\theta(p) = 0$ for $p \leqslant p_c$ and $\theta(p) = 1$ for $p > p_c$. Far from $p_c (\xi \to a)$ the last term can be neglected and Eq. (5) reduces to the standard form for noncontacting inclusions.[11] In the opposite limit of $p \to p_c (\xi \to \infty)$, Eq. (5) ensures the dominance of the induced magnetic moments of large clusters even in the case of a weak skin effect ($\delta \gg a$). It can be clear from the asymptote of μ_{eff} for $\xi/Z_{cl} \to \infty$

$$\mu_{\text{eff}}(\xi/Z_{cl} \to \infty) = [1 - \exp(1/B_1)] Z_{cl} / \ln(\xi/a). \tag{6}$$

It follows from Eq. (6) that at any fixed frequency the effective permeability tends to become zero on approach to the percolation threshold. This conclusion is valid for p approaching p_c from both $p < p_c$ and $p > p_c$. For $\mu' > 1$, near p_c a "ν"-form anomaly appears on the plot of $\mu'_{\text{eff}}(p)$, as can be seen in Fig. 1(a). The corresponding anomaly in the imaginary part μ''_{eff} arises in the immediate vicinity of p_c. For lower frequency this behavior is seen closer to p_c.

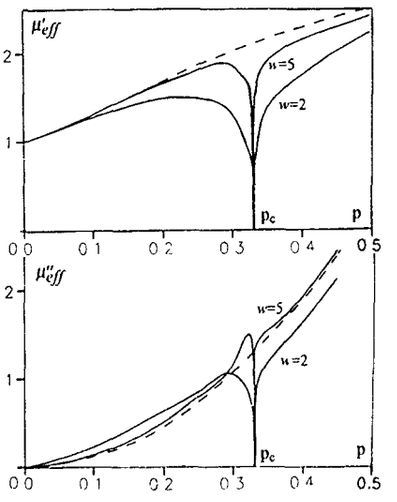

FIG. 1. Concentration dependencies of the effective magnetic permeability $\mu_{\text{eff}} = \mu'_{\text{eff}} + i\mu''_{\text{eff}}$ calculated from Eq. (5) for different values of $w = \delta/a$. The dashed lines correspond to the case of noncontacting inclusions [Eq (5) at $\xi \to a$] The other parameters were chosen as follows: $B_1 = B_2 = 1$, $\mu' = 4$, $\mu'' = 9$.

III. EXPERIMENT

As a ferromagnetic composite material we used a polymer matrix—butadiene-nitrile rubber—with fine iron particles of an elongated form with a maximal size of 1–2 μm and an axis ratio of 3/5. A composite material was formed by a tape casting method. Flexible composite film obtained with thickness of 0.1 mm were packed and rolled to have a required thickness and concentration.

The measurement technique was based on the method of a standing wave in a rectangular or a coaxial waveguide.[12] The experimental setup is shown in Fig. 2. The measurements were made for frequencies from 1 to 10 GHz (below 4 GHz a coaxial waveguide was used). A sample in the form of a slab or a ring disc of thickness $d = 0.5$–1 mm occupied the whole cross section of the waveguide. The magnetic permeability and the dielectric constant can be obtained from a pair of measurements of the complex reflection factor ζ for two different positions of the specimen in the waveguide, defined by the distances h_1 and h_2 from the shorting plate as seen in Fig. 2. The result for μ_{eff} and ϵ_{eff} can then be averaged over various pairs of h_1 and h_2. In the case of a composite material near p_c there is a question if the sample can be considered macroscopically homogeneous so that μ_{eff} and ϵ_{eff} can be applicable. As long as the effective parameters can be used, the values of μ_{eff} and ϵ_{eff} have to be independent of the chosen sample positions. The dependence of μ_{eff} and ϵ_{eff} on h_1 and h_2 would give an indication that samples are not homogeneous and the effective parameters cannot be used. Thus, the method of arbitrary sample positions allows us to test whether the composite material has μ_{eff} and ϵ_{eff} at a given frequency and concentration.

Solving a standard problem of electromagnetic wave propagation in a waveguide,[13] one can relate the parameters $\check{\mu}_{\text{eff}}$ and $\check{\epsilon}_{\text{eff}}$ to the reflection factor ζ, or the input impedance $Z_{\text{in}} = (1+\zeta) Z_0/(1-\zeta)$ through the following expressions

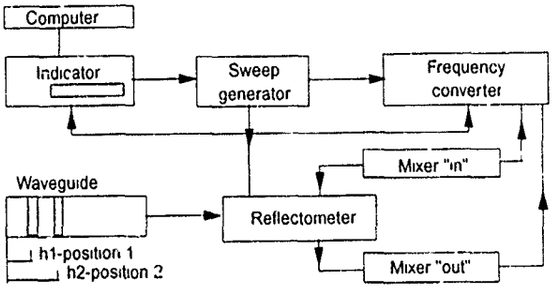

FIG. 2 Experimental scheme

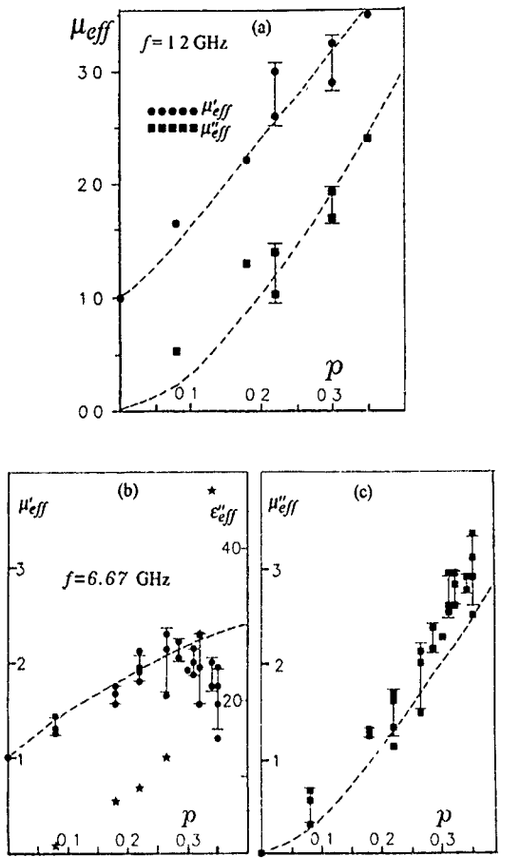

FIG. 3. Experimental concentration dependencies of the effective magnetic permeability for frequencies 1.2 GHz in (a) and 6.67 GHz in (b) and (c). In (b) the concentration dependence of the imaginary part of the dielectric constant is given to determine the percolation threshold. The dashed lines were obtained by using a simplex method to fit the effective medium equation for noncontacting particles, which is valid far from p_c. We used this equation in the form $\mu_{\text{eff}}=1+p\mu_{\text{eff}}(\mu_m-1)/[(1-n)\mu_{\text{eff}}+n\mu_m]$, where n is a correction factor for a particle shape (for $n=1/3$ it coincides with (5) far from p_c). The fitting parameters were $n=0.15$, $\mu'=8$, $\mu''=11$ for 1.2 GHz, $\mu'=4$, $\mu''=9$ for 6.67 GHz.

$$\mu_{\text{eff}}/\sqrt{\epsilon_{\text{eff}}\mu_{\text{eff}}-(\lambda_0/\lambda_c)^2}=Z_{\text{eff}}/Z_0,$$
$$\sqrt{\epsilon_{\text{eff}}\mu_{\text{eff}}-(\lambda_0/\lambda_c)^2}=k\lambda_0/2\pi;$$
$$-i(Z_{\text{eff}}/Z_0)\tan(kd)=(Z-Z_{\text{in}})/(ZZ_{\text{in}}-1);$$
$$Z=-iZ_0\tan[2\pi h\sqrt{1-(\lambda_0/\lambda_c)^2}/\lambda_0], \tag{7}$$

where Z_0 is the characteristic impedance of a waveguide, λ_c is the cutoff wave length. Equations (7) are valid for both rectangular and coaxial waveguides. By applying (7) to two sample positions: $h=h_1$ and $h=h_2$, both complex parameters $\check{\mu}_{\text{eff}}$ and $\check{\epsilon}_{\text{eff}}$ can be found.

IV. EXPERIMENTAL RESULTS AND DISCUSSION

Figure 3 shows the concentration dependencies of the complex magnetic permeability for different frequencies. The value of the percolation threshold $p_c=0.35$ corresponds to a sharp increase in the imaginary part of the effective dielectric constant. At a relatively low frequency (<2 GHz) the parameter $\mu_{\text{eff}}(p)$ increases with concentration up to the percolation limit. On the other hand, as the frequency is increased above 6 GHz, the real part of the magnetic permeability considerably decreases near p_c. The magnetic permeability of iron particles is estimated to be $\mu'=4$, $\mu''=9$ at a frequency of 6.7 GHz, then the effective permeability of a composite with noncontacting inclusions has to monotonically increase. Therefore, we can relate the drop in $\mu'_{\text{eff}}(p)$ to the formation of large percolation clusters.

According to our analysis (see Fig. 1), an anomaly in μ_{eff} at $p\to p_c$ appears at any frequency, however, it shifts closer to p_c at lower frequency. In the limit of ($\delta\gg a$) it exists just in the immediate vicinity of p_c and can hardly be found experimentally. This is probably the case with Fig. 3(a), since at a frequency of 1 GHz the skin depth δ in an iron particle is estimated to be about 2 μm and $\delta/a>3$ (where a is a minimal size of a particle), then the percolation effect is not seen in a sufficiently large concentration region, and the behavior of $\mu_{\text{eff}}(p)$ can be well described by a standard effective medium equation which follows from (5) at $\xi\to a$ (far from p_c), as shown in Fig. 3(a) in dashed lines. However, the sharp drop in $\mu'_{\text{eff}}(p)$ which is seen near p_c for frequencies above 6 GHz ($\delta/a\sim1$) is not consistent with the noncontacting particle equation. The values of $\mu''_{\text{eff}}(p)$ are also higher. Comparing such behavior with that shown in Fig. 1, we can conclude that at certain frequencies ($\delta/a<1$) the effective magnetic permeability of a composite material near p_c can be greatly affected by the magnetic moments induced by eddy currents in large conducting clusters. This effect can strongly suppress the ferromagnetic properties of a composite, resulting in an anomaly in $\mu_{\text{eff}}(p)$ on approaching the percolation threshold.

In this paper the time variation of the thermoremanent magnetization (TRM) is examined. From a simple theory based on the relaxation of magnetic moments over the associated energy barrier we explain the various forms for the time variation of thermoremanent magnetization. For a narrow distribution of energy barriers the variation of TRM with $\ln(t)$ is predicted to be concave downwards when the relaxation takes place over barriers less than the average barrier. For barriers greater than the average barrier the variation of TRM vs $\ln(t)$ is predicted to be concave upwards. In the region where the relaxation takes place over barriers close to the average barrier the variation is initially concave downward and then concave upward.

I. INTRODUCTION

Thermoremanent magnetization is usually measured in the following way: the system is cooled in the presence of a dc magnetic field from a temperature where all moments can fluctuate rapidly between energy minima to a temperature where some of these fluctuations become slower and take place over the measured time scale. Finally the magnetic field is switched off and the remanence obtained is called the TRM.

Time dependence of magnetization is a well-known phenomenon and arises due to the fact that there is a finite time for transitions over the energy barrier. According to this phenomenology the time dependence of the remanent magnetization is given by Néel[1]

$$M_r(t)=M_r(0)e^{-t/\tau}, \tag{1}$$

where τ is the relaxation time and in zero field τ^{-1} is given by

$$\tau^{-1}=f_0 e^{-\Delta E/kT}, \tag{2}$$

where ΔE is the height of the barrier for reversal. For the case where ΔE is distributed and the distribution function of the barriers over which fluctuations are taking place remains approximately constant during the time of observation, following Street *et al.*,[2] the formalism of Eqs. (1) and (2) gives

$$M_r(t)\propto \ln(t). \tag{3}$$

The time variation of TRM is often measured and used as one of the characteristics of the disordered system since this variation is usually observed not to follow a $\ln(t)$ law. Hence the time variation of TRM in spin glass and other disordered systems is often analyzed using empirical expressions like the stretched exponential function, $M_r(t)=M_r(0)\exp(-t/\tau_p)^{1-n}$,[3-5] where τ_p is the characteristic relaxation time and n is the time-stretched exponent. In other studies the time variation of TRM has been described in terms of a power law $M_r(t)\propto t^{-a}$,[6] and on other occasions a product of power law and stretched exponential functions was used.[7]

Recently, further attempts have been made in order to explain the nonlinear $\ln(t)$ behavior of $M_r(t)$ in a reentrant ferromagnet.[8] In Ref. 8 the $M_r(t)$ data were analyzed in terms of a percolation model of relaxation which was proposed earlier by Chamberlin *et al.*[9] In this new model similar expressions to that of Eqs. (1) and (2) were used and in addition a distribution of cluster sizes was introduced

$$M_r(t)=M_r(0)\int_0^\infty x^{10/9}\exp(-x^{2/3})e^{-t/\tau_p}dx, \tag{4}$$

where $\tau_p=f_\pm e^{\pm C/x}$ is the relaxation time, the $(-)$ and $(+)$ signs are associated with slow and fast relaxations, respectively, and $C=C'\Delta/kT$ where C' is an adjustable parameter. The new formalism of Eq. (4) contains the physics of the problem unlike the empirical powers n and a as used in previous models. However, in Eq. (4) the distribution function and energy barrier have been calculated using an assumed model. The analysis of the $M_r(t)$ data according to Eq. (4) suggested that the change of the curvature in $M_r(t)$ vs $\ln(t)$ curves as the temperature increases is due to different relaxation regimes, i.e., slow and fast. Due to the treatment of the $M_r(t)$ problem via Eq. (4), the origin of the curvature in the $M_r(t)$ and its variation with temperature was used to infer different types of dynamic behavior.

In this paper we show that the experimentally observed behavior can be reproduced using a simple model in which the energy barrier and its distribution are independent of temperature.

II. THEORY

For a system with a distribution of energy barriers $f(\Delta E)$ Eq. (1) becomes

$$M_r(T,t)=M_r(H,T,t_w)\int_0^\infty e^{-t/\tau(\Delta E)}f(\Delta E)d\Delta E, \tag{5}$$

where ΔE can have various origins like cluster sizes, anisotropy, and orientation effects. $M_r(H,T,t_w)$ is the initial remanent magnetization, a quantity which at a given cooling field and temperature, depends on the aging time t_w, i.e., the waiting time that elapses after the system has reached the required measuring temperature while the field is still on. Also in Eq. (5) we assume that the field is switched to zero in an extremely short time, otherwise the time dependence during switching should be taken into account.[10,11]

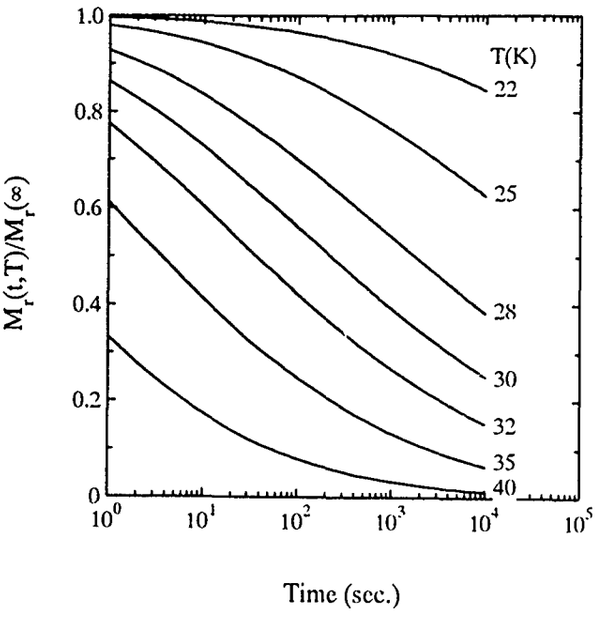

FIG. 1. The time dependence of thermoremanent magnetization at different temperatures for a system with a narrow distribution of energy barriers.

Equation (5) can be rewritten in terms of a distribution of reduced energy barriers $f(y)$ where $y=\Delta E/\Delta E_m$, then

$$M_r(T,t)=M_r(H,T,t_w)\int_0^\infty e^{-t/\tau(y)}f(y)dy, \tag{6}$$

where $\tau^{-1}(y) = f_0 e^{-a_m(T)y}$, $a_m(T)=\Delta E_m/kT$, and ΔE_m is the average barrier in the system. Assuming a distribution function of energy barriers with a certain value of ΔE_m and standard deviation σ, an exact numerical calculation for Eq. (6) can be made and the data of $M_r(T,t)$ at different temperatures can be fitted using only two parameters ΔE_m and σ. For a system with a narrow distribution of energy barriers, the calculated $M_r(T,t)/M_r(\infty)$ curves at different temperatures are shown in Fig. 1 where $M_r(\infty)\equiv M_r(H_{sat})$ which is the TRM obtained in a saturating cooling field. In these calculations a log-normal distribution function of reduced energy barriers were used, $f(y) = \exp\{ - [\ln(y)]^2/2\sigma^2\}/\sqrt{2\pi}\sigma y$ with $\Delta E_m=1.2\times10^{-13}$ erg, and $\sigma=0.18$. The form of $f(y)$ can be easily determined by measuring the temperature variation of the maximum TRM, i.e., cooling in a saturating field, then $f(y)\propto dM_r(H_{sat})/dT$.[12] Thus the form of the distribution is not an adjustable parameter and can be determined by experiment. The data shown in Fig. 1 exhibit similar behavior as those always observed for disordered systems.[4,5,8] Thus, from first-principles Eq. (6) can describe the shape of $M_r(T,t)$ vs $\ln(t)$ curves at all temperatures without the need to imply a phase transition or using different forms of the relaxation rate at different temperatures. In order to describe the origin of the curvature in the $M_r(t)$ vs $\ln(t)$ curves Eq. (6) can be simplified and an analytical expression can be derived following our previous work.[13,14]

The function $e^{-t/\tau(y)}$ varies strongly with y about the critical energy barrier y_c which can be defined when $t=\tau(y_c)$. Hence, for $y<y_c$ the fluctuations between minima happen very quickly and the system exhibits no remanence, while for $y>y_c$ the moments show remanence and time-dependent behavior. Using this criterion Eq. (6) can be simplified to

$$M_r(T,t)=M_r(H,T,t_w)-M_r(H,T,t_w)\int_0^{y_c}f(y)dy, \tag{7}$$

where y_c is given by

$$y_c=\frac{kT}{\Delta E_m}\ln(tf_0). \tag{8}$$

Equation (7) is a good approximation to Eq. (6) and gives the same behavior for $M_r(t)$ vs $\ln(t)$ curves as those shown in Fig. 1. In addition, an analytical solution for Eq. (7) can be obtained by expanding $f(\Delta E)$ about y_c due to the fact that time-dependence effects are mainly due to fluctuations over barriers close to y_c.[14] Then, Eq. (7) can be rewritten as

$$M_r(t,T)=M_r(t_0,T)-M(H,T,t_w)\int_{y_c(t_0)}^{y_c(t_0)+\delta y_c}f(y)dy, \tag{9}$$

where $\delta y_c=y_c(t)-y_c(t_0)=\ln(t/t_0)/a_m(T)$ and t_0 is the initial time of measurement. $M_r(t_0,T)$ is the initial TRM at $t=t_0$ and it is given by: $M_r(t_0,T) = M_r(H,T,t_w) - M_r(H,T,t_w)\int_0^{y_c(t_0)}f(y)dy$. Now by expanding $f(y)$ about $y_c(t_0)$ the change in the remanent magnetization with time is given by

$$\Delta\tilde{M}_r(t,T)=-\sum_{n=0} f^n[y_c(t_0)][\Delta\ln(t)/a_m(T)]^{n+1}, \tag{10}$$

where $\Delta\tilde{M}_r=\tilde{M}_r(t)-\tilde{M}_r(t_0)$ is the change in remanence normalized to $M_r(H,T,t_w)$, $f^n=d^nf(y)/dy^n$, and $\Delta\ln(t)=\Delta\ln(t/t_0)$. For constant $f(y)$, Eq. (10) gives a logarithmic time dependence of $\Delta M_r(t)$ which is consistent with Eq. (3). However, in general, $f(y)$ is not a constant function and higher orders of $\Delta\ln(t)$ should be considered when $f(y)$ varies with y around the critical barrier. The higher order terms in the series expansion are found to become increasingly important as the distribution becomes narrower.[14] Thus, in general, the $\Delta M_r(t)$ vs $\Delta\ln(t)$ curve can be represented by a series expansion in $\Delta\ln(t)$ and the number of terms required to describe the data depends on the behavior of the function $f(y)$ about y_c. In order to show explicitly the origin of the curvature changes in $\Delta M_r(t)$ vs $\Delta\ln(t)$ curves, at any instant t, the slope of this variation is given by

$$\frac{d\tilde{M}_r(t,T)}{d\ln(t)}=-\frac{kT}{\Delta E_m}f(y_c). \tag{11}$$

Thus, according to Eq. (11) the slope of $\Delta\tilde{M}_r(t)$ vs $\Delta\ln(t)$ at any instant is directly proportional to $f(y_c)$. Thus, at very low temperatures where fluctuations are due to the small energy barriers $\Delta E<\Delta E_m$, i.e., y_c is at the left-hand side of the distribution, thus in this region $f(y)$ is increasing with y and the slope is increasing which causes the variation of $\Delta\tilde{M}_r(t)$ vs $\Delta\ln(t)$ to be concave downward. Since $y_c\propto T$, at higher temperatures the fluctuations of moments will taking place over barriers $\Delta E>\Delta E_m$, where $f(y)$ is decreasing with y

and accordingly the slope $\Delta \tilde{M}_r(t)/\Delta \ln(t)$ at any instant will be decreasing with y_c and cause the variation to curve upward. Thus, in the case where fluctuations are taking place over barriers around ΔE_{m_2}, i.e., about the peak in the distribution, the variation of $\Delta \tilde{M}_r(t)$ vs $\Delta \ln(t)$ will initially curve downwards and finally curve upwards and in the intermediate range it will exhibit some degree of linearity due to those fluctuations associated with the most probable energy barrier within the system, i.e., at the peak where $f(y_c)$ remains constant.

Thus from this simple theory the shape of the $\Delta M_r(t)$ vs $\Delta \ln(t)$ curve and the degree of nonlinearity is directly related to the distribution of energy barriers within the system and not necessarily to the type of the relaxation regime. The relaxation mechanism at all temperatures is governed by the same dynamic equation [Eq. (2)]; however the contribution of these fluctuations to the remanence is determined by the distribution of energy barriers.

A. The effects of aging on TRM

In the work of Li *et al.*[8] effects of aging were measured and showed that the initial value of TRM $[M_r(t_w)]$ depends on the waiting time t_w at the required measuring temperature while the cooling field (H) is still applied. The effects of t_w can also be derived from first principles using the rate equation which can be solved to give[11]

$$M_r(H,T,t_w) = [M_r(H,T,0) - M_e] \int_0^\infty e^{-t/\tau(y,H)} f(y)\,dy + M_e, \qquad (12)$$

where $M_e = [\tau_-^{-1}(H) - \tau_+^{-1}(H)]/[\tau_-^{-1}(H) + \tau_+^{-1}(H)]$ is the equilibrium magnetization and τ_-^{-1} and τ_+^{-1} are the relaxation rates into the field direction and out of the field direction, respectively. Thus the value of $M_r(t_w)$ obtained before switching the field depends on the arrangement of moment axes with respect to the cooling field. Hence the aging observations in Ref. 8 suggest that t_w must depends on the detailed distribution of spins and is currently the subject of further work.

B. Previous treatment of the problem

The time dependence of remanent magnetization in spin glasses has been discussed by Aharoni.[15] Similar formalism to that of Eq. (5) was considered, but a distribution of relaxation times rather than a distribution of energy barriers was used. In addition a gamma distribution function of $f(\tau)$ was assumed in order to obtain an analytical solution for Eq. (5). In this formalism, the data for $M_r(t)$ at a given temperature can be fitted using two parameters, the mean and width of the gamma distribution of relaxation. Hence, according to the formalism of Aharoni the analysis of the $M_r(t,T)$ curves gives an average relaxation time and width for every temperature whereas our formalism in terms of the energy barrier distribution gives an average energy barrier (ΔE_m) and width (σ) for the whole system. In addition, the form of $f(\Delta E)$ can be determined directly from experiment and is not assumed. Furthermore, by linking the problem to the energy barrier distribution, the origin and shape of the curvature in the $\Delta M_r(t)$ vs $\Delta \ln(t)$ can be explained.

III. CONCLUSIONS

In this paper, a simple first principle theory for the time dependence of TRM in disordered magnetic systems is described. The theory shows that the origin and shape of the curvature in the $M_r(t)$ vs $\ln(t)$ data at different temperatures are mainly due to the form of the distribution of energy barriers. For a system with a narrow distribution of energy barriers a similar variation of $M_r(t,T)$ to those observed in a disordered system can be predicted without the need to assume different relaxation regimes at different temperatures.

Magnetization of amorphous $Fe_{0.82}B_{0.18}$ and $Fe_{0.90}Zr_{0.10}$ compounds with additions of Tb

S. J. Clegg, J. H. Purdy, R. D. Greenough, and F. Jerems
Department of Applied Physics, The University of Hull, Hull HU6 7RX, United Kingdom

The addition of Tb to melt spun iron-boron or iron-zirconium compounds raises the magnetostriction to practically useful levels (≥450 ppm) at room temperature. The present work examines the corresponding compositional and temperature dependencies of the magnetization in $Tb_x(Fe_{0.82}B_{0.18})_{1-x}$ for $0 \leq x \leq 0.5$ and $Tb_y(Fe_{0.90}Zr_{0.10})_{1-y}$ for $0 \leq y \leq 0.1$. Increasing the Tb content in Fe-B compounds decreases the room-temperature magnetization towards a compensation point and lowers the Curie temperature T_c. In Fe-Zr compounds, Tb increases the room-temperature magnetization and raises T_c. Magnetic phase diagrams are presented for each group of compounds and exchange frustration effects identified by comparing the observed temperature dependencies of the reduced magnetization with predictions from the Handrich mean field model. Only 3 at. % Tb in Fe-Zr is sufficient to annul exchange fluctuations, but in Fe-B compounds exchange frustration persists throughout the compositional range.

I. INTRODUCTION

Magnetostriction in amorphous compounds is of theoretical interest to understand how macroscopic anisotropic strains are developed from randomly oriented moments and of practical importance as an alternative to crystalline highly magnetostrictive pseudobinary rare-earth (RE)-iron compounds for applications.[1,2] Amorphous compounds with RE =Sm, Dy, or Tb prepared by melt spinning[3] or sputtering[4] develop useful levels of magnetostriction (~500 ppm). Iron-boron and iron-zirconium amorphous compounds can be melt spun with relative ease and hence the present choice of two groups of compounds, $RE_x(Fe_{0.82}B_{0.18})_{1-x}$ with $0 \leq x \leq 0.50$ and $RE_y(Fe_{0.90}Zr_{0.10})_{1-y}$ with $0 \leq y \leq 0.10$; terbium is selected for the RE ion because of its outstanding magnetostrictive properties. However, as terbium is added to each of the chosen groups of compounds, changes in their room-temperature magnetostrictions are markedly different.[5] Hence, the present study of magnetic properties was undertaken in order to obtain a better understanding of their behavior to assist in theoretical calculations of magnetoelastic coupling and, in the longer term, enhance the room-temperature magnetomechanical properties for practical applications.

II. EXPERIMENTAL TECHNIQUES

Polycrystalline compounds in the ranges $Tb_x(Fe_{0.82}B_{0.18})_{1-x}$ for $0 \leq x \leq 0.5$ and $Tb_y(Fe_{0.90}Zr_{0.10})_{1-y}$ for $0 \leq y \leq 0.1$ were produced using start material of at least $3N$ purity. Melt spinning was conducted in an argon atmosphere, producing samples 30–50-μm thick, 1–2-mm wide and of varying lengths. X-ray diffraction (XRD) has been employed to ensure that all samples were amorphous. Using CuK_α radiation, angles corresponding to the position of the intensity maxima have been used to estimate the average interatomic spacings. A vibrating sample magnetometer (VSM) was employed to measure magnetization from ~4 K to the Curie temperatures with dc fields up to 1000 kA m^{-1}. Curie temperatures were obtained from differential scanning calorimetry (DSC) for Tb-Fe-B alloys and from magnetization measurements for Tb-Fe-Zr alloys.

The random anisotropy (RA)–ferromagnetic (F) phase boundaries were detected with ac susceptibility measurements for the iron-boron compounds[6] and in the iron-zirconium compounds by comparing field annealed and zero field annealed temperature dependent magnetization data.[7]

III. RESULTS

RE-Fe-B: Room temperature data for the variation of saturation magnetization with Tb content (Fig. 1), are in agreement with previous measurements[5] which showed that the materials are magnetically soft. A compensation point at $x=0.22$ is due to antiferromagnetic (AF) coupling between the iron and terbium subnetworks. The magnetization at 1000 kA m^{-1} has been measured as a function of temperature from 4.2 K to T_c, for each Tb composition. Competing effects of local anisotropy and exchange interactions are evident, viz: at high temperatures ($T < T_c$) the system appears to

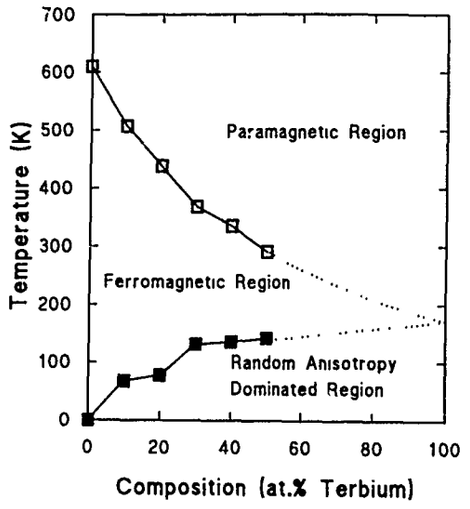

FIG. 2. Magnetic phase diagram for Tb-Fe-B showing T_c(□) and T_f (■).

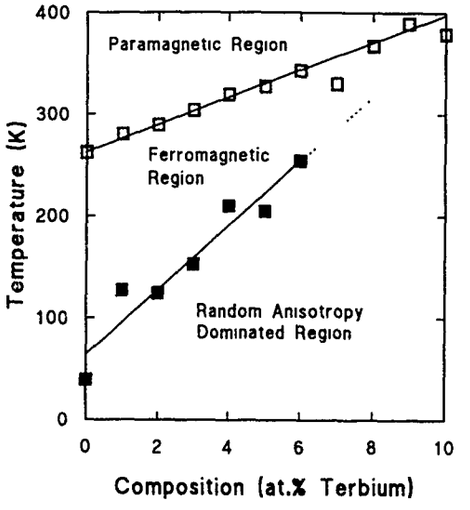

FIG. 4. Magnetic phase diagram for Tb-Fe-Zr showing T_c (□) and T_f (■).

be magnetically ordered, but with sufficiently high Tb content at low temperatures, random local anisotropy begins to dominate, which causes a "freezing" of the magnetic moments. The fields employed are then insufficient to align all the moments leading to an apparent decrease in magnetization at low temperatures below the "spin freezing" temperature T_f. These features of magnetic behavior are summarized in a magnetic phase diagram (Fig. 2).

RE-Fe-Zr: The variation of saturation magnetization with terbium content at room temperature (Fig. 3) demonstrates a different behavior to the RE-Fe-B system. The magnetization is seen to increase with the addition of Tb up to 9 at. %, before dropping sharply as further Tb is added. From magnetization measurements as a function of temperature,[7] a magnetic phase diagram has been constructed (Fig. 4). The addition of terbium again has the effect of "freezing" the magnetic moments at low temperatures although values for T_f are much higher than for the Tb-Fe-B system. A little extrapolation of the RA-F phase boundary indicates that at room temperature (~295 K) each of the three magnetic phases can be obtained in the range 2–8 at. % Tb.

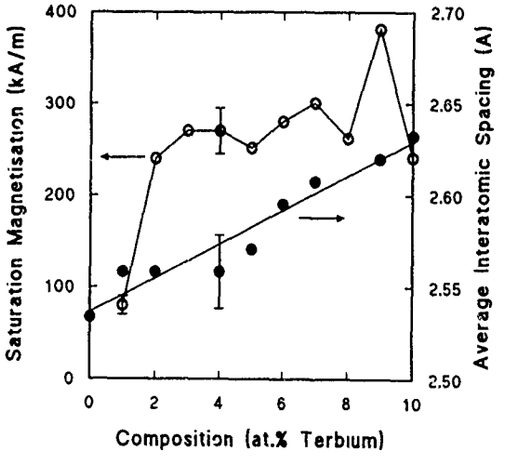

FIG. 3. Saturation magnetization (○) and average interatomic spacing (●) as a function of Tb content in $Tb_x(Fe_{0.90}Zr_{0.10})_{1-x}$.

IV. DISCUSSION AND CONCLUSIONS

In both the magnetic phase diagrams (Figs. 2 and 4) a region has been labeled "ferromagnetic" based on the observed magnetization versus applied field curves. However, previous work on similar metallic glasses without rare earths, by Buchholtz *et al.*,[5] (Metglas 2605 S2), Cowley *et al.*[9] ($Fe_{83}B_{17}$) and Thomas *et al.*[10] (VAC 0040), indicates that in the absence of any well-defined anisotropy, exchange fluctuations disturb the collinear structure. Present data for the reduced magnetization as a function of temperature have therefore been compared with Handrich's mean field model[11] in which the reduced magnetization is expressed as

$$\sigma = \tfrac{1}{2}[B_s(x)(1+\Delta)+B_s(x)(1-\Delta)] \qquad (1)$$

where $B_s(x)=\tanh(x)$, $x=(3S/S+1)(\sigma/\tau)$, S is the spin quantum number, τ is the ratio T/T_c, and Δ is the level of exchange fluctuation. Even with the limitations of a mean field model, it is presently observed that in *iron-boron* compounds (Fig. 5), for either 10 or 50 at. % Tb, $\Delta=0.5$, indicating exchange fluctuations persist regardless of the amount of Tb, consistent with the previous observation of noncollinear moments in metallic Fe-B glasses. For $Fe_{0.90}Zr_{0.10}$ (Fig. 6) the best fit to the experimental reduced magnetization data is achieved with $\Delta=0.6$, but with the addition of Tb, Δ quickly decreases to zero, implying that frustration effects are lifted with only 3 at. % Tb.

The lowering of the room-temperature magnetization and T_c with the addition of Tb to Fe-B can be explained by the antiferromagnetic coupling of terbium-iron moments which lowers the overall exchange. Reduction in the exchange frustration in Fe-Zr accounts for the increase in both the room-temperature magnetization and T_c.

With the addition of only 3 at. % Tb to Fe-Zr, the total lifting of frustration effects cannot be attributed directly to

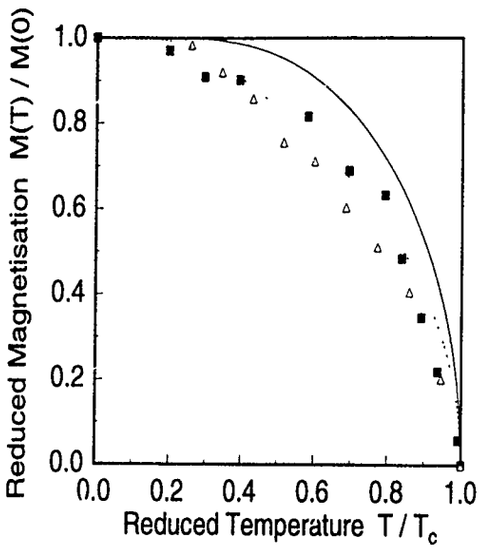

FIG. 5. Reduced magnetization as a function of reduced temperature for $Tb_x(Fe_{0.82}B_{0.18})_{1-x}$ where $x=10\%$ (■) and $x=50\%$ (△) with theoretical predictions from the Handrich model for $\Delta=0.5$ (·····) and $\Delta=0$ (——).

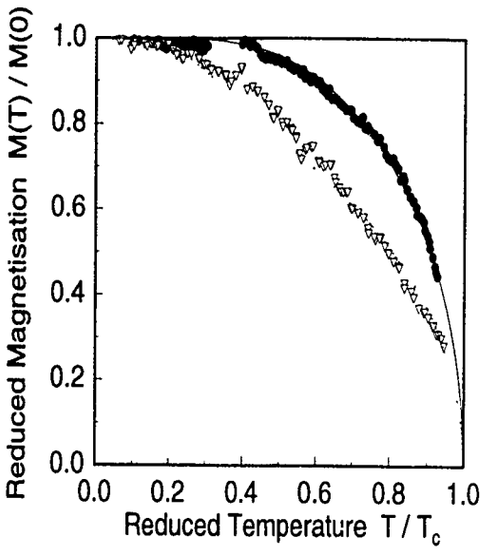

FIG. 6. Reduced magnetization as a function of reduced temperature for $Tb_y(Fe_{0.90}Zr_{0.10})_{1-y}$ where $y=0$ at. % (▽) with Handrich fit for $\Delta=0.6$ (.....) and $y=3$ at. % (●) with Handrich fit for $\Delta=0$ (——)

Fe-Tb bond effects and in the light of previous work by Ryan,[12] changes in mean interatomic separation is likely to be a significant factor. According to Ryan, exchange in the Fe-Zr system is very sensitive to nearest-neighbor distances and changes the sign from positive to negative below 2.4 Å. From the present data (Fig. 3) the mean interatomic spacing for $Fe_{0.90}Zr_{0.10}$ is ~2.5 Å, so that a small but significant number of Fe-Fe pairs will be antiferromagnetically coupled. With the addition of 3 at. % Tb, the mean interatomic spacing increases slightly but is sufficient for the majority of Fe-Fe pairs to be coupled ferromagnetically.

Finally, there are the, as yet, unexplained increases in the room-temperature magnetostriction as Tb is added to either the Fe-B or Fe-Zr compounds. Present observations show that these increases are not simply due to increases in T_c. What is common to both groups of compounds is the change in average interatomic spacing which increases by ~7% for the addition of ~10 at. % Tb. While this alone cannot explain the observed magnetostrictive effects, it is significant when the local field gradients at the Tb ion sites are considered. Work is in progress to quantify their effects on the magnetostriction.

Magnetic ordering in the three-dimensional site frustrated Heisenberg model

Morten Nielsen, D. H. Ryan, Hong Guo, and Martin Zuckermann
Centre for the Physics of Materials, Department of Physics, McGill University, 3600 University Street, Montreal, Quebec H3A 2T8, Canada

We study transverse spin freezing in the site frustrated three-dimensional classical Heisenberg model using Monte Carlo simulations. For small values of the site randomness, there is no transverse spin freezing in the ferromagnetic state. As the fraction of the antiferromagnetic sites is increased beyond 16%, we observed that the transverse component of the spins freeze in random directions at temperatures below some value T_{xy}. Similar behavior is observed in the antiferromagnetic state. We compare results of this model to those of the bond frustrated model. Finally an approximate phase diagram of this model is presented.

I. INTRODUCTION

Recent experimental studies[1-3] of partially frustrated magnetic systems have demonstrated the existence of a transverse spin freezing phenomenon below the ferromagnetic transition. Such a freezing is characterized by the sudden increase of the local spin length, as measured by Mössbauer spectroscopy, when the temperature is lowered below some value T_{xy}. This behavior is found for a range of frustrations in systems such as a-Fe_xZr_{1-x} and $Au_{1-x}Fe_x$.[1] In a recent paper,[4] we examined theoretically the spin freezing phenomenon and the critical behavior of a bond frustrated three-dimensional Heisenberg model. Our Monte Carlo calculations gave results in qualitative agreement with the experimental findings. In particular, we found that at a low temperature T_{xy} below the Curie temperature T_c, the transverse spin component freezes out, leading to an increase in the total spin length.[4]

The bond-frustrated model seems to describe the transverse spin freezing in systems such as a-Fe_xZr_{1-x}, where there is only one magnetic compound, and the magnetic interaction are determined from nearest-neighbor distances. However, there are other magnetic systems for which this model is not appropriate. An example is $Eu_{1-x}Gd_xS$ in which the spin glass phase is induced by site frustration.[5] Theoretically, site randomness can be introduced by replacing a fraction f of ferromagnetic sites by antiferromagnetic sites. If f is small then no frustration is expected. However, at larger values of f when the antiferromagnetic sites start to form a percolating network, the randomness will lead to frustration and change the magnetic behavior of the system. Thus, we expect that site frustration will give rise to a somewhat different phase diagram compared with the bond frustration model, especially for transverse spin freezing which crucially depends on the degree of frustration. It is the purpose of this work to investigate the behavior of the site frustrated Heisenberg model using Monte Carlo simulations.

II. MODEL

We consider a system of classical Heisenberg spins $\mathbf{S}_i$ on a simple cubic lattice in zero magnetic field. The Hamiltonian is given by $H=-\Sigma_{n\,n} J_{ij}\mathbf{S}_i\mathbf{S}_j$. Here, J_{ij} is the exchange interaction between nearest-neighbor spins on lattice sites i and j, respectively. We introduce site randomness into the system by replacing a fraction f of ferromagnetic sites by antiferromagnetic sites. The values for the Curie temperature of the ferromagnetic Heisenberg model ($f=0$) and the Néel temperature of the antiferromagnetic Heisenberg model ($f=1$) are identical, $T_H=1.44J$.

The model with site frustration was investigated using the standard Metropolis Monte Carlo method. A three-dimensional system of 8^3 spins on a simple cubic lattice was initiated with high-temperature configurations.[6] The system was then annealed via 25 temperature intervals to a low temperature of $0.0005T_H$. At each temperature, statistical averages of relevant physical quantities were taken. A calculation of the relaxation time for temperatures away from T_H revealed that about 2000 Monte Carlo steps per spin (MCSs) were needed to reach equilibrium at such temperatures, and a larger number of MCSs were needed close to T_H where critical slowing down becomes important. After the system reached equilibrium, statistical averages of physical quantities were collected over 4000 MCSs. We found that fluctuations in the energy were indeed Gaussian distributed for 4000 MCSs thus our choice of the number of steps was reasonable. Finally, results for ten different realizations of the site randomness for a given f were averaged. The values of f used in the simulations ranged from 0 to 1 and we were thus able to calculate the entire magnetic phase diagram for the system.

We compute a time average of the spin components and of the square of the transverse spin components at each site, i.e.,

$$\mathbf{m}_i=\frac{1}{\tau}\sum_{\tau'=1}^{\tau}\mathbf{S}_i(\tau')$$

and

$$m_{\perp i}^2=\frac{1}{\tau}\sum_{\tau'=1}^{\tau}[S_{ix}(\tau')^2+S_{iy}(\tau')^2]$$

where, as mentioned above, $\tau=4000$ MC steps. From these local quantities we calculate the following spatially averaged quantities: (1) the root-mean-square spin length $S_{\rm rms}=1/N\Sigma_{i=1}^{N}(\mathbf{m}_i\cdot\mathbf{m}_i)^{1/2}$, (2) the bulk magnetization $M_f=1/N|\Sigma_{i=1}^{N}\mathbf{m}_i|$, (3) the staggered magnetization

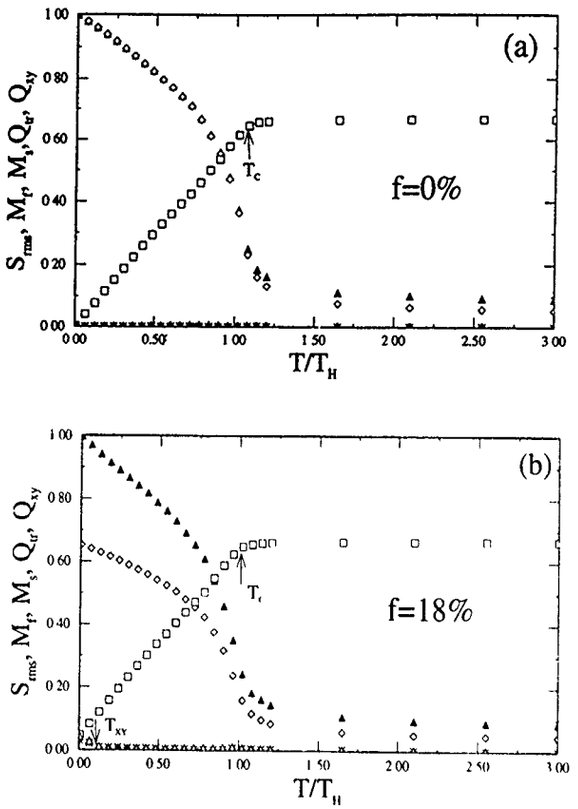

FIG. 1. Temperature dependence of the different spin averages. (▲) $S_{\rm rms}$, (◇) M_f, (*) M_s, (□) $Q_\perp$, and (△) Q_{xy} T_c is the temperature where $Q_\perp$ starts to decrease from 2/3. (a) $f=0$; (b) $f=18\%$. T_{xy} in (b) is the temperature where Q_{xy} becomes nonzero.

$M_s=1/N|\Sigma_{i=1}^{N}\mathcal{S}\mathbf{m}_i|$, where $\mathcal{S}$ is a matrix with the symmetry of the antiferromagnetic structure of the lattice, (4) the mean square of the spin projection on the x-y plane $Q_\perp=1/N\Sigma_{i=1}^{N}m_{\perp i}^2$; (5) the x-y projection of the time-averaged spin components $Q_{xy}=1/N\Sigma_{i=1}^{N}(m_{ix}^2+m_{iy}^2)$. The last two quantities take into account ordering in the x-y plane and may therefore exhibit the onset of anisotropy and spin freezing in the system.

III. RESULTS

Figures 1(a) and 1(b) show data for quantities M_f, $S_{\rm rms}$, M_s, $Q_\perp$, and Q_{xy} as functions of temperature, for several values of site frustration f. In Fig. 1(a) the pure ferromagnetic case ($f=0$) is shown. This shows, as expected, that the order parameter M_f and the local spin length $S_{\rm rms}$ are identical below the critical temperature T_c (which is equal to T_H in this case), as the system orders to a collinear configuration. Above T_c, $Q_\perp$ takes the value 2/3 since the spins are randomly rotating in three dimensions thus spending 2/3 of the time in the transverse plane where $Q_\perp$ is computed. Below T_c, $Q_\perp$ decreases to zero at $T=0$ as expected for $f=0$. Naturally the quantity Q_{xy} is zero for all T when $f=0$ since there is no spin freezing.

Up to $f\approx0.16$, the behavior is similar to the $f=0$ case. As we further increase the site randomness f, interesting features start to show. Figure 1(b) are the data for $f=0.18$. Here, we can see that Q_{xy} becomes nonzero at a low temperature T_{xy}. Since Q_{xy} measures the time-averaged length of the spin components in the transverse plane, a nonzero value of Q_{xy} signals the freezing out of that component. In this situation $Q_\perp$, the mean square of the spin projection on the x-y plane, remains nonzero as T approaches 0. For a simple cubic lattice there are six neighboring spins per site, thus we expect that, on average, all the spins will be affected when the site randomness reaches 16%–17%. Indeed, spin freezing is observed around this value of frustration. This is very different from the behavior of the bond-frustrated system. There, any finite f gives rise to the transverse freezing.[4] In the bond frustrated system, frustration is induced by just replacing one ferromagnetic bond by an antiferromagnetic bond. In the site frustrated model, however, the replacement of a single ferromagnetic site by an antiferromagnetic site only decreases the bulk magnetization and has no other effect. Frustration for the site frustrated model can only occur when there are at least two neighboring antiferromagnetic sites. This occurs on average at a value given by $f=q^{-1}$ where q is the coordination number of the lattice. For our case, $q=6$ at $f=0.167$. Finally we notice the different values of M_f and $S_{\rm rms}$ below T_c: part of the difference is now contributed by the transverse spin freezing as $S_{\rm rms}$ is the vector sum of the z as well as the transverse components of the spins. For higher values of f, all features are similar to those of Fig. 1(b). Due to more frustration in the system with higher f, it is easier to freeze out the transverse spin components, thus T_{xy} has increased to higher values.

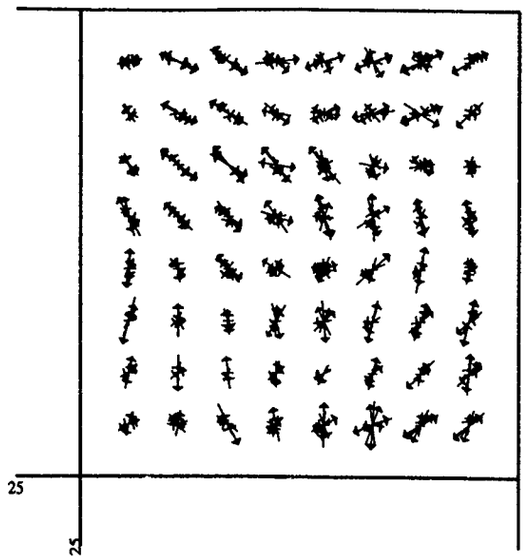

FIG. 2. Time averaged spin configuration for $f=36\%$ and $T=0.12T_H$ of a 8^3 system projected onto the x-y plane. Each point therefore is a stack containing eight spins.

An interesting result is the behavior of the staggered magnetization as f is increased from zero. We found that M_{st} starts to have nonzero values at the same temperature as T_{xy}. This seems to indicate that in the x-y plane the spin components freezes antiferromagnetically. To see this, we plot a typical configuration of the spin components in the x-y plane in Fig. 2 for $f=0.36$ at $T=0.12T_H$. Indeed, we see that the

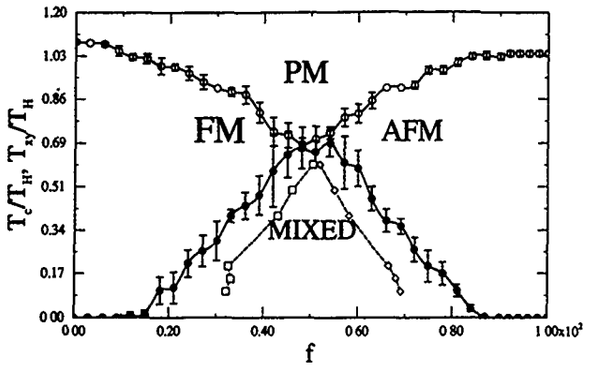

FIG. 3. An approximate phase diagram of the model. Open circles are temperatures T_c. Solid circles are temperatures T_{xy}. The dashed line with open boxes and diamonds roughly separates the mixed phase from the FM and AFM regions. The line is determined from the peak position in the susceptibility as we sweep f at fixed temperature. The error bars are determined as standard deviation from ten realizations of site randomness for each value of f.

transverse components try to order antiferromagnetically.

In Fig. 3 we present an estimate of the phase diagram for this model. The phase transition lines from the paramagnetic state (PM) to the ferromagnetic (FM) and antiferromagnetic (AFM) states were determined by calculating the susceptibility of the system. We took the peak position of the susceptibility as the transition point.[7] The T_{xy} line was determined as the temperature where $Q_\perp$ just became nonzero. We note that there is no phase transition across the line of T_{xy} and it represents the short-range behavior of the transverse spin freezing. The onset of the freezing occurs at frustration $f\sim16\%$ in the ferromagnetic state, and $f\sim84\%$ in the antiferromagnetic state. At these values of f, the phase transition temperature T_c starts to decrease. In the region between $f=45\%$ and $f=55\%$, T_c and T_{xy} merge together.

Apart from the usual states, at the middle region of the phase diagram there is a state we termed "mixed phase." We found that in the mixed phase $Q_\perp$ remains nonzero down to zero temperature and, in fact, it has rather substantial values at low temperatures. For instance with $f=51\%$, $Q_\perp\approx0.45$ at $T=0$. We have checked from the spin configurations that this large value of $Q_\perp$ was due to the fact that many spins lie almost completely in the transverse plane in the mixed phase, and that they actually form antiferromagnetic configurations (Fig. 2). Thus this part of the phase diagram is characterized by ferromagnetic domains pointing in the z direction mixed with antiferromagnetic domains pointing in the transverse plane. We have performed simulations to compute the susceptibility at fixed temperatures by sweeping f. A peak occurred in the susceptibility at the broken line in the phase diagram which separates the FM and AFM from the mixed phase. Unfortunately, we were not able to determine the nature of the region near this line as extremely large simulations are needed to determine whether there is a true phase transition from the FM or AFM states to the mixed phase as f or T is varied. We hope to report such a study in the future.

IV. CONCLUSIONS

Our Monte Carlo simulations on the site frustrated Heisenberg model give qualitatively similar results to those of the bond frustrated model. In particular the transverse spin freezing phenomena are observed which lead to an increase of the local spin length. However, the frustration does not set in until the site randomness reaches ~16%. Thus, the transverse spin freezing temperature T_{xy} remains zero until f reaches that value. We have observed a mixed phase for large values of the site randomness at low temperatures. Such a disordered phase is characterized by the configurations of mixed ferromagnetic and antiferromagnetic domains. Finally we have estimated the phase diagram of this model and it is in qualitative agreement with experimental findings.[5]

[6] To check finite size effects some simulations were performed using 20^3 spins and qualitatively the same results were obtained.
[7] To accurately determine the transition points a proper finite size scaling analysis should be performed, as was done in Ref. 4 However, here we are only interested in the general phase behavior, thus we simply took the peak position of the susceptibility as the transition temperature.

Mössbauer measurements of spin correlations in a-$(Fe,Ni)_{90}Zr_9Sn$

Centre for the Physics of Materials and the Department of Physics, McGill University, Rutherford Building, 3600 University Street, Montréal, Québec H3A 2T8, Canada

The local spin structure of the partially frustrated amorphous $Fe_{90-x}Ni_xZr_9Sn$ system was investigated by Mössbauer spectroscopy for $x=1,3$. The magnetic probe atom ^{57}Fe and the nonmagnetic ^{119}Sn were used to monitor the local correlation of the spins. The additional Ni renders the system less frustrated. We measured the temperature dependence of the hyperfine fields of the two probe atoms. The ratio $\langle B_{hf}(^{119}Sn)\rangle/\langle B_{hf}(^{57}Fe)\rangle$ rises with increasing temperature. This is in contrast to the temperature independence found for this ratio in $Fe_{92}Zr_7Sn$. A similar rise was found in the crystalline spin-glass AuFe where the slope was much larger and was related to a loss of longitudinal correlations.

INTRODUCTION

In amorphous and crystalline materials with competing antiferromagnetic (AF) and ferromagnetic (FM) exchange couplings two magnetic transitions have been observed in the low to medium frustration range.[1] The first transition marks the onset of ferromagnetic ordering at T_c. At the second transition temperature, T_{xy}, the transverse degrees of freedom freeze.[1,2] Overlaying the gross ordering behavior, are a series of phenomena associated with magnetic correlations and excitations. Neutron depolarization[3] and Lorentz microscopy[4] clearly show the existence of long-range ($\sim$10 μm) magnetic correlations which appear at T_c and persist through T_{xy}, consistent with the formation of a ferromagnetic state. By contrast, small angle neutron scattering reveals significant contributions from short-range ($\sim$10 nm) correlations,[5] which are sensitive to both magnetic transitions, and exist well above T_c.

One way to probe short-range magnetic correlations is to use Mössbauer spectroscopy. For a magnetic probe atom like ^{57}Fe the main contribution to the measured hyperfine field stems from the local moment of the atom itself. For a nonmagnetic probe atom like ^{119}Sn only the transferred fields from the neighboring magnetic moments contribute to the measured hyperfine field. If the spin structure is collinear, then the fields from the neighboring moments should add coherently, and a large transferred field should be observed at the nonmagnetic site, while a noncollinear or random spin structure should lead to a partial cancellation of the contributions and thus a smaller transferred field. The ratio of the (transferred) ^{119}Sn field to the (generating) ^{57}Fe field contains information about the degree of collinearity, and the temperature dependence of the ratio can be used to scale out the large changes due to thermal fluctuations, and reveal smaller effects due to changes in spin structure. This technique has been used to study spin correlations in several frustrated magnetic systems. In amorphous $Fe_{92}Zr_7Sn_1$, where the frustration arises through the distance dependence of the Fe-Fe direct exchange interaction, the transverse spin components were found to be correlated[6] as no change in the field ratio was observed on cooling through T_{xy}. Similarly, in AuFe, where the frustration is due to competition between long-ranged Ruderman–Kittel–Kasuya–Yosida (RKKY) and nearest-neighbor direct exchange interactions, both ^{196}Au and ^{119}Sn Mössbauer resonances have been employed, and clear evidence for strongly correlated transverse spin components was obtained.[7,8] However, more detailed examination of the temperature dependence of the $^{119}Sn/^{57}Fe$ field ratio, revealed evidence for a decay in the longitudinal spin correlations on cooling,[6] a result that is consistent with observations on similar compositions by neutron depolarization.[3]

In order to further understand the behavior of the field ratio it is necessary to study a range of frustrated magnetic systems. We have previously reported work on the a-$(Fe_{1-x}Mn_x)_{78}G_{22}$ system (G is a mixture of glass forming elements like Si, B, Al, P), which is frustrated through the addition of manganese,[9] however interpretation is complicated by the large magnetic moment of the Mn atoms. Here we report work on a simpler system, a-$(Fe_{90-x}Ni_x)_{90}Zr_{10}$, in which the addition of Ni reduces the frustration in the alloy, raising T_c and suppressing the transverse spin freezing transition.[10] In addition to the reduction of noncollinearity with increasing nickel content, the excitations become better behaved.[11] No spin waves were observed by inelastic neutron scattering for $x=0$, and while spin waves are seen below T_c for $x=1$, they soften on cooling, and were not resolved below $0.1T_c$. Well-defined spin waves are present for $x\geqslant 5$. Nickel carries a relatively small moment in this system ($\sim 0.6\mu_B$[12]) and as it is only present in low concentrations, its direct effects on the ^{119}Sn hyperfine field should be small. Therefore, the dominant contributions to the ^{119}Sn field should come from changes in the magnetic structure. The two samples considered here contain 1 and 3 at. % nickel; insufficient nickel to render the materials ferromagnetic.

EXPERIMENTAL METHODS

Ingots for melt spinning were prepared by first melting appropriate quantities of Zr (99.8%) and Ni (99.99%) in an arc furnace under titanium-gettered argon, then the Fe (99.98%) was added and the constituents were alloyed by rf melting under an Ar atmosphere. Enriched ^{119}Sn was used in order to get approximately 8 mg ^{119}Sn per 1 g sample weight to ensure a usable absorption in the ^{119}Sn spectra. Melt spinning was done under a helium atmosphere on to a copper wheel. The amorphous structure of the sample was verified by x-ray diffraction, DSC measurements, and room-temperature Mössbauer spectroscopy. The resultant amor-

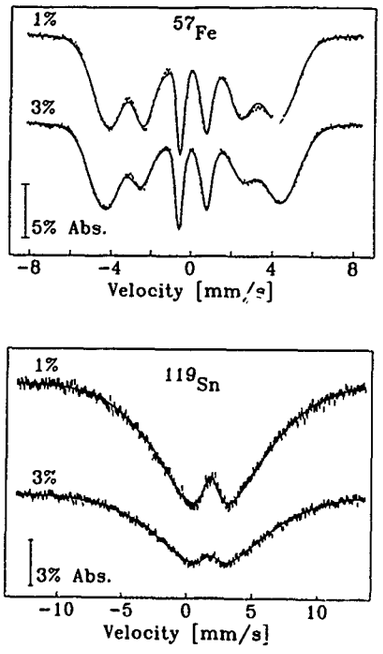

FIG. 1. ^{57}Fe and ^{119}Sn Mossbauer spectra for $Fe_{90-x}Ni_xZr_9Sn$ taken at 12 K.

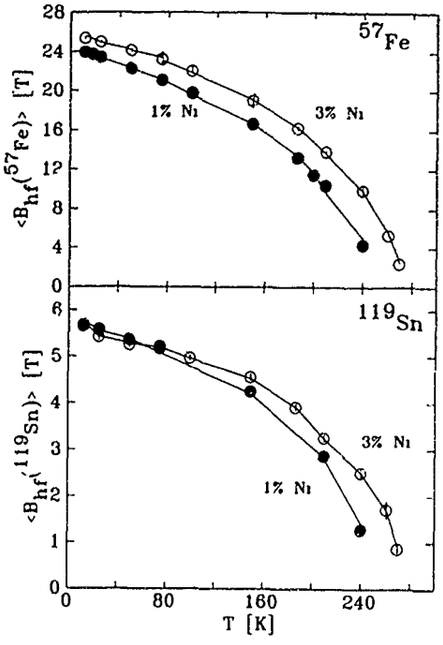

FIG. 2. Temperature dependence of the average ^{57}Fe and ^{119}Sn hyperfine fields for the two compositions of $Fe_{90-x}Ni_xZr_9Sn$.

phous ribbons were mounted on tape in order to make a Mössbauer absorber. The MS spectra were taken with a conventional constant acceleration spectrometer with a ^{57}Co/Rh source for the ^{57}Fe spectra and a $Ca^{119}SnO_3$ source for the ^{119}Sn spectra. The temperature was varied by means of a vibration-isolated, closed cycle He cryostat or a continuous flow cryostat.

The ^{57}Fe spectra were fitted using two Gaussian distributions to describe the hyperfine field distribution. For the ^{119}Sn spectra a single Gaussian distribution with different widths on the low and high field side was used. As the sample is an amorphous ribbon the intensity of the 2nd and 5th lines could not be fixed to its powder average value. Therefore the intensity was fitted in the ^{57}Fe spectra, and then set to the value found in those fits (~1) in order to fit the ^{119}Sn spectra. A linear correlation between the isomer shift and the hyperfine field was assumed in order to fit the slight asymmetry in the spectra. Spectra taken at 12 K for the different compositions and the two probe atoms along with the fits are shown in Fig. 1.

RESULTS

As expected, T_c increases on adding Ni, being 247±5 K for $x=1$ and 270±5 K for $x=3$, compared with 230±5 K for $x=0$. The temperature dependence of the average ^{57}Fe and ^{119}Sn hyperfine fields is given in Fig. 2. The curves show Brillouin-like behavior in all cases, and the derived T_c for each alloy is the same for both the Fe and Sn measurements, confirming that the Sn probes the same magnetic behavior as Fe.

The ^{57}Fe hyperfine field at 12 K rises on adding nickel, increasing 4% on going from $x=0$ to $x=1$, and a further 6% on going to $x=3$. The width of the hyperfine field distribution also narrows slightly. These results are in accordance with more collinear ordering, and the increased magnetization observed in this system on adding Ni.[10]

The behavior of the ^{119}Sn transferred hyperfine field however, is less straightforward. The shapes of the ^{119}Sn spectra shown in Fig. 1 are different, reflecting a 4% increase in the width of the hyperfine field distribution on going from $x=1$ to $x=3$, however, this broadening does not translate into an increased average. It is immediately apparent from Fig. 2, that the average Sn field at 12 K does not match the increase in the iron moment derived both from magnetization measurements and the ^{57}Fe Mössbauer spectra. In clear contrast to the ^{57}Fe data, the average ^{119}Sn hyperfine field does not change with composition, and the slight difference in temperature dependence, apparent in Fig. 2, simply reflects the higher T_c of the $x=3$ sample.

Plotting the ratio: $\langle B_{hf}(^{119}\mathrm{Sn})\rangle/\langle B_{hf}(^{57}\mathrm{Fe})\rangle$ (Fig. 3) reveals another puzzle. Since the Sn field does not increase with the Ni content, the Sn/Fe field ratio decreases on moving to the less frustrated, and thus more collinear, sample. Furthermore, a clear temperature dependence is apparent, with a slope of $\sim 1.5\times10^{-4}$ K^{-1}, at least an order of magnitude greater than the largest slope consistent with the data from $Fe_{92}Zr_7Sn_1$.[6] This slope should also be compared with the much stronger temperature dependence of $\sim 9\times10^{-4}$ K^{-1} observed in AuFe by ^{119}Sn Mössbauer spectroscopy. In the case of AuFe, the decline in the field ratio on cooling was interpreted as evidence for a loss of longitudinal order, a conclusion consistent with neutron depolarization measurements. However in the case of a-$Fe_{90-x}Ni_xZr_{10}$ no temperature dependence was seen for $x=0$, and adding nickel reduces frustration, making the system more ferromagnetic.

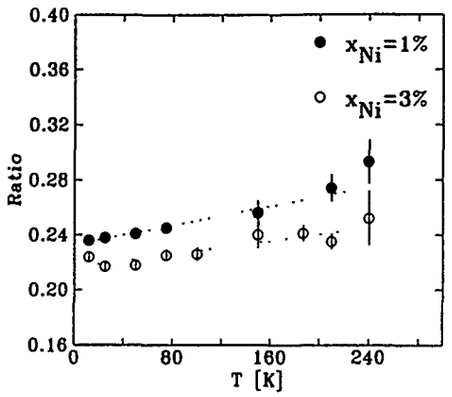

FIG. 3. Temperature dependence of the ratio $\langle B_{hf}(^{119}\mathrm{Sn})\rangle/\langle B_{hf}(^{57}\mathrm{Fe})\rangle$ for the two compositions of $Fe_{90-x}Ni_xZr_9Sn$.

Two possible conclusions can be reached. (i) There is, in fact, a loss of collinear order on cooling in a-$Fe_{90-x}Ni_xZr_{10}$. Independent confirmation of this behavior will be difficult to obtain, as the effect is quite small. The reduction of thermal fluctuations on cooling from 100 to 0 K, leads to a factor of two increase in the magnetization, while the change in the field ratio, and hence in the degree of collinearity, over the same temperature range is only about 1%. Unambiguously separating these two contributions would be extremely difficult. The existence of a collinearity loss in this system is unexpected since magnetization and neutron scattering measurements both show that the material becomes more ferromagnetic with increasing Ni content. Moreover, a more frustrated, binary a-Fe-Zr alloy showed no evidence of a collinearity decay. (ii) The Sn hyperfine field does not probe correlations between the neighboring Fe moments in the simple manner proposed, perhaps as a result of a greater tendency to form covalent bonds. The failure of the Sn field to rise with the increase in the Fe moment certainly provides support for this view. However, both ^{196}Au and ^{119}Sn Mössbauer measurements in AuFe yielded the same result, and confirmed neutron depolarization measurements. This agreement suggests that Sn does not sample its environment any more selectively than Au, and also shows that a loss of collinear order does yield the correct signature in the hyperfine field ratio. It is possible that the additional Ni leads to changes in the Fe moments which are not probed by the Sn. For example, even small changes in the orbital contribution to the iron moment can have significant effects on the ^{57}Fe hyperfine field,[13] but would not be seen by neighboring Sn atoms. It is not clear why the temperature dependence of such effects should differ from that of the average moment so as to yield a temperature dependent field ratio.

SANS experiments of an amorphous $Fe_{90}Zr_{10}$ alloy were carried out in the temperature region 20–300 K with and without the application of a magnetic field. The scattering versus temperature for different Q values (zero field cooled magnetization) shows two transitions at T_c=240 K and T_f=40 K. However, both transitions are not observed in magnetic field (2.6 kG) cooling down curves. By switching off the magnetic field and warming up the sample only the transition at T_f=40 K is observed. Application of a magnetic field at different temperatures in a zero field cooled sample reduces the scattering; the scattering returns to its initial value after switching off the field.

INTRODUCTION

Amorphous $Fe_{1-x}Zr$ alloys, where $x \approx 0.1$, exhibit an unusual complex magnetic behavior. At T_c=240 K they exhibit a transition from the paramagnetic state to the long-range ferromagnetic (FM) ordering, whereas at the lower temperature $T_f(H=0)=40$ K another transition to a "spin-glass-like" (SG) (reentrant) state occurs.[1] Most of the experimental evidence referred to the T_f transition could be explained by the coexistence and competition of ferromagnetic and antiferromagnetic interactions.[2] Recent magnetization and Mössbauer measurements[3] of the $Fe_{90}Zr_{10}$ alloy have been interpreted as being consistent with finite ferromagnetic clusters in a ferromagnetic matrix.[4] However, questions have been raised as to whether the T_f transition is indeed a FM to true SG state transition. The ac susceptibility could be explained by either a SG transition or domain pinning effects. TEM and Lorentz microscopy studies[5] have revealed the existence of magnetic domains down to 6 K. However, SANS experiments[6,7] on $Fe_{91}Zr_9$ revealed the existence of two different spin–spin correlation lengths, the longest persisting up to temperatures even higher than T_c, whereas the shortest appears below T_c.

In this paper, we report small angle neutron scattering (SANS) measurements of an amorphous $Fe_{90}Zr_{10}$ alloy. The two transitions in zero field cooled (ZFC) magnetization, reported previously, are observed around the same temperatures. However, in a FC sample only the lower temperature transition (T_f) is observed. Interesting results are obtained when a field is applied after cooling the sample at different temperatures.

EXPERIMENT

Amorphous $Fe_{90}Zr_{10}$ alloy was prepared in an argon atmosphere by the melt spinning method. The amorphicity of the alloy was verified by x-ray diffraction. ac susceptibility measurements showed two transitions at 40 and 240 K. Ribbons of about 1 g were stuck together and their low angle scattering was measured using the LOQ instrument at the spallation source ISIS, Rutherford-Appleton Laboratory, England. In this instrument a neutron wavelength band from 0.22 to 1 nm is utilized. The averaged counts from the different wavelength bands are pulled together giving a Q-range ($Q=4\pi \sin\theta/\lambda$) from 0.07 to 2.0 nm^{-1}. The scattering of this alloy was measured in the temperature range 300–15 K with or without the application of a magnetic field.

RESULTS AND DISCUSSION

The change in the scattering versus temperature in zero magnetic field is shown in Fig. 1. These measurements were obtained during the cooling of the sample; a few spectra were repeated during the warming up and showed that the scattering was reversible. From Fig. 1 we clearly observe two transitions: the first at 240 K and the second at around 40 K. From 300 to 250 K the scattering remains almost constant. Below 250 K a gradual increase in the scattering is observed which peaks at 230 K. As the temperature de-

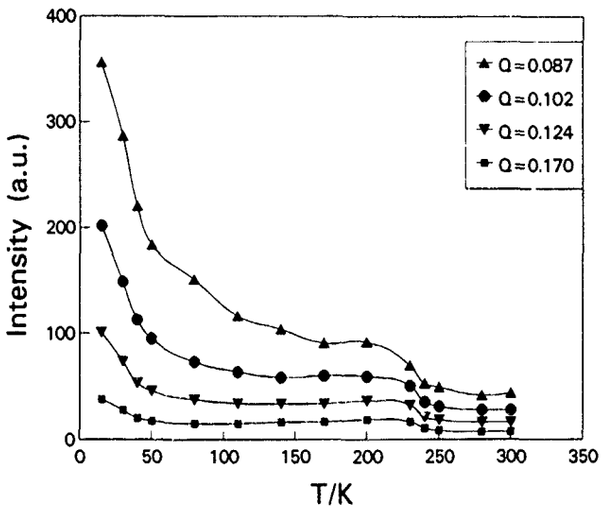

FIG. 1. Scattering vs temperature at different Q values. The sample has been cooled in zero field (the solid lines are a guide to the eye).

 0021-8979/94/76(10)/6380/3/$6.00 © 1994 American Institute of Physics

creases from 230 K the scattering for $Q>0.12$ nm^{-1} remains almost constant, whereas for lower Q values a continuous increase in the scattering is observed. At around 40 K a sharp increase in the scattering for all Q values is observed. These two transition temperatures coincide with those observed from ac susceptibility measurements carried out on the same sample.

The transition at 240 K has been attributed to a transition from a paramagnetic state to a long-range ferromagnetic ordering. In a ferromagnetic system the neutron scattering within the static approximation is given by a Lorentzian form (L)

$$I(Q)=\frac{A}{Q^2+\kappa^2}, \tag{1}$$

where κ is the inverse spin correlation length which approaches zero at the phase transition. In order to examine whether the scattering follows a Lorentzian line shape the data were plotted as $1/I(Q)$ vs Q^2. The data do not show a linear behavior when the whole experimental Q range is used. However, if we restrict our attention to the low Q region (0.07 to 0.6 nm^{-1}), we observe two linear regions, and in the temperature range 300–110 K. The Q value of the inflection decreases with temperature (at 250 K around $Q=0.5$ nm^{-1}) and is not observed within the experimental window below 110 K. These results are very similar to those discussed by Rhyne *et al.*[7]

As discussed above, the data in a plot of $1/I(Q)$ vs Q^2 [Eq. (1)] are curved and the departure from the Lorentzian-type shape increases as the temperature decreases. At these temperatures irreversibility effects have been observed in ac susceptibility measurements and if we assume a random anisotropy system the scattering can be expressed in Lorentzian plus Lorentzian-squared ($L-L2$) form[8]

$$I(Q)=\frac{A}{Q^2+\kappa^2}+\frac{B}{(Q^2+\kappa^2)^2}. \tag{2}$$

A least-squares fit of the experimental intensities to Eq. (2) using the full Q range gives physically meaningful values ($\kappa^2>0$) only in the temperature range 240–110 K. This is the temperature region in which the intensity varies slowly with temperature (Fig. 1). The value of the coefficient A decreases with temperature (around 30% from 240 to 110 K), whereas the correlation length as determined from κ^2 increases with temperature from 7.5 nm at 240 to 19 nm at 110 K. The decrease of A with temperature is in accordance with the behavior expected from a normal ferromagnet. It should be noted that the experimental intensity and that calculated from the fitted A, B, and κ values agree very well apart from a small deviation at the very low Q values. It has been proposed that the spin clusters can be presented by a Maxwellian distribution.[7] However, by using such a model it is difficult to fit the whole Q range and the values of A increase with decreasing temperature. Thus, we can only say that the L-$L2$ Eq. (2) describes the experimental data in the temperature regions defined from the first transition at $T_c=240$ K to the onset of the second one. In order to understand the origin of the low-Q scattering experiments in an even lower Q range are required. The interpretation of the scattering at temperatures around the two transitions probably requires a more sophisticated model.

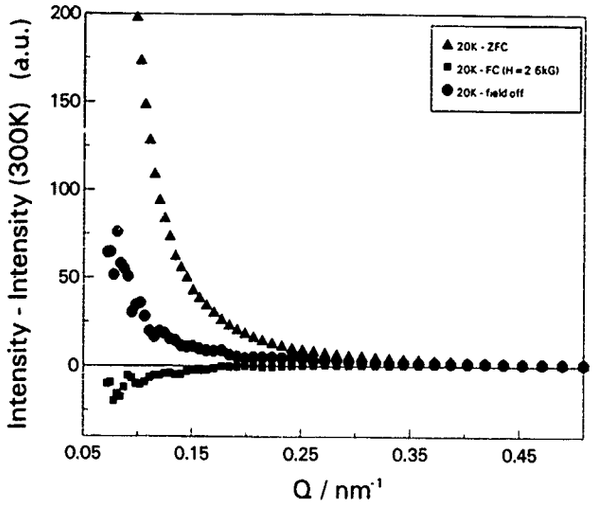

FIG. 2. The effects of the magnetic field at 20 K. The scattering at room temperature has been subtracted from all spectra. Triangles: ZFC, squares: FC from 300 K, circles: scattering after switching off the magnetic field.

The application of a magnetic field at 300 K reduces the scattering. This reduction is initially proportional to the field and at 5 kG saturation has been reached. The field-dependent scattering cannot be described by the simple Lorentzian form of Eq. (1). However, a plot of the $\ln[I(Q)]$ vs $\ln Q$ exhibits a linear behavior for the whole Q range and the slope obtained is around 2. This shows that the scattering after the application of the magnetic field can be described with a function of the form A/Q^2. This behavior is expected from an ordered ferromagnetic system.

Cooling the sample from 300 K in a 2.6 kG field, we observe no change in the scattering with temperature. Neither of the two transitions is observed. By switching off the magnetic field at 20 K the scattering increases, but it does not reach the value of the scattering observed during the cooling of the sample with zero magnetic field (Fig. 2). The increase of the scattering observed after switching off the field at 20 K occurs within 5 min, the time required to obtain the first measurement. No change in the scattering is observed in subsequent measurements, while remaining at 20 K. Warming up, we observe the lower transition at 40 K. However, the higher transition at $T_c=240$ K is not observed (Fig. 3), the scattering slowly increases to its original 300 K value in zero field.

In order to examine the spin reorientation at different temperatures, a magnetic field was applied after cooling the sample to a specific temperature (230, 110, 80, and 40 K). The change in the scattering induced by the field occurs within less than 2 min (time of the measurement) and the scattering returns to its previous value by switching off the magnetic field within the same time interval. In Fig. 4 the effect of the magnetic field ($H=2.6$ kG) applied after the sample was cooled at 230 K is presented. For comparison, the scattering obtained when the same field is applied at 300

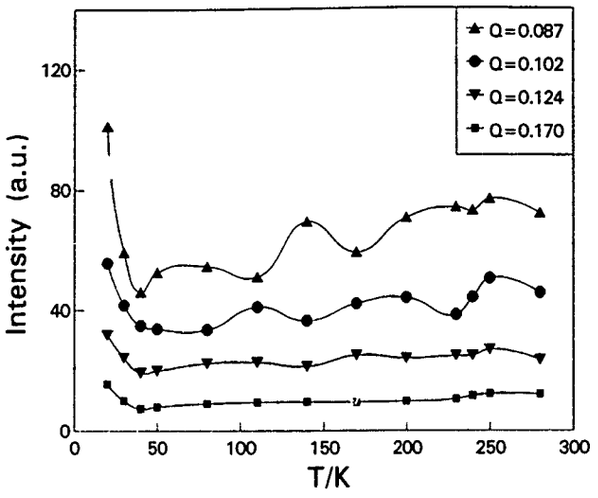

FIG. 3. Scattering vs temperature at different Q values during the heating of the sample in zero field from 20 to 300 K. The sample was previously cooled in a magnetic field of 2.6 kG.

K is also presented. In order to show the effect of the magnetic field, the scattering at room temperature has been subtracted from all the spectra. The field-induced scattering for the low Q values is lower than the 300 K scattering in zero field. As Q increases it reaches the 300 K scattering, further increases to peak at 0.44 nm^{-1}, then decreases to the 300 K scattering at Q around 1.2 nm^{-1} (see inset of Fig. 4) and remains unchanged for $Q>1.2$ nm^{-1}. As the temperature of cooling is reduced these effects become less pronounced and the field-induced scattering at 40 and 300 K almost coincide.

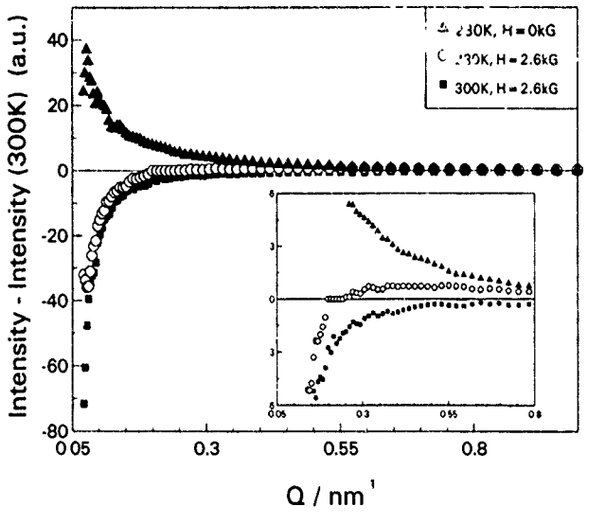

FIG. 4. The effect of a 2.6 kG magnetic field after the sample was cooled at 230 K. The scattering at room temperature has been subtracted from all spectra. Triangles: ZFC to 230 K, circles: cooling from 300 to 230 K in zero field and application of a magnetic field of 2.6 kG, squares: application of 2.6 kG at 300 K.

CONCLUSIONS

The ZFC SANS from an amorphous $Fe_{90}Zr_{10}$ alloy shows two transitions at 240 and 40 K which coincide with those observed from ac susceptibility measurements carried out on the same sample. The scattering in the temperature range 300–110 K and in the low Q region shows a behavior which departs from either L or L-$L2$ form [Eqs. (1) and (2)]. This scattering cannot be attributed to chemical effects or clustering since it is temperature dependent. If we ignore the low Q scattering we can fit a L-$L2$ equation to the data only in the range 240–110 K. The correlation length obtained from such a fit increases with temperature from 7.5 to 19 nm and the coefficient A which contain contributions from both finite range spin waves and from the static spin glass order decreases with temperature as expected. The 300 K scattering is reduced with the application of a magnetic field and saturation is observed at 5 kG. No change in the scattering is observed during the cooling of the sample from 300 to 20 K. The temperature independence of the scattering during cooling and its form (A/Q^2) indicate an ordered ferromagnetic system. By warming up the sample after switching off the field at 20 K only the lower transition at T_f=40 K is observed. The switching off of the field unlocks the spin cluster units which undergo their transition at 40 K. The unlocking of the spin clusters is not complete since the scattering at 20 K, after switching off the field, is not restored to its ZFC value. The FM matrix remains frozen at low temperatures and the scattering slowly recovers to its previous value at 300 K without showing the T_c=240 K transition. The application of a magnetic field after cooling the sample to a specific temperature results in a reduction of the scattering. The effect is more pronounced at 40 K where the field has almost the same effect as when applied at room temperature. No hysteresis is observed in the restoration of the scattering to its previous value after switching off the field. We may assume that the field mainly modifies the spin cluster units. At 40 K a larger part of the sample is occupied by the spin clusters so the effect is greater. This is in agreement with the unlocking of the spin clusters when the magnetic field is switched off at 20 K after a field cooling of the sample.

Magnetohistory effects in $YFe_{12-x}Mo_x$ (x=1.5–3.0) have been investigated. The freezing temperature T_f increases with increasing Mo concentration. Irreversible behavior still appears in an applied field up to 6 T for $YFe_{9.5}Mo_{2.5}$. These magnetohistory behaviors may be understood by domain-wall pinning.

I. INTRODUCTION

Since 1990, when $Sm_2Fe_{17}N_3$ and $NdFe_{11}TiN$ compounds were discovered,[1,2] interstitial compounds have been intensively investigated due to their excellent magnetic properties for permanent magnet applications. Anagnoston *et al.*[3] and Wang *et al.*[4] first studied the series of $RFe_{10}Mo_2$ nitrides and the series of $NdFe_{12-x}Mo_x$ nitrides, respectively. The studies showed that the $RFe_{12-x}T_x$ series with T=Mo has different magnetic behavior from the other series with T=Ti, V, Cr, W, and Si.[5,6] Recently, $YFe_{12-x}Mo_x$ and their nitrides were also investigated by Sun *et al.* in order to get information on the magnetic properties of the Fe sublattice.[7,8] Some magnetohistory effects were observed in both $YFe_{10}Mo_2$ and $LuFe_{10}Mo_2$ by Christides *et al.*[9] These magnetohistory phenomena are very close to the behavior which exists in spin glasses and amorphous alloys.[10] The authors in Ref. 9 believed that such phenomena result from the variation of Fe–Fe distances for $YFe_{10}Mo_2$ and $LuFe_{10}Mo_2$ on different Fe sites and the distribution of Mo atoms leads to a randomness of the exchange interaction and an establishment of noncollinear-type of magnetic order (helimagnetic structure). However, such a mechanism is still a matter of debate. In fact, magnetohistory phenomena are often exhibited by some rare-earth transition-metal alloys, for example, in YCo_2Ni_3 observed in 1976[11] and recently in $Ho_2Fe_{17-x}Al_x$[12] and $R_2Fe_{14-x}Mn_xC$.[13] The narrow-Bloch-wall pinning mechanism developed by Barbara *et al.* in the early 1970's[14] for understanding the huge coercive force in the crystalline rare-earth-transition metal alloys has been used to explain the magnetohistory effects.[13]

In this work, we investigate the magnetohistory effects of the series alloys of $YFe_{12-x}Mo_x$ (x=1.5–3.0) and discuss the origin of these effects.

II. EXPERIMENT

Alloys of $YFe_{12-x}Mo_x$ with x=1.5, 2.0, 2.5, and 3 were prepared by arc melting from 99.9% starting materials under an argon gas atmosphere and then vacuum annealed at 1100 °C for 24 h. By x-ray diffraction and thermomagnetic analysis, all samples were found to be single phase with $ThMn_{12}$-type structure. Experimental data of structural and intrinsic magnetic properties have been reported separately.[15] Samples of cylindrical shape with a diameter of 3 mm and a length of 6 mm were made at room temperature by aligning the alloy powders along the cylinder axis in a magnetic field of 1 T and fixing their direction with epoxy resin. The low-temperature thermomagnetic data were obtained using an extraction sample magnetometer in the temperature range from 1.5 to 300 K in an applied field up to 6 T.

III. RESULTS AND DISCUSSION

Figure 1 shows the temperature dependence of the magnetization of $YFe_{12-x}Mo_x$ series ($1.5<x<3.0$) in an applied field of 0.045 T after zero-field cooling (ZFC) and field cooling (FC) processes. Here the ZFC curve is obtained by cooling the sample from room temperature to 1.5 K in zero applied field, and then measuring the magnetization with the increase of temperature in a certain applied field, while the FC curve is produced by cooling the sample in the same applied field. The thermomagnetic cycle of ZFC and FC processes exhibits an irreversible behavior. Values of the magnetization after ZFC are obviously lower than those after FC. The ZFC and FC magnetization curves are coincident at high temperatures and are separate at low temperatures. The irreversible phenomena observed here in the $YFe_{12-x}Mo_x$ series are similar to that in $YFe_{10}Mo_2$.[9] Moreover, the freezing temperature T_f, which is marked by the arrows at the cusps of the ZFC curves in the figure, decreases with decreasing Mo concentration.

Figure 2 shows the temperature dependence of the ZFC and FC magnetization curves in different applied fields for the $YFe_{9.5}Mo_{2.5}$ compound. It can be seen that T_f decreases with increasing applied field. Even if the applied field goes up to 6 T, the irreversible behavior does not vanish. This is

different from the case of $YFe_{10}Mo_2$, observed by Christides *et al.*,[9] where the irreversible phenomenon disappeared when the applied field went up to 0.7 T.

Understanding the magnetohistory effects observed in rare-earth transition-metal intermetallic compounds has been

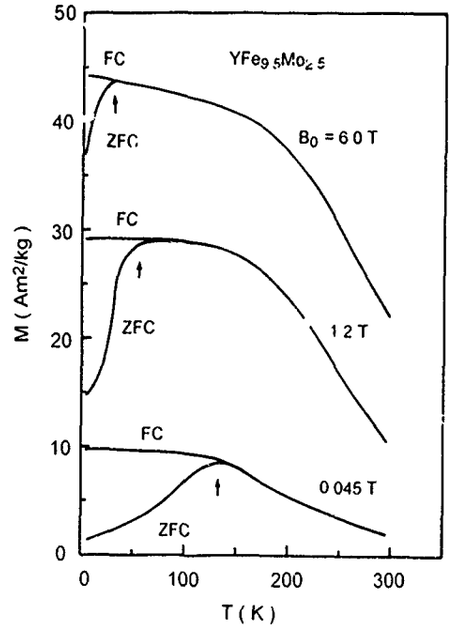

FIG. 2. Temperature dependence of magnetization of $YFe_{9.5}Mo_{2.5}$ by zero field cooling and field cooling in different applied fields. The arrows mark the freezing temperature T_f.

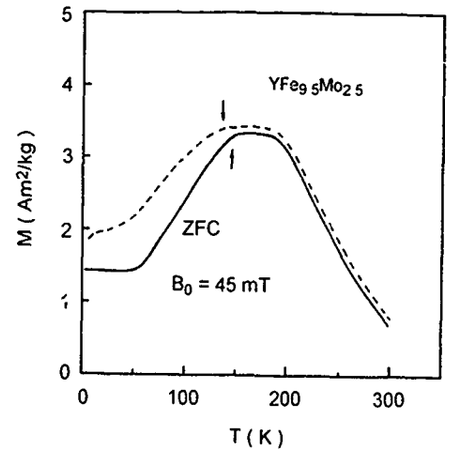

FIG. 3. Temperature dependence of magnetization of $YFe_{9.5}Mo_{2.5}$ by zero-field cooling for thermal demagnetized ingot (solid line) and magnetized ingot (dashed line). The arrows mark the freezing temperature T_f.

an interesting subject for scientists working on magnetism. The magnetohistory effects may be described in terms of cluster glasses[10] or in terms of the narrow-Bloch-wall.[12,13] For the magnetohistory, effects observed in $RFe_{10}Mo_2$ (R=Y and Lu) were explained in terms of cluster glasses by the authors in Ref. 9, which were established by a competition between the positive and negative exchange interactions due to the variation of Fe–Fe distances in different lattice sites, since the Fe–Fe interactions with short interatomic distance (~0.24 nm) may cause the antiferromagnetic coupling, but the authors did not explain why there is no magnetohistory effect in $GdFe_{10}Mo_2$ which has similar lattice parameters to $YFe_{10}Mo_2$.[3] A recent neutron-powder-diffraction study on $YFe_{12-x}Mo_x$[8] at a temperature of 10 K showed that all the Fe atomic magnetic moments are parallel over the three crystallographic sites. This does not support the proposal made by the authors in Ref. 9. For the cluster glass model, the magnetohistory effect is independent from the magnetic domain structure. Figure 3 shows two types of ZFC curves for $YFe_{9.5}Mo_{2.5}$. It can be seen that at 1.5 K the thermal demagnetized ingot has a lower magnetization value than the ingot magnetized in a field of 6 T at 200 K. This indicates that the magnetohistory effect observed here is associated with the distribution of the domain wall. Therefore the narrow-Bloch-wall model may be suitable for explaining the magnetohistory effects in $YFe_{12-x}Mo_x$.

The neutron-powder-diffraction study on $YFe_{12-x}Mo_x$[8] at a temperature of 10 K also showed that the Mo has an atomic magnetic moment of 1.0 μ_B which is antiparallel to the Fe-sublattice magnetization and the Mo atoms are mainly distributed on 8*i* sites. The distribution of Mo substitution in the iron sites in $YFe_{12-x}Mo_x$ may cause the necessary fluctuation of the exchange interaction and anisotropy to form the pinning of domain walls, so that irreversible magnetic behavior occurs at low temperatures. This is similar to that observed in YCo_2Ni_3.[11] If the nonmagnetic Y is replaced by magnetic R, which enhances the relative value of magnetocrystalline anisotropy to exchange interaction, the magneto-

history effects in $RFe_{12-x}Mo_x$ can be expected. We have found that the magnetohistory effects do exist in $RFe_{12-x}Mo_x$ with light rare-earth R=Pr, Nd, and Sm.[16] The reason for the absence of magnetohistory effects in $GdFe_{10}Mo_2$[9] may be attributed to the magnetic Gd^{3+} which couples antiparallel to Fe and parallel to Mo. The magnetic Gd sublattice smoothes the magnetic fluctuation caused by Mo atoms.

In conclusion, magnetohistory effects in $YFe_{12-x}Mo_x$ (x =1.5–3.0) have been investigated and may be understood by domain-wall pinning. The experimental data give a strong evidence that magnetohistory effects are related to the domain structures rather than the cluster glasses.

Magnetic viscosity, fluctuation fields, and activation energies (invited)

R. Street
Research Centre for Advanced Mineral and Materials Processing, Nedlands 6009 Australia

S. D. Brown
Department of Physics, Keele University, Keele, Staffordshire ST5 5B9, United Kingdom

Time dependence of magnetization in ferromagnetic materials was first described towards the end of the 19th century. Subsequently, two types of mechanisms responsible for time dependent behavior were identified and became known as "diffusion" and "fluctuation" after-effect or viscosity. The former depends on thermally induced motion of impurity atoms. The latter is a consequence of thermal activation of irreversible domain processes such as domain-wall motion and the nucleation of domains of reverse magnetization. Fluctuation viscosity affects, to a greater or smaller extent, all magnetic materials subject to hysteresis. In the late 1940s descriptions of magnetic viscosity in terms of fluctuation fields (Néel) and activation energy distributions (Street and Woolley) were developed. The two approaches will be described. An analysis of the time dependent phenomena exhibited by magneto-optical films will be presented as a simple example of the application of activation energy modeling.

I. INTRODUCTION

Two different types of magnetic viscosity or after-effect have been recognized. The first observations of the time dependence of magnetization in a constant field were made by Ewing[1] and Rayleigh[2] in their measurements of the magnetic properties of soft magnetic materials. Later Preisach[3] and others observed a different kind of time dependence in the magnetization of harder magnetic materials. Different processes are involved in the two effects. In the first, magnetic processes are affected by the diffusion of impurity atoms and the temperature dependence of the magnetic effects are typical of diffusion processes. The phenomenon underlying Preisach's observations affect all magnetic materials which exhibit hysteresis. The magnetization processes of these materials exist in metastable states which transform to stable states by a combination of field induced transitions and thermal activation. Under constant field conditions the evolution of magnetization is the result of thermal activation of irreversible magnetization processes. Observations of magnetic viscosity are made by measuring the magnetization $M(t)$ as a function of time elapsed after a discontinuous increment of magnetic field. In many cases, over restricted ranges of elapsed time,

$$M(t)=S \ln t+\text{const}, \tag{1}$$

where the parameter S depends on the point of measurement on the magnetization curve. S also depends on the demagnetization factor of the sample on which measurements are made.

Two independent descriptions of the effects of thermal activation on magnetization were given by Street and Woolley[4,5] and Néel.[6,7] The latter considered the effects associated with thermally induced random fluctuations of spontaneous magnetization vectors in terms of a fluctuation field:

$$H(t)=H_f(Q+\ln t), \tag{2}$$

where Q is a constant and H_f is known as the fluctuation field. The time dependence of irreversible magnetization is obtained in terms of the irreversible susceptibility χ_{irr} as

$$M_{\text{irr}}(t)=\chi_{\text{irr}} H(t)=S \ln t+\text{const}, \tag{3}$$

where $S=\chi_{\text{irr}} H_f$.

In the approach adopted by Street and Woolley to magnetic viscosity, thermally activated rate processes involving metastable states with a distribution of activation energies are considered. Thus $N(E)\,dE$ is the number per unit volume of metastable states having, at a given field H, activation energies lying between E and $E+dE$.

II. MODELS

A domain model exhibiting field dependent metastability is based on the work of Stoner and Wohlfarth[8] in which they examined the magnetic behavior of anisotropic single domain particles. The results of many studies of magnetic viscosity have been discussed in terms of this model. A simple case of an aligned uniaxial domain subjected to a demagnetizing field H is shown in Fig. 1. It is assumed that the magnetization proceeds by coherent rotation.

In the case of an assembly of noninteracting aligned particles with a distribution of volume $f(V)\,dV$, the distribution of activation energy at a fixed field will be given by $Kf(V)\,dV\,(1-H/H_k)^2$. The variation of the activation energy E as a function of H is shown in Fig. 2. The activation energy distribution functions at two different values of field

 0021-8979/94/76(10)/6386/5/$6.00 © 1994 American Institute of Physics

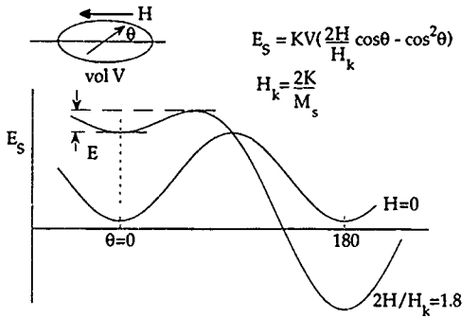

FIG. 1. Energy of an aligned uniaxial domain as a function of the angle between the field and the magnetization vector at two different fields. The activation energy for reversal is indicated.

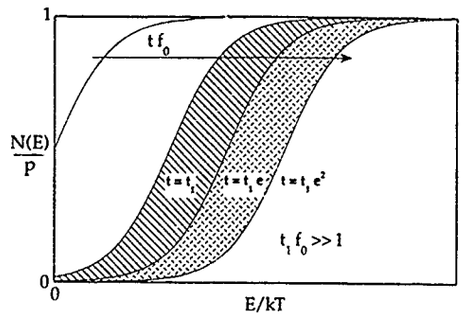

FIG. 3. The distribution of energy barriers $N(E)/p$ as a function of E/kT for various values of time after a discontinuous step change in field. The model assumes that at $t=0$, $N(E)=p$ for all E. For values of $tf_0 \gg 1$ the curve sweeps out equal areas in equal logarithmic increases in time (the shaded regions).

are also indicated. It is clear that determination of the field variation of activation energy requires measurements to be made at constant values of magnetization.

Other examples of magnetization processes which involve metastable states include domain-wall motion subject to weak and strong pinning[9,10] and the nucleation of domains of reverse magnetization.[11]

As noted by Street and Woolley[4,5] the rate of transformation of metastable to stable states is given by

$$\frac{d}{dt}N(E)dE = -f_0 N(E)dE\ \exp\left(-\frac{E}{kT}\right), \tag{4}$$

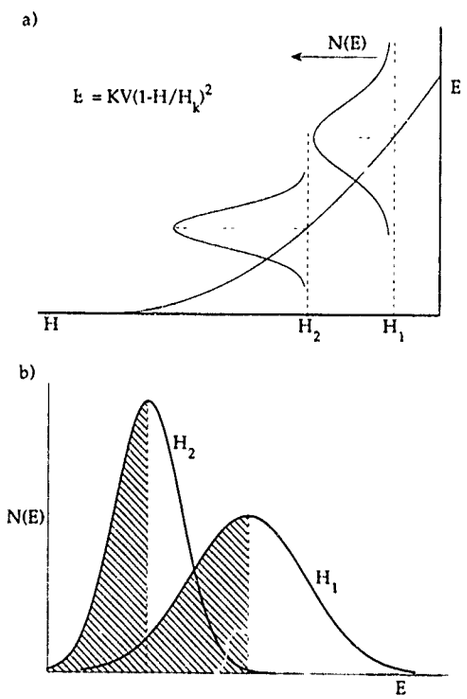

FIG. 2. (a) Activation energy as a function of demagnetizing field for an aligned uniaxial domain. The distribution of activation energies due to a distribution of volumes is indicated at two values of field. (b) The distribution of activation energies at two values of field. To determine $\partial E/\partial H$, measurements must be made at constant magnetization, represented by the shaded area.

where f_0 is the attempt frequency, assumed to be constant.

The solution to Eq. (4) is

$$N(E) = N_0(E)\exp[-tf_0\ \exp(-E/kT)], \tag{5}$$

where $N_0(E)$ is the initial number of metastable states per unit volume with activation energies lying between E and $E+dE$ at $t=0$.

For the case that the initial value of the distribution function $N_0(E)$ is independent of E and equals a constant p, Eq. (5) becomes

$$N(E)/p = \exp[-tf_0\ \exp(-E/kT)]. \tag{6}$$

The variations of the ratio $N(E)/p$ as a function of E/kT with the dimensionless product tf_0 as parameter are shown in Fig. 3. Assuming that each successful activation makes the same contribution to the magnetization, the total change in magnetization of the assembly from time $t=0$ to t_1 is proportional to the area between the curve at $t=t_1$ and the $N(E)/p$ axis. For values of the parameter $tf_0 \gg 1$ the curve sweeps out equal areas in equal logarithmic increases in time. That is, the magnetization increases logarithmically with time in accordance with the experimentally observed variation, Eq. (1). Making the simplifying assumption that each successful activation involves a change in magnetic moment μ, the viscosity parameter S is given by

$$S = \mu pkT. \tag{7}$$

Changes in magnetization may also be achieved by stepwise changes in the applied field ΔH. It may be shown that the irreversible susceptibility $\chi_{\rm irr}$ is given by[12]

$$\chi_{\rm irr} = \mu p\ \frac{\partial E}{\partial H}. \tag{8}$$

Hence

$$\frac{S}{\chi_{\rm irr}} = H_f = \frac{kT}{\partial E/\partial H}; \tag{9}$$

cf. Eq. (3).

Conventionally, the quantity H_f has been derived from measurements of S and $\chi_{\rm irr}$. The operational definition of $\chi_{\rm irr}$ to be substituted in Eq. (9) is a matter of some uncertainty in

materials, such as high coercivity permanent magnets, which exhibit pronounced time dependence of magnetization. It has been shown that in this context,[13]

$$\chi_{\rm irr}=\left.\frac{\partial M_{\rm irr}}{\partial H}\right|_{\dot{M}}. \tag{10}$$

An alternative method of deriving values of H_f from experimental observations of time dependence is discussed by Folks and Street.[14]

At a given point on a magnetization curve, H_f is a measure of $\partial E/\partial H$, the variation with field of the activation energy of the irreversible metastable processes which are active at that point. For example, the $\partial E/\partial H$ vs H curve for an assembly of aligned Stoner–Wohlfarth domains is given by the slope of the $E_{\rm ac}$ vs H curve of Fig. 2, i.e., a linear decrease as the magnitude of the reverse field is increased. In the case of the activation of aligned nuclei of reverse magnetization,

$$\frac{\partial E}{\partial H}=vM_{\rm sp}, \tag{11}$$

where v and $M_{\rm sp}$ are the volume and spontaneous magnetization of the nucleus.

Some interesting features arise from the study using an activation energy model of the time dependence of a system in which the metastable states all have the same value of activation energy $E(H)$. Specifically, we consider a thin film in which there exist identical uniaxial grains each of volume V. The magnetic moment of a grain VM_s may be aligned only either in a positive or negative direction with respect to the normal of the plane of the film.

Let N_t be the total number of grains per unit volume of the film and N_+ and N_- be the number of grains per unit volume aligned in the positive and negative directions, respectively. Then $N_t=N_++N_-=1/V$ and the intensity of magnetization of the film when $N=N_+$ is given by

$$M=N_tVM_s(2N/N_0-1)$$

or

$$m=2n-1, \tag{12}$$

where

$$m=M/M_s$$

and

$$n=N/N_0.$$

The rate equation is

$$\frac{dn}{dt}=-f_0n\,\exp\left[-\frac{E(H)}{kT}\right]. \tag{13}$$

Solving Eq. (13) and substituting for n from Eq. (12) gives

$$m=2\,\exp(-t/\tau)-1, \tag{14}$$

where

$$\tau=\frac{1}{f_0}\exp\left[\frac{E(H)}{kT}\right].$$

The variations of m as a function of $\ln t$ with $E(H)/kT$ as parameter are shown in Fig. 4.

E as a function of H may be derived from Eq. (14) by considering constant $m=m_c$ conditions which implies

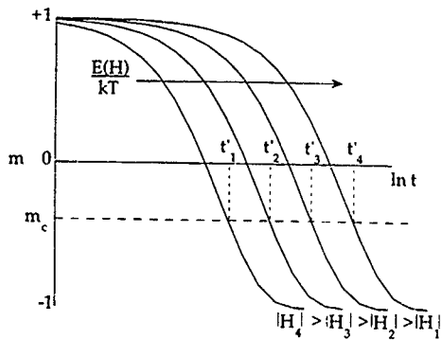

FIG. 4. The decay of magnetization with $\ln t$ for a uniaxial perpendicular thin film at various fixed values of field. The coercivity is clearly time dependent.

$$2\,\exp(-t'/\tau)=m_c+1, \tag{14a}$$

where t' = time at which $m=m_c$ for a given value of τ. Thus,

$$-\frac{t'}{\tau}=\ln\left(\frac{m_c+1}{2}\right). \tag{14b}$$

Substituting for τ from Eq. (14) gives

$$t'\,\exp\left[-\frac{E(H)}{kT}\right]=-\frac{1}{f_0}\ln\left(\frac{m_c+1}{2}\right)=\text{const.} \tag{14c}$$

Hence

$$\ln t'-E(H)/kT=\text{const.} \tag{15}$$

The derivative of both sides of Eq. (15) with respect to H may be cast in the form

$$\Delta\,\ln t'=\frac{1}{kT}\left.\frac{\partial E}{\partial H}\right|_M\Delta H. \tag{16}$$

The associated values of ΔH and $\Delta \ln t'$ in Eq. (16) are derived from the constant values of H associated with successive m vs $\ln t$ curves and the $\ln t$ coordinates of the points of intersection of the line $m=m_c$ with those curves.

The value of H_f may be derived from the gradient of the curve ΔH vs $\ln t$ since

$$\Delta H=\frac{kT}{\left.\partial E/\partial H\right|_M}\ln t'=H_f\ln t'. \tag{17}$$

III. EXPERIMENTAL APPLICATION TO THIN FILMS

The above analysis has been applied to study the time dependence and mechanisms of magnetization reversal in Tb-Fe-Co films by Brown *et al.*[15] Magneto-optic magnetometer measurements were made of the time dependence of the magnetization of thin films of Tb-Fe-Co when subjected to various fixed values of reversing field. The experimental results obtained using a 48.5 nm thick film of $Tb_{0.22}(Fe_{0.9}Co_{0.1})_{0.78}$ are shown in Fig. 5. Associated values of H_a and $\ln t'$, obtained from the intersections of the experimental curves with lines $m=m_c$ within the range $-0.9\leq m_c\leq 0.9$, are plotted in Fig. 6. The average of the five values of H_f is 87.3 ± 1 Oe. It follows that the activation energy of the process responsible for magnetization reversal

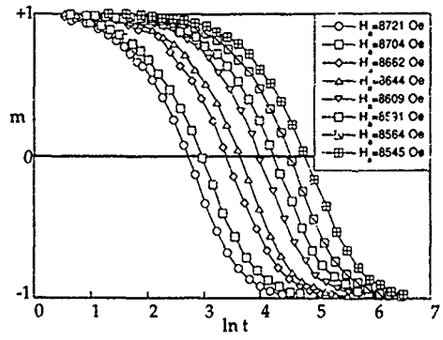

FIG. 5. Experimental results for the decay of magnetization with $\ln t$ at fixed values of reversing field for a 48.5 nm thick film of $Tb_{0.22}(Fe_{0.9}Co_{0.1})_{0.78}$. Note the similarity with Fig. 4.

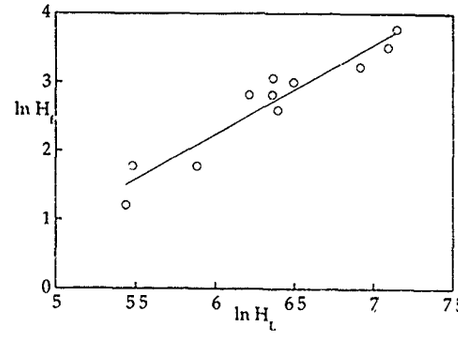

FIG. 7. The Barbier plot of $\ln H_f$ vs $\ln H_L$ for the data of Labrune *et al* (see Ref. 16). The slope of the line is 1.22.

in this film is a linear function of field, at least over the measured range of 8.55–8.76 kOe, and within the range $-0.9 \leq m_c \leq 0.9$. This observation is consistent with the view that magnetization reversal proceeds by activation of reversal of magnetization in regions of constant volume v. Using a value of 86 G for the spontaneous magnetization of the material of the film, v was found to be 5.5×10^{-18} cm^3, the volume of a sphere of diameter 22 nm.

Labrune *et al.*[16] have also measured the time dependence of magnetization processes in rare-earth-transition-metal alloys including alloys of Gd-Fe and of GdTbFe. Application of the above analysis to their results, which are given in detail for a GdTbFe film, show that at $m=0$ a linear relation exists between ΔH and $\ln t'$ [Eq. (16)], leading to a value of $H_f=18.9$ Oe. It appears in this case that H_f is not independent of m, decreasing by approximately 10% as m decreases from 1 to -1.

The apparent coercivity H_c of magneto-optic films, i.e., that field at which the holomagnetization is zero, depends on the time at which the measurement of m is made after the reversing field is switched on. The shorter the time, the higher the apparent coercivity will be. There exists a limiting field H_L for which the activation energy is zero. In this circumstance, reversal of magnetization will occur in a time $t=1/f_0$.

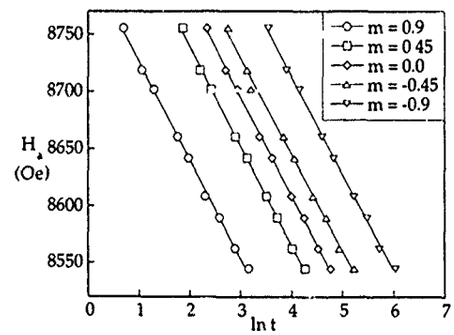

FIG. 6. Associated values of H_a and $\ln t$ from the intersections of lines of constant m with the experimental curves in Fig. 5. The average slope of the five lines is 87.3±1 Oe, which is equivalent to the fluctuation field H_f.

The value of H_L may be calculated using Eq. (17) assuming that the value of H_c', say at time $t=1$ s, is known and that the value of H_f remains constant over the field range H_c' to H_L:

$$H_L = H_c' + H_f \ln f_0 \cong H_c' + 21 H_f,$$

taking $f_0 \approx 10^9$ Hz.

In the case of the TbFeCo film considered above, $|H_L| = 11.01$ kOe.

Labrune *et al.*[16] have provided data for 11 different samples of GdFe and GdTbFe alloys having values of H_c ranging from about 200 to 1300 Oe. These data have been used to construct the Barbier plot of $\ln H_L$ vs $\ln H_f$ shown in Fig. 7. The slope of the line is 1.22. Wohlfarth[17] found in an analysis of a Barbier plot of data for different materials with coercivities ranging from 1 to 1000 Oe that the slope was 1.37.

Extension of the activation energy analysis of the magnetic properties of thin films leads to information on the mechanisms responsible for the growth of regions of reverse magnetization.[15,16] Details of the fractal or other nature of the magnetization of thin films may also be obtained from observations of time dependent behavior.

IV. CONCLUSIONS

The important information derived from magnetic viscosity measurements concerns the variation of the fluctuation field H_f as a function of magnetic state parameters. Reliable values of H_f, derived from the slope of M vs $\ln t$ curves and irreversible susceptibility χ_{irr} as $H_f = S/\chi_{irr}$, can only be obtained when χ_{irr} is carefully defined as $\partial M_{irr}/\partial H|_{M_{irr}}$.

The value of measurements of H_f lies in the fact that its definition involves $\partial E/\partial H|_M$, the variation with field of the activation energy of the metastable states responsible for irreversible magnetization at the point of measurement. It then becomes possible to check numerical values of $\partial E/\partial H|_M$ against the predictions of postulated models of magnetic behavior.

The application of activation energy modeling of magnetic behavior of some magneto-optic films is particularly simple. It produces information on the growth of magnetized regions and the micromagnetic structure of the films.

Analysis and interpretation of time dependent magnetic phenomena (invited)

L. Folks and R. Street
Research Centre for Advanced Mineral and Materials Processing, The University of Western Australia, Nedlands 6009, Australia

Time dependence of intensity of magnetization is the result of thermal activation of metastable domain processes. The simple (M,H) representation of magnetic behavior may be extended to include time dependent effects using a constitutive equation. Magnetic processes may be described by the movement of a point over a three-dimensional surface with coordinates M, H, and $\dot{M}$. The parameters required to define the surface, Λ (or fluctuation field H_f) and χ, may be derived from measurements of the time dependence of magnetization. A review of the utilization of the constitutive equation is given and simple methods for obtaining the material parameters from conventional magnetic viscosity measurements (under constant applied field conditions) are described. Measurements of Λ in particular provide additional quantitative information on magnetization processes which may be compared with predictions of proposed models of magnetization. The results of measurements of Λ and susceptibility χ for CrO_2 powders and sintered and melt-quenched rare earth-transition metal borides are presented. Conclusions about the magnetization mechanisms of these materials are discussed.

I. INTRODUCTION

Hysteresis in ferromagnets arises from domain processes which progress through states of metastable equilibrium. Examples are

(1) coherent or incoherent rotation of magnetization in single domain particles (Stoner and Wohlfarth[1]),
(2) pinning and unpinning of domain boundary walls (Gaunt[2,3]), and
(3) nucleation of domains of reverse magnetization (Chikazumi[4]).

Transitions from metastable to stable states may be achieved by the supply of activation energy, for example, by changing the applied field or by thermal agitation. At constant field, thermal activation alone may lead to significant variations in magnetization, amounting in some cases[5] to greater than 20% of the saturation magnetization in 10^2 s. Time dependence of magnetization under constant field conditions is referred to as magnetic viscosity or magnetic aftereffect. All ferromagnets subject to hysteresis exhibit time dependence of magnetization to a greater or lesser extent. As a general rule time dependent behavior is more pronounced in higher coercivity materials (Barbier[6]). It follows that the representation of the magnetic behavior by (M vs H) data is incomplete in that time dependence is neglected. Investigations of magnetic viscosity were described by Street and Woolley[7] in 1948 and Néel[8] in 1949 and led to phenomenological descriptions of time dependent behavior in terms of distributions of activation energies and fluctuation fields, respectively.

Estrin *et al.*[9] developed an alternative approach by analogy with the phenomenological description of plastic deformation of crystals. The magnet analog of plastic strain and stress were taken as the irreversible component of intensity of magnetization M_{irr} and the internal magnetic field H_i acting on the sample, respectively. The time dimension was introduced through $\dot{M}_{irr}$, the choice of which was determined by the Arrhenius relation

$$\dot{M}_{irr}(E)=\dot{M}_{irr}(E_0)\exp\left(-\frac{E(H)}{kT}\right), \tag{1}$$

from which

$$\ln \dot{M}_{irr}(E)=\ln \dot{M}_{irr}(E_0)-\frac{E(H)}{kT}, \tag{2}$$

where $\dot{M}_{irr}(E_0)$ is the rate of change of M_{irr} for activation energy $E(H)=0$.

Then, the constitutive equation of state is written in differential form:

$$dH_i=\frac{1}{\chi^i_{irr}}\,dM_{irr}+\Lambda\; d\,\ln(\dot{M}_{irr}), \tag{3}$$

where

$$\chi^i_{irr}=\left.\frac{\partial M_{irr}}{\partial H_i}\right|_{M_{irr}} \quad \text{and} \quad \Lambda=\left.\frac{\partial H_i}{\partial \ln \dot{M}_{irr}}\right|_{M_{irr}}. \tag{4}$$

Hence *isothermal* magnetization behavior may be represented by the movement of a point on a three-dimensional surface in $(M,H,\dot{M})$ space defined by Eq. (3), for which the intrinsic irreversible susceptibility χ^i_{irr} and Λ are required as functions of M. The functional dependence of both the intrinsic irreversible susceptibility χ^i_{irr} and Λ can be determined from magnetic viscosity measurements. In this paper the use of the constitutive equation to describe the field and time dependence of magnetization is discussed.

II. MAGNETIC VISCOSITY MEASUREMENTS

The constitutive equation may be applied to predict the behavior of magnetic systems subject to specified time constraints and initial conditions, e.g., predictions of the M vs H curves as the field is varied at uniform rates (conventional hysteresis curves).[10] Conventionally, measurements of magnetic viscosity are carried out at constant applied field, i.e., during the measurements, $\dot{H}_a=0$. The solution of Eq. (3) for M as a function of t requires the specification of the initial values of M_{irr} and $\dot{M}_{irr}$ at the origin of time for the measure-

 0021-8979/94/76(10)/6391/5/$6.00 © 1994 American Institute of Physics

ment. For simplicity, consider a specimen which has zero demagnetization factor. Then $\dot{H}_i=\dot{H}_a=0$ and the differentiation of Eq. (3) leads to

$$\dot{H}_i=\frac{1}{\chi'_{\rm irr}}\dot{M}_{\rm irr}+\Lambda\frac{\ddot{M}_{\rm irr}}{\dot{M}_{\rm irr}}=0. \tag{5}$$

The solution of Eq. (5), assuming that Λ and $\chi'_{\rm irr}$ are independent of M during a magnetic viscosity experiment, is

$$M_{\rm irr}=M_{\rm irr}(0)+\Lambda\chi'_{\rm irr}\ln(t+t_0), \tag{6}$$

where $M_{\rm irr}(0)$ is the value of $M_{\rm irr}$ at $t=0$ and $t_0=\Lambda\chi'_{\rm irr}/\dot{M}_{\rm irr}(0)$. $\dot{M}_{\rm irr}(0)$ is the rate of change of irreversible magnetization at $t=0$.

Equation (6) may be written as

$$M_{\rm irr}=\text{const}+S(0)\ln(t+t_0), \tag{7}$$

where

$$S(0)=\Lambda\chi'_{\rm irr}. \tag{8}$$

It is customary to present magnetic viscosity data in the form of $M(t)$ vs $\ln(t)$ graphs. It follows from Eq. (7) that $M(t)$ will be a linear function of $\ln(t)$ only for times of observation $t\gg t_0[=S/\dot{M}_{\rm irr}(0)]$ and when S is constant over the range of values of $M_{\rm irr}$ observed during a magnetic viscosity measurement. Nonlinear $M(t)$ vs $\ln(t)$ curves arising from both these causes have been observed.[5,11]

An expression for the parameter Λ, which has dimensions in Oersteds, introduced in the constitutive equation (3) may be obtained by differentiation of Eq. (2) with respect to H_i by

$$\left.\frac{\partial\ln\dot{M}_{\rm irr}}{\partial H_i}\right|_{M_{\rm irr}}=-\frac{1}{kT}\left.\frac{\partial E(H_i)}{\partial H_i}\right|_{M_{\rm irr}}=\frac{1}{\Lambda}, \tag{9}$$

i.e.,

$$\left.\frac{\partial E}{\partial H_i}\right|_{M_{\rm irr}}=-\frac{kT}{\Lambda}. \tag{10}$$

The slope of the $M_{\rm irr}$ vs $\ln(t+t_0)$ is written $S(0)$ to denote that it applies to measurements on specimens with demagnetizing factor $D=0$.

The parameter Λ is directly related to the field dependence of the activation energy required to activate the irreversible domain processes responsible for magnetic viscosity effects. The value of $(\partial E/\partial H_i)|_{M_{\rm irr}}$ is determined by the physical nature of the domain processes involved. Expressions for $\partial E/\partial H$ for different models of magnetization behavior may be calculated and compared with measured values of Λ. In Néel's model of viscosity[8] the effects of thermal energy on magnetization were represented by a fictitious fluctuation field H_f which is identical with the parameter Λ.

For example, consider a material consisting of aligned uniaxial ferromagnetic grains with spontaneous magnetization $M_{\rm spont}$ initially magnetized in the positive direction. If demagnetization proceeds by reversal of magnetization from nuclei of negative magnetization of fixed volume v then,

$$\frac{\partial E}{\partial H}=-vM_{\rm spont}. \tag{11}$$

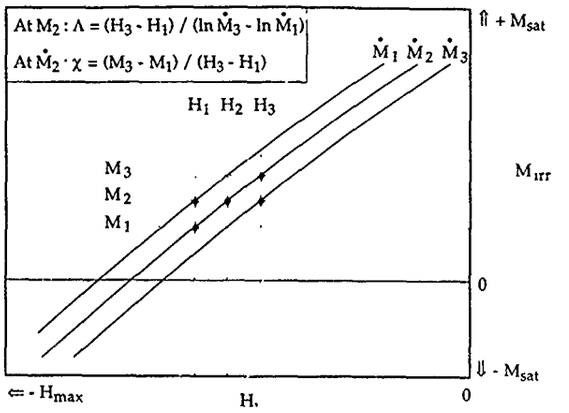

FIG. 1. Illustration of determination of Λ from experimental data.

From Eq. (10) for this idealized model,

$$v=\frac{kT}{\Lambda M_{\rm spont}}. \tag{12}$$

Thus, in principle, additional quantitative information about the mechanisms of magnetization may be obtained from measurements of Λ.

Cammarano[12] has pointed out the interrelation of Λ and χ which arises from consideration of Eq. (3) as a perfect differential, i.e.,

$$\frac{\partial}{\partial\ln\dot{M}_{\rm irr}}\left(\frac{1}{\chi'_{\rm irr}}\right)=\frac{\partial}{\partial M_{\rm irr}}(\Lambda). \tag{13}$$

It follows that if Λ is constant independent of M then $\chi'_{\rm irr}$ is independent of $\dot{M}_{\rm irr}$. A characteristic feature of many permanent magnet materials is that Λ is constant over large ranges of values of M. Also, within these ranges of M it has been shown that experimental values of $\chi'_{\rm irr}$ are independent of $\dot{M}_{\rm irr}$ as predicted by Eq. (13).[13]

III. FINDING Λ AND χ

Using the definitions given in Eq. (4), Λ and $\chi'_{\rm irr}$ may be evaluated from data obtained from magnetic viscosity experiments as illustrated in Fig. 1. In order to construct these graphs, which are almost invariably derived from results of measurements on specimens with nonzero demagnetization factors D, it is necessary to account for the demagnetizing fields, i.e., $H_i=H_a-DM_{\rm tot}$ where $M_{\rm tot}$ is the measured intensity of magnetization, and it is also required to derive values of $M_{\rm irr}$ as $(M_{\rm tot}-M_{\rm rev})$, where $M_{\rm rev}$ is the reversible component of intensity of magnetization.

The variation of magnetization for a specimen with demagnetization factor D may be derived from the constitutive equation as

$$M_{\rm tot}=M_{\rm tot}(0)+t'_0\dot{M}(0)\ln\left(1+\frac{t}{t'_0}\right), \tag{14}$$

where

$$t_0' = \frac{\Lambda \chi_{\rm irr}^i}{\dot{M}(0)} \frac{1}{(1+D\chi_{\rm tot}^i)}.$$

The values of the susceptibilities are obtained from slopes of the M vs H curves taken at constant $\dot{M}_{\rm irr}$.

The variation of $M_{\rm tot}$ is predicted to be a linear function of $\ln(t + t_0')$ but the slope

$$S(D) = \frac{\Lambda \chi_{\rm irr}^i}{1+D\chi_{\rm tot}^i} = \frac{S(0)}{1+D\chi_{\rm tot}^i} = \frac{\Lambda(\chi_{\rm tot}^a - \chi_{\rm rev}^a)}{1-D\chi_{\rm rev}^a}. \quad (15)$$

If $D\chi_{\rm rev}^a \ll 1$, then

$$\Lambda \doteq \frac{S(D)}{(\chi_{\rm tot}^a - \chi_{\rm rev}^a)}. \quad (16)$$

Equation (16) has been widely used to determine Λ. However, it follows from the above that unequivocal values of Λ will be obtained from Eq. (16) only if $\chi_{\rm tot}^a$ is evaluated as $(\partial M_{\rm tot}/\partial H_a)|_{\dot{M}_{\rm irr}}$.

The magnetic viscosity data required to construct graphs of the form shown in Fig. 1 may be obtained by measuring the time dependence of magnetization at different constant values of applied field on both the initial magnetization (first quadrant) curve and the demagnetization (second and third quadrant) curve. Measurements are made using a vibrating sample magnetometer under computer control. If a demagnetizing curve is to be measured, the sample is first exposed to a saturating field in the positive direction. Then the field is ramped to some negative value and held constant while the magnetic viscosity is recorded. A small recoil curve is then performed by ramping the field first in a positive direction by an amount which is small compared to Λ, then in a negative direction back to the measurement field. The field is then either ramped in a negative direction to the next measurement field and the process repeated (called a "multiple step per loop" experiment) or cycled through negative saturation and back to positive saturation before continuing to the next measurement field (called a "single step per loop" experiment). The small curves are used to estimate $\chi_{\rm rev}^a$ at the measurement field. The experimental technique is illustrated in Fig. 2.

Some care should be taken with sample preparation in the case of bulk materials as the condition of the surface and nonuniform magnetization may have a significant impact on the magnetic behavior.[14] It is best that measurements of bulk materials be performed on well polished spheres[15] so that the impact of the surface is minimized and the demagnetizing factor is known. Then Eq. (16) may be used to find Λ.

IV. RESULTS AND DISCUSSION

The mechanisms of magnetization in permanent magnets and in particulate recording media are of continuing interest in the search for improved materials. Comparisons may be made of the measured values of the parameters Λ and χ with those predicted by models of magnetic processes.

For example, measurements performed on a sample of acicular CrO_2 particles, commonly used as a recording medium, are shown in Fig. 3. The specimen, of volume 0.134 cm^3, was prepared by embedding 0.120 g of CrO_2 powder in

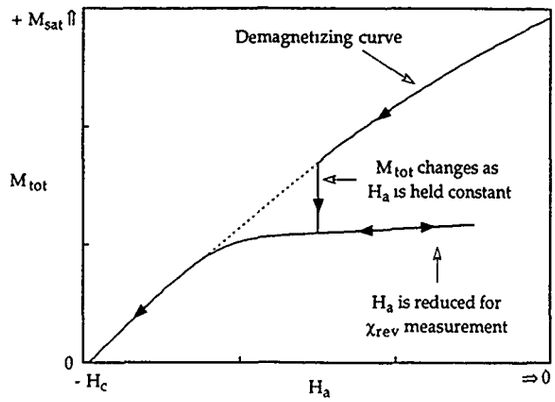

FIG. 2. Schematic of experimental technique. The magnetic viscosity is measured at a constant value of H_a for a period of time. Then the applied field is ramped towards zero by a small amount and the apparent reversible susceptibility determined from the slope of $M_{\rm tot}$ vs H_a. The field is then ramped in a negative direction to the next measurement field.

paraffin wax, hence the average density of CrO_2 in the specimen was 0.895 g cm^{-3}. The magnetization curve and the hysteresis curve for this sample are shown in Fig. 3(a). Figure 3(b) shows the values of Λ, calculated as described above, as a function of the specific magnetization σ during

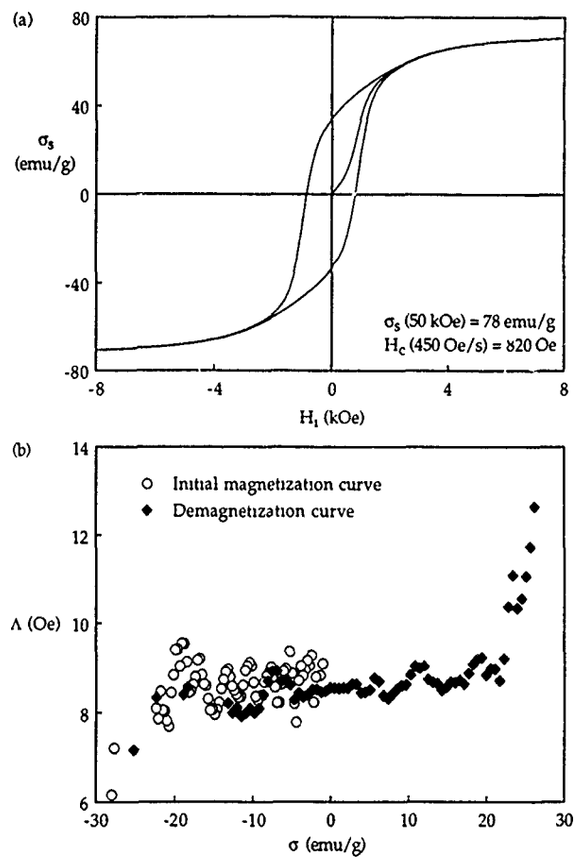

FIG. 3. (a) Magnetization curve and hysteresis curve for CrO_2 particles measured at room temperature with a maximum field of 50 kOe and a ramp of 450 Oe/s. (b) Λ vs specific magnetization for CrO_2 particles at room temperature with a maximum field of 50 kOe.

the magnetizing of the sample (from a thermally demagnetized state) and the demagnetization curve. Over the range of specific magnetization from +20 to −20 emu g^{-1} for the demagnetizing curve, the results reported here may be represented by a line $\Lambda=8.52+0.02\,\sigma$. Within experimental error, for initial magnetization Λ is independent of σ within the range 0 to −25 emu g^{-1} and its value is 8.7±0.4 Oe.

The CrO_2 particle volumes V, estimated from SEM images, are about 4×10^{-16} cm^3 compared with the value of 6.2×10^{-16} cm^3 reported by de Witte *et al.*[16] The activation volume v calculated from Eq. (12) using $\Lambda=8.6$ Oe and $M_{spont}=330$ G is 1.5×10^{-17} cm^3 which is about 4% of the particle volume. A similar ratio was obtained by de Witte *et al.*[16]

As another example, the hysteresis curve and the variation of Λ with M_{irr} for a polished 5 mm diameter sphere of sintered $Pr_2Fe_{14}B$ material are shown in Fig. 4. Over the range +400 to −400 G, $\Lambda=99.5-0.02\,M_{irr}$. Over this range the activation volume, calculated from Eq. (12) using $M_{spont}=1100$ G, $v=3.79\times10^{-19}+6.26\times10^{-23}\,M_{irr}$, has linear dimensions corresponding to about six crystalline unit cells.[17] Givord *et al.*[18] have related v to δ^3, where δ is the average domain-wall width in the material. For sintered permanent magnet materials of the Nd-Fe-B type initial magnetization involves the movement of domain boundary walls through individual grains. The discontinuous nature of this motion has been observed in the form of Barkhausen pulses.[19] Attempts to observe time dependent behavior here have been unsuccessful, presumably because of the small values of activation energy required to release the domain walls from pinning centers within the grains. Values of $\chi^i_{irr}|_{\dot{M}_{irr}}$ as functions of M_{irr} are shown in Fig. 4(c). The different symbols represent measurements made at different values of $\dot{M}_{irr}$. All the values lie on the same curve which, since Λ is almost independent of M_{irr}, is a consequence of Eq. (13).

Towards the ends of the ranges of magnetization it is not possible to make accurate measurements of Λ or χ^i_{irr} since the curves of constant $\dot{M}_{irr}$ converge and Eq. (4) becomes difficult to evaluate with certainty. It follows that for a given material there is a limited range of magnetization over which reliable measurements of Λ and χ^i_{irr} may be made.

The observations on both CrO_2 and $Pr_2Fe_{14}B$ show that Λ is approximately constant over a substantial part of the total change of intensity of magnetization. These results are consistent with the assumption that the major part of magnetization reversal in both materials results from activation of nuclei of reverse magnetization having volumes which are substantially independent of M. There is additional evidence to support this supposition in the case of $Pr_2Fe_{14}B$, specifically the ease with which the material may be magnetized and the dependence of coercivity on the maximum magnetizing field.[20]

The case of magnetization reversal of acicular particles has been considered by Sharrock.[21] He notes that theoretical studies by Schabes and Bertram[22] have concluded that a strong field applied to one end of an acicular particle tends to switch the magnetization of the entire particle by means of a propagating magnetic reversal—a microscopic analog of the classic Sixtus and Tonks experiment.[23] A mechanism of this kind would be consistent with the proposition that magnetization reversal may be initiated by thermal activation in a small volume of the particle.

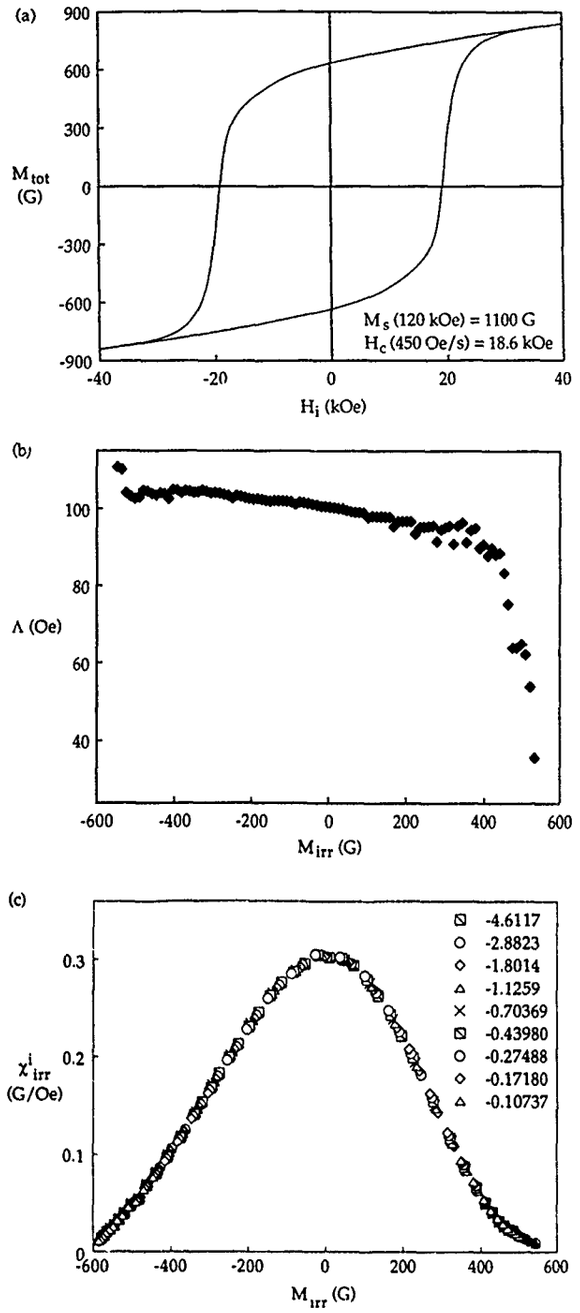

FIG. 4. Measurements of a sample of sintered $Pr_2Fe_{14}B$ at room temperature with a maximum field of 50 kOe and $H_a=450$ Oe/s. (a) A hysteresis curve. (b) Λ vs M_{irr}. (c) χ^i_{irr} vs M_{irr} at many values of $\dot{M}_{irr}$ as indicated in the legend.

V. SUMMARY

Time dependent magnetization may be analyzed in terms of a constitutive equation involving variables H_i, M_{irr} and two parameters $\Lambda(M_{irr})$ and $\chi^i_{irr}(M_{irr})$. The functions $\Lambda(M_{irr})$ and $\chi^i_{irr}(M_{irr})$ may be determined experimentally from mag-

netic viscosity experiments. For representative magnetic recording media (CrO_2) and high-energy permanent magnet materials (PrFeB) the $\Lambda(M_{irr})$s are found to be slowly varying functions of M_{irr} and the $\chi^i_{irr}(M_{irr})s$ are peaked around $M_{irr}=0$.

The constitutive equation with values of $\Lambda(M_{irr})$ and $\chi^i_{irr}(M_{irr})$ for a particular material may be used to analyze its time dependent magnetization with given external constraints, e.g., with an applied field ramped at a uniform rate or under impulsive field conditions.

Ubiquitous nonexponential decay: The effect of long-range couplings? (invited)

Many physical systems exhibit a dynamic response referred to either as slow relaxation, a quasilogarithmic time dependence, or a stretched exponential response. Historically this time dependence has been attributed to the presence of disorder which creates a distribution of relaxation times. In two papers [D. K. Lottis, E. Dan Dahlberg, J. Christner, J. I. Lee, R. Peterson, and R. White, J. Appl. Phys. **63**, 2920 (1988); D. K. Lottis, R. M. White, and E. Dan Dahlberg, Phys. Rev. Lett. **67**, 362 (1991)], we have shown that this time dependence can alternatively be explained to be a consequence of interactions or couplings. In the model, the interactions between relaxing spins, the dipole–dipole couplings, drive the system from an initial state towards equilibrium. As the system relaxes, the dipolar energy is reduced and the driving force diminishes. This process gives rise to the observed slow relaxation-time dependence in a very natural manner. To guarantee the absence of disorder, the model considers the dipolar coupling or interaction between relaxing spins with a mean-field approximation, the demagnetization field. Another feature observed in physical systems which the model explains is the nonmonotonic temperature dependence of the logarithmic decay slope. In addition to a description of the model, measurements to determine the presence of interactions in some of the systems will be discussed.

I. INTRODUCTION

A remarkable number of diverse physical systems exhibit the phenomenon which is referred to as slow relaxation.[1] The manifestation of this phenomenon is best explained graphically, as in Fig. 1, where the temporal decay of the remanent magnetization of an archetypal spin glass, AgMn, is shown. The system was prepared by cooling from high temperature to low temperatures with a magnetic field applied. This process results in a magnetization in the system known as the remanent magnetization. As can be seen, the field cooled magnetic state of the system relaxes after the removal of the cooling field with the remanent magnetization decaying quasilogarithmically with time. Other systems which exhibit this strange time dependence in response to an external stimulus include the trapped flux in superconductors,[2] the decay of the charge carriers in amorphous semiconductors,[3] and the strain fields or structure in glasses and polymers,[1] to name a few. That these systems are so diverse yet exhibit the same relaxation dynamics has confounded researchers in their quest for a simple explanation of this phenomenon.

We recently developed an explanation in which interactions or couplings between the relaxing entities are responsible for this seemingly ubiquitous time dependence.[4,5] In what follows, we will develop this view of slow relaxation starting with the simple Debye relaxation model. This will be followed by an extensive discussion of how it explains various observed features in physical systems. How to more fully test the applicability of the model is discussed at the end of the discussion session.

II. INTERACTION MODEL SYSTEM

As a starting point for understanding this phenomenon, it is useful to recall the expected response of a relaxing system, Debye relaxation. Debye relaxation can be understood by considering the relaxation of a collection of two level systems with an energy barrier (E_b) separating the levels as shown in Fig. 2. Each entity (one may call them either particles, spins, or moments) in the collection acts independently of all others. If the system of N particles is prepared

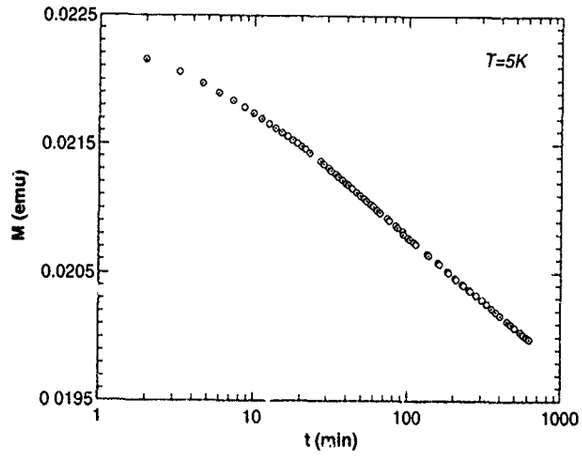

FIG. 1. An example of slow relaxation. The system is an alloy of 7.8% Mn in Ag The sample was cooled in a field of 3 kG which resulted in a remanent magnetization. The resulting decay was observed after removal of the cooling field.

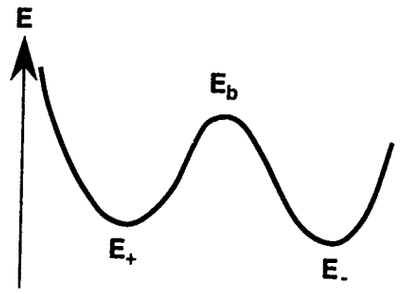

FIG. 2. A two level system with the energy minima separated by an energy barrier. This system provides a useful description for a number of physical systems and, in the absence of interactions, a collection of these systems with identical parameters exhibits an exponential time dependence.

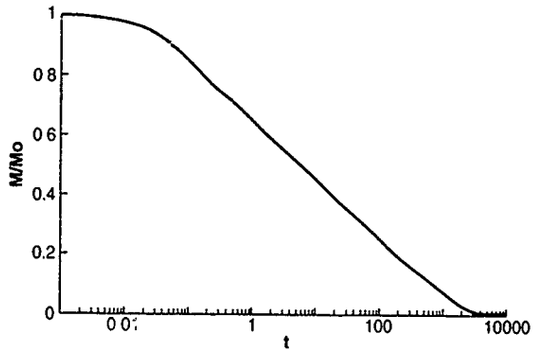

FIG. 3. The effects of disorder on exponential decay. This artificial relaxation curve is the result of averaging the relaxation curves for five exponential decays. The decay times are 0.1, 1, 10, 100, and 1000 s. Note that the quasilogarithmic time dependence is roughly a decade less than the number of decades in the average.

with all the particles in the higher energy state, it will relax to a distribution of particles in the higher energy state (or up state, E_+) and lower energy state (or down state, E_-) where the ratio of the number of particles in the up state to the down state will be given by the Boltzmann factor, $\exp(-\beta\Delta E)$, where β is k_BT and ΔE is (E_+-E_-). The dynamics of this relaxation process depend upon the attempt frequencies for the particles in the up and down states to try to get over the barrier, ω_+ and ω_-, respectively, in addition to the three energies defined above and in Fig. 2. By recognizing that the number of particles hopping over the barrier at any given instant from the up state to the down state depends upon the number of particles in that state at that instant, N_+, one is led to the differential equation for dN_+/dt,

$$\frac{dN_+}{dt} = -\omega_+ N_+ \exp[-\beta(E_b-E_+)] + \omega_- N_- \exp[-\beta(E_b-E_-)]. \quad (1)$$

This differential equation includes the possibility for particles in the down state to return to the up state. By assuming that the attempt frequencies ω_+ and ω_- are equal, and recognizing that the total number of particles $N=N_++N_-$, this equation can be rewritten as

$$\frac{dN_+}{dt} = -\omega N_+ \exp[-\beta(E_b-E_+)] + \omega(N-N_+)\exp[-\beta(E_b-E_-)]. \quad (2)$$

A solution to this differential equation leads to a decaying N_+ which is exponential in time, described by a single relaxation time τ; the τ is of the form $\tau=\omega^{-1}\exp(E_{\text{barrier}}/kT)$. This exponential decay is generally referred to as Debye relaxation. Although this derivation is very straightforward, as stated earlier, many systems do not obey this relationship.

Rather than abandon this simple model, it has long been the usual practice to assume distributions of energies E_+, E_-, and E_b which gives rise to a distribution of relaxation times, i.e., a distribution of τ's. As an example, a system containing five discreet τ's, each separated by a decade, provides a quasilogarithmic relaxation over four decades in time. To illustrate this, Fig. 3 is the relaxation of a system of particles with equal numbers of particles having relaxation times of 0.1, 1, 10, 100, and 1000 s. This may seem to be a rather large amount of disorder to be present in a physical system, but because the τ's are exponential functions of energy, this distribution corresponds to a spread in energy barriers of only one decade, approximately. Clearly, with this approach, most investigations of the relaxation processes of the various physical systems argue that the energy distribution is the measured entity. For one example of this approach, the temperature dependence of the relaxation rate has been used by the Grenoble spin-glass group to determine the energy distribution using $T\ln(t)$ scaling.[6]

An alternative view of slow relaxation was presented by some of us in a series of publications starting in 1988.[4,5] The fundamental premise for the model is that interactions, without any disorder, can result in the quasilogarithmic relaxation observed in so many physical systems.

The model system we developed consists of a plane of spins or magnetic moments with an anisotropy energy such that the energy minima are with the moments aligned perpendicular to the plane, i.e., the energy minima states are up and down states which are perpendicular to the plane. These spins interact through dipole–dipole interactions which are treated in a mean-field approximation. In the ground state this system contains no net magnetization, with one spin up for every spin down. When the system is saturated along the positive z axis, the demagnetizing field of the system will be along the negative z axis, driving the system back to equilibrium. Because the remanent field decreases as equilibrium is approached, the thermal energy needed to overcome the anisotropy energy barrier increases. This slows the relaxation process over time, leading to quasilogarithmic relaxation. As will be shown later, if there were no interactions the system would still relax but since the barriers remain at their maximum height, the decay, with an exponential time dependence, would take a much longer time.

In this model each moment has a uniaxial magnetic anisotropy energy of the form $-K_u v\cos^2(\phi)$, where v is the volume of the spin grain, ϕ the angle between the spin vector and the positive z axis, and K_u a positive constant. This system of particles fits the two level model presented earlier; E_+ and E_- occur at values of $\phi=0$ and π and are degenerate

at an energy $-K_u v$. Assuming coherent rotation of the individual magnetic moments, the energy barrier maximum E_b occurs at $\pi/2$ and has a value of 0.

In the presence of an external magnetic field applied along the $\phi=\pi$ direction (taken to be the negative z-axis direction), the magnetic energy $M_s H v \cos(\phi)$, where M_s is the saturation magnetization of the spin grain, must be considered in addition to the anisotropy energy. This gives a total energy per particle of

$$E=-K_u v \cos^2(\phi)+M_s H v \cos(\phi). \tag{3}$$

There are two important changes when a magnetic field is applied. First, the energy minima are no longer degenerate although they still occur for $\phi=0$ and π. Second, the energy barrier is no longer at $\phi=\pi/2$. The value of ϕ corresponding to E_b is obtained by the usual process of differentiating and setting the result to zero. Using the E_b determined above and the E_+ and E_- determined from $\phi=0$ and π, respectively, the differential equation which describes the dynamics of the moments is then given by

$$\frac{dN_+}{dt}=-\omega_+ N_+ e^{-\beta\left[\frac{v}{4K_u}(M_s H-2K_u)^2\right]}+\omega_- N_- e^{-\beta\left[\frac{v}{4K_u}(M_s H+2K_u)^2\right]}, \tag{4}$$

where N_+ is the number of spins pointing up, N_- the number of spins pointing down, ω_+ and ω_- the attempt frequencies, and $\beta=1/K_b T$. This expression is an explicit development of Eq. (2) and would therefore describe the usual Debye relaxation with an exponential time dependence as in Eq. (3). In general, the attempt frequencies for the + and − spins are functions of the applied magnetic field and are not equivalent. However, setting the ω_+ and ω_- to be equal and independent of the applied field introduces little error as the relaxation is dominated by the argument of the exponential, not the prefactor. Therefore in the remaining discussion they will be given by ω.

This expression, of course, neglects any coupling between the particles. In particular, the dipole–dipole coupling between the magnetic moments of the particles is lacking. As the particles are arranged in a plane and restricted by the anisotropy energy to orient perpendicular to the plane, the dipolar interaction energy would be a minimum for the case where the alternating spins are antiparallel to each other, i.e., a dipolar antiferromagnet. In order to guarantee the absence of disorder, the dipolar couplings between the spins can be treated with an average or mean-field approximation, the demagnetization field. For the limiting case of planar symmetry with the magnetization perpendicular to the plane, as is appropriate for the present situation, this gives a field of $-4\pi M$ where $M=M_s(N_+-N_-)/N$, where N is the total number of moments. Defining ΔN such that $N_{+(-)}=N/2+(-)\Delta N/2$ (so $\Delta N=N_+-N_-$), one obtains

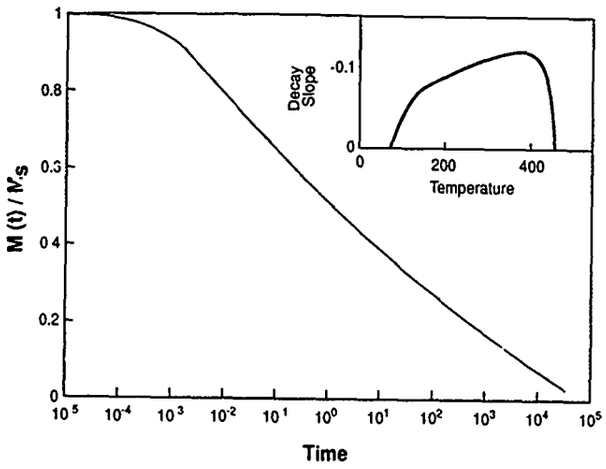

FIG. 4. An example of a slow decay of the model system given by Eq. (5). For this decay the relevant parameters are $K=5\times10$ ergs/cm, $M=200$ emu/cm, $T=300$ K, $v=2\times10^{-18}$ cm^3, and $\omega=\omega=2\times10^4$ s^{-1}. Note that the decay is measured over nine decades in time. The inset in the figure is the temperature dependence of the logarithmic slope of the decay taken at a time of 100 s. The nonmonotonic behavior of the slope is observed in magnetic and superconducting systems (see Refs. 12 and 2).

$$\frac{d\Delta N}{dt}=-\omega\left(\frac{N}{2}+\frac{\Delta N}{2}\right)\exp\left[-\frac{\beta v}{K_u}(2\pi M_s^2\Delta N/N-K_u)^2\right]+\omega\left(\frac{N}{2}-\frac{\Delta N}{2}\right)\exp\left[-\frac{\beta v}{Ku}(2\pi M_s^2\Delta N/N+K_u]^2\right]. \tag{5}$$

This nonlinear differential equation now describes the situation where the magnetic field of the spins are driving the system to a state with equal numbers of up and down spins. As the relaxation progresses, the field which drives the system decreases and thus the relaxation slows down. The result of this decreasing drive field is shown in Fig. 4. This figure is a numerical solution to the differential equation with the parameters listed in the figure caption. As shown, the relaxation rate slows down as the system relaxes. This quasilogarithmic time dependence occurs over six decades in time.

Several comments are necessary concerning this relaxation. The first is that although the data exhibit a quasilogarithmic time dependence, there is absolutely no disorder in the system. The couplings are treated in a mean-field approximation such that it is only the average field, $2\pi M_s\Delta N/N$, which enters the expression. The second is that various functional forms of slow dynamics must be considered, and while the data here is plotted against the log of time, it can also be fitted to a stretched exponential over several decades. Maybe without much surprise, it would appear that fitting to various functional forms of slow dynamics must be considered carefully before completely ascribing the behavior to a single one. Finally, for times longer than about 4×10^4 s, the slowly decaying function becomes exponential.[7] This long time regime can be understood by considering the limit in Eq. (4) where ΔN becomes small enough that the exponential is dominated by the K_u. In this limit, the differential equation becomes linear and the decay is expo-

nential. In the other time extreme, at short times, the initial time dependence is a result of the attempt frequency ω chosen for the generation of this data (about 10^9 s^{-1} for this figure).

The long time observation makes another point clear, that the relaxation is not slow; it is actually fast. If there were no interactions, the full energy barrier height would be present at all times; with interactions present, the barrier height is a function of the state of the system, but it is always less than it would be without the interactions. To further explain, if two otherwise identical systems, one with and one without couplings, were prepared in a state with all the spins parallel, they would both relax to a state with equal numbers of up and down spins. The main difference is that in the system without interactions there would be little decay until the time decade which is equivalent to the relaxation time over the full barrier height.[8]

III. DISCUSSION

To summarize the constraints of the model, we must note that it is for particles with constant magnetization, uniaxial anisotropy, and considers only coherent rotation for the magnetization reversal process in a single particle. Although the model system certainly exhibits a reasonable time dependence, it is necessary to show that the model does have a basis in fact with physical systems. We have previously shown that the decay of the remanent magnetization in thin films of CoCr can be fitted to the model over a limited magnetization decay range.[5] However, the volume of the magnetic entities, the only adjustable parameter in the fit, was several orders of magnitude smaller than that measured by electron microscopy. Although seemingly problematic, simple calculations show that this is a reasonable volume for a domain wall in one of the cobalt rich particles in the CoCr. This would indicate, at the very least, that the coherent rotation assumption is incorrect, a fact consistent with observed domain reversal in small particles.

Another feature which appears in many systems which exhibit this slow relaxation is a nonmonotonic decay slope. This feature is usually considered anomalous since one would expect any thermally activated process to accelerate at higher temperatures. However, the magnetization decay in superconductors,[2,9] ferrofluids,[10] and the CoCr alloys[11] exhibits a maximum as a function of temperature. This characteristic has been used as evidence that there is a collective transition of the decaying system. In the present model, this anomalous feature occurs in a very natural fashion for the following reason.

All experiments are constrained to measure the decay in a fixed time window. For example, in a SQUID magnetometer measurement, it may be that the measurements start approximately 1 min after a change in the external field. The measurements may then proceed for times up to hours or days. In any event, the time range of 1 min–1 day sets the measurement time window, and the decay slopes at all temperatures and initial states are defined in this window. At low temperatures, even though the interactions may be large, there is not enough thermal energy for the system to decay in the time window. At sufficiently high temperatures, the decay process is so rapid that, by the time the measurements start, the system has already relaxed, and again in the time window of the measurements, there is no measurable decay. Between these two extremes the decay rate measured in the time window goes through a maximum. If one could measure the initial decay rate, which occurs at zero time, it would continue to increase. The inset in Fig. 4 shows the temperature dependence of the decay slope from the model at the fixed time of 100 s (or a factor of $10^6\times$ the attempt frequency).

Another test of the applicability of the model is to confirm the presence of interactions. In the case of the magnetic aftereffect in ferromagnets, there was work which showed how the demagnetization factor altered the measured dynamics.[12] In this work, the larger the demagnetization factor, the more resistant the system was to being magnetized. This fact is consistent with Eq. (5) where the interaction or coupling term, $2\pi M_s \Delta N/N$, has a different numerical constant from 2π. In the case of superconductors, the frozen flux is associated with trapped vortices. Each vortex acts as a single magnetic dipole which can interact with the others via the dipole–dipole coupling. With only a very general argument, Tinkham used a similar rationale to get the logarithmic time dependence of the flux decay.[13]

For general applicability, one needs to determine the presence of interactions in these systems and their relevance to the magnetization process. We have previously used an approach developed by Wohlfarth[14] and Henkel[15] plotting the remanent magnetizations in what are referred to as Henkel plots. In that work[16] we were successful in showing how known interactions in a system, the perpendicular-to-the-plane demagnetization field, explained the observed remanances. It is important to note that Henkel plots may suffer from a nonrandom demagnetized state. Thus it would be best to work with a system which can be annealed prior to measurement. For this reason, and because it is an archetypal slow relaxation system, we have recently been studying the Henkel plots of spin glasses. Although in a preliminary stage, we note that all Henkel plots on the spin glass Ag:Mn indicate interactions are in fact present.[17]

A final comment to make is that the interactions in the model are treated to assure that disorder is not present and so the interactions must be responsible for any slow relaxation. In real systems, the interaction range is finite; therefore disorder is present. For example, starting from a saturated sample, after the very first spin or moment flips, its neighbors see a different dipolar field than the spins farther away. As the system evolves, this situation is exacerbated. So in the interaction driven model presented here, with the mean-field approximation, the slow relaxation occurs as a result of the couplings and disorder does not play a role. In real systems, with finite ranged interactions, some disorder is always present. The relevant question is then how important this disorder is compared to the interactions. To test this question, disorder must be included in the calculations, a process we have recently begun.[8]

It is important to point out that in addition to the work presented here, the model has been used by others with the inclusion of a domain-wall energy term, to model the magnetization process in magneto-optic media.[18]

As a final note, although the model developed here has focused on condensed-matter systems, there are other physical systems which are manifestly affected by interactions. A very simple way to understand how interactions can dominate the relaxation process is to consider radioactive decay. Most sophomore level modern physics textbooks derive the Debye relaxation law for β decay. This relaxation derivation is also applicable to other decays, such as U^{235} provided the decaying nuclei are well separated so that there are no interactions, i.e., independent decay. In the case of U^{235}, when the radioactive nuclei are close enough so that there are interactions, the decay process is changed considerably!

Mesoscopic model for the primary response of magnetic materials (invited)

R. V. Chamberlin
Department of Physics and Astronomy, Arizona State University, Tempe, Arizona 85287-1504

A model for the relaxation of thermal fluctuations is applied to the dynamical response of magnetic materials. Systems investigated include paramagnets, spin glasses, and ferromagnets. The key feature which distinguishes the model is that it describes the behavior of localized normal modes (e.g., magnons), *not* barrier hopping or domain-wall motion. Mathematical approximations to the model reproduce several previously used empirical formulas, such as the stretched exponential, power-law, and logarithmic time dependences, but the unapproximated model gives generally better agreement with observed response. Data of sufficient quality and range allow quantitative confirmation of all assumptions of the model. The model provides a common physical basis for observed magnetic after-effects, the magnitude and distribution of Landau–Lifshitz damping parameters, and $1/f$ noise.

I. INTRODUCTION

Despite the fact that all classical systems must ultimately relax exponentially, single relaxation rate (Debye-like) behavior is rarely observed in condensed matter. Nevertheless, some remarkably "universal" empirical expressions have been used to characterize the observed response from many different materials. Since 1854,[1] the most popular empirical expression for characterizing amorphous materials has been the Kohlrausch–Williams–Watts stretched exponential $M(t) \propto e^{-(t/\tau)^{\beta}}$. For crystals, the Curie–von Schweidler power law[2] $M(t) \propto t^{-\beta}$ is often preferred. For magnetic after-effects, the Néel[3,4] logarithmic time dependence $M(t) \propto \log(t/\tau)$ is also popular. These empirical expressions are simple mathematical formulas that give generally good agreement with a wide variety of measurements. Unfortunately, they are also common mathematical approximations to a wide variety of models; hence demonstrating agreement with these formulas tells you nothing about the physical mechanism of response. Furthermore, all of these formulas have infinite slope at $t=0$; hence they must only be approximations valid over a limited time range. Indeed, measurements over sufficient range invariably demonstrate deviations from such simple mathematical formulas.

Here we review a physical model for the observed response of condensed matter. The model is based on two assumptions: that nonexponential relaxation is due to a heterogeneous distribution of exponentially relaxing regions, and that these regions obey elementary thermodynamics. Various mathematical approximations to the model reproduce all of the previously used empirical formulas, but the unapproximated model gives generally better agreement with observed behavior. The model provides a physical description for the dynamical behavior of dozens of different systems including dielectric, structural, and thermal response in liquids, glasses, polymers, and crystals.[5–8] Here we focus on application to magnetic systems,[6,7,9–11] including resonance spectra, magnetic after-effects, and $1/f$ noise in paramagnets, spin glasses, and ferromagnets.

II. MESOSCOPIC MODEL

We assume that nonexponential response is due to a heterogeneous distribution of independently relaxing regions, that we call "dynamically correlated domains" (DCDs). Perhaps the earliest picture of dynamical heterogeneity was the 1907 Einstein model for the specific heat of solids, in which it was assumed that each atom was an independent harmonic oscillator.[12] In 1912, Debye recognized that, due to interactions between local sites, a solid can lower its energy by dynamical correlation into normal modes.[13] Examples of normal modes include phonons, polaritons, and magnons. In a perfect harmonic crystal, all normal modes are infinite plane waves; in real systems, however, some normal modes may become localized. Even in simulated perfect crystals, some normal modes are localized by assuming realistic (anharmonic) interactions, but direct observation often requires suppression of the plane-wave excitations.[8] In real systems, intrinsic inhomogeneities may augment the localization of normal modes.

Considerable evidence indicates that dynamical heterogeneity is common in condensed matter. In glass-forming liquids, four-dimensional (4D) NMR measurements[14] unambiguously establish that nonexponential relaxation is due to a heterogeneous distribution of independently relaxing regions (DCDs) that become homogeneous only after essentially all of the primary response is complete; typical diameters are found to be ~35 Å.[15] In spin glasses, neutron-scattering measurements,[16] and the 2D to 3D crossover,[17] indicate dynamical heterogeneity on a scale of 40–1000 Å. In EuS crystals, the thermal hysteresis of the remanent magnetization can only be explained by regions with distinct dynamical behavior, while the relaxation of this remanence quantitatively confirms a specific distribution of DCDs. It is important to emphasize that DCDs are related to a dynamical correlation length, *not* a region of static order. For example, in pure Fe at low temperatures, statically aligned regions are macroscopic, while the magnetic exchange length[18] $l_{ex} = \sqrt{A/M_s^2}$ (A is the anisotropy energy and M_s the saturation magnetization) gives $l_{ex} \sim 80$ Å, suggesting that each statically aligned region contains a myriad of independently relaxing DCDs, as is quantitatively confirmed from the observed magnetic response.

Generally, the relaxation rate of a DCD (w_s) will depend on its size s, where s is the number of responding particles (proportional to volume) in the domain. For a distribution of

 0021-8979/94/76(10)/6401/6/$6.00 © 1994 American Institute of Physics

sizes (n_s), and size-dependent initial response (M_s), the net relaxation is the weighted sum over all sizes: $M(t)=\Sigma_{s=0}^{\infty} n_s M_s e^{-tw_s}$. A change of variable ($w_s=1/\tau$) may be used to convert this sum to include the customary distribution of relaxation times, but we prefer to parameterize relaxation in terms of DCD size; since s is a thermodynamic variable, the expressions for n_s and M_s will be simpler.

The size dependences of n_s, M_s, and w_s are obtained by assuming simple thermodynamics. Thermodynamic extensivity suggests that the net response of a DCD should be proportional to its size, $M_s \propto s$. The central-limit theorem suggests that near thermodynamic equilibrium, DCDs should have a Gaussian size distribution $n_s \propto e^{-[(s-\bar{s})/\sigma]^2}$, where σ is the variance about an average size $\bar{s}$. Detailed balance suggests that, if the system is to approach thermodynamic equilibrium, relaxation rates between energy levels separated by an amount δE_s must vary as $w_s \propto e^{-\delta E_s/2k_BT}$. The key feature which distinguishes our approach is that we consider the relaxation of localized normal modes (e.g., magnons, phonons, polaritons, etc.), for which energy-level spacings are *inversely* proportional to size: $\delta E_s \propto 1/s$.

The fact that normal-mode energy-level spacings generally vary inversely proportional to size may be pictured in many ways. In a simple magnon picture,[19] the bandwidth (Δ) depends only on the local spin and exchange integral, independent of domain size, whereas the number of excitations that fill this bandwidth is proportional to the number of spins in the domain; hence $\delta E_s \sim \Delta/s$. In fact, this is the thermodynamic requirement that densities of states are extensive quantities, $\delta N/\delta E_s \propto s$, so that the energy spacing between adjacent ($\delta N=1$) levels is $\delta E_s \propto 1/s$. Of course, we are not the first to consider finite-size effects in condensed matter. In 1937, Fröhlich[20] calculated the energy spacing for quantized excitations in perfect spheres, and obtained the textbook expression $\delta E_s \propto 1/D^2 \propto 1/s^{2/3}$. In 1962, Kubo[21] recognized that imperfections in real systems break the degeneracies inherent in perfect spheres, yielding $\delta E_s \propto 1/s$. Thus $\delta E_s \propto 1/s$ for mesoscopic systems governed by either quantum mechanics, or thermodynamics. We implement this requirement to obtain relaxation rates that vary exponentially with *inverse* size.

Combining the ingredients of finite-size thermodynamics, using $x=s/\sigma$ and converting the sum over all sizes to an integral, the net relaxation of an ergodic system (e.g., rapidly relaxing crystal or liquid) becomes

$$M(t)=M_0\int_0^{\infty} dx\, x e^{-(x-\tilde{x})^2} e^{-tw_\infty e^{-C/x}}. \tag{1}$$

Equation (1) has four adjustable parameters: the prefactor (M_0) accommodates the magnitude of response, the asymptotic relaxation rate (w_∞) governs the time scale of relaxation, the correlation coefficient (C) controls the spectral width, whereas the scaled average size ($\tilde{x}=\bar{s}/\sigma$) influences the magnitude, time scale, and width of response. Note[7] for simple relaxation between adjacent energy levels, detailed balance yields $C<0$, and Eq. (1) may be approximated by the stretched exponential with w_∞ the slowest relaxation rate, whereas if relaxation requires activation over an intermediate energy barrier, $C>0$ (see Sec. IV) and Eq. (1) may be approximated by a power law with w_∞ the fastest relaxation rate.

In principal, both $\tilde{x}$ and C could adjust the spectral shape of Eq. (1). Experimentally, however, for all ergodic systems that we have examined, the ratio ($\tilde{x}/C$) is constant, independent of temperature. For example, from the dielectric susceptibility of glass-forming salol over 24 K we find[7] $\tilde{x}/C=-0.182\pm0.003$. Furthermore, we find a similar ratio from dozens of measurements on many different glass-forming liquids, and even $\tilde{x}/C=0.197\pm0.02$ from magnetic relaxation in single-crystal Fe.[11] We now speculate as to a possible reason for this "universality."

A specific expression for the correlation coefficient (C) in the relaxation rate ($w_s=w_\infty e^{-C\sigma/s}$) may be obtained by combining detailed balance with Fermi's golden rule. The transition rate from energy E_i to E_f is $w_{i\to f} \propto |V_{i\to f}|^2 \times \sqrt{(n_f/n_i)}$, where $V_{i\to f}$ ($=V_{f\to i}$) is a matrix element that connects the initial and final states, and $n_f/n_i = e^{-(E_f-E_i)/k_BT}$ is the factor that ensures detailed balance. At normal temperatures ($k_BT \gg \delta E_s \sim \Delta/\bar{s}$), thermal fluctuations strongly influence transitions between levels, so that the matrix element is dominated by the probability that a fluctuation will cause the initial and final energies to overlap, $V_{i\to f} \propto P_{i=f}$. Near thermal equilibrium[22] $P_{i=f} \propto \exp[-(E_f-E_i)^2 F''(E_e)/2k_BT]$, where $F''(E_e)=sf''(E_e)$ and $f''(E_e)$ is the Helmholtz free-energy curvature *per particle* about the equilibrium energy. The net relaxation rate into equilibrium is obtained by integrating over all possible initial states

$$W_s \sim \int_{-\infty}^{\infty} dE_i |P_{i=e}|^2 \sqrt{(n_e/n_i)} \propto e^{1/[16sf''(E_e)k_BT]},$$

yielding[7] $C=-1/[16\sigma f''(E_e)k_BT]$, so $\tilde{x}/C=-16\bar{s}f''(E_e)k_BT$. As expected for response that is governed by thermal fluctuations, the relaxation rate is independent of Δ, consistent with a ratio of shape parameters in Eq. (1) that does not depend on the details of interactions in a substance.

Some thermodynamic identities can be used to simplify $\tilde{x}/C$. The free-energy curvature of an average-sized DCD may be written[23]

$$\bar{s}f''(E) \equiv (\partial^2/\partial E^2)(E-TS) = -T(\partial^2 S/\partial E^2) = 1/(TC_V)$$

(where $C_V=\partial E/\partial T$ is the "heat capacity" of an average-sized DCD due to excitations that contribute to observed response), so that $\tilde{x}/C=-16k_B/C_V$. For a system of N classical particles, the law of Dulong and Petit gives $\tilde{x}/C=-16/3N$, leaving no explicit temperature dependence. Of course, with decreasing temperature, the heat capacity per particle diminishes, $C_V<3k_B$, while the number of particles in an average-sized DCD increases, $\bar{s}>N$. Evidently, since $\tilde{x}/C$ is found to be constant, the effective number of classical degrees of freedom must not change, $\bar{s}c_V=3Nk_B$. Finally, we speculate that N corresponds to the minimum number of classical particles necessary to support nontrivial excitations in three dimensions, $N\sim 3^3$, which gives $\tilde{x}/C \approx -0.198$. Empirically, regardless of interpretation, Eq. (1) with $\tilde{x}/|C| = 0.19\pm0.02$ provides excellent agreement with observed re-

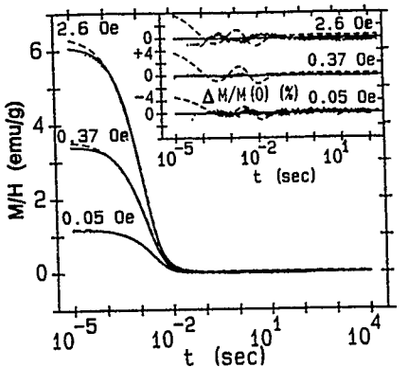

FIG. 1. Relaxation of the remanent magnetization in a single-crystal whisker of Fe at 4.2 K after removing three different fields. Dashed curves are best fits to the data using the stretched exponential function. Solid curves are best fits to the data using Eq. (1) with $\tilde{x}/C=0.20$. Inset: deviation between the data, model function (solid line at each origin), and stretched exponential.

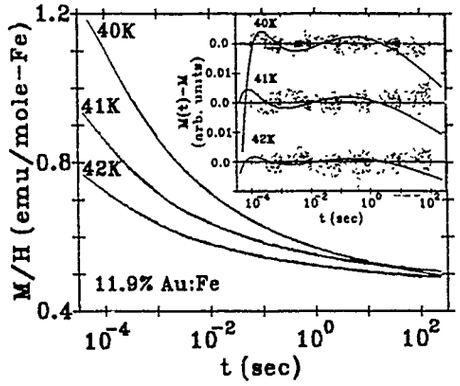

FIG. 2. Relaxation of the remanent magnetization in an 11.9%Au:Fe sample at three temperatures above the spin-glass transition $T_g=39$ K. Solid curves are the best fits to the data using Eq. (2). Inset: deviation between the data, model function (solid line at each origin), and simple power law.

sponse from a wide variety of ergodic systems with only one parameter governing the width and entire shape of the response.

Nonergodic systems (e.g., slowly relaxing crystals or glasses) have quenched (local) randomness that may be characterized by the Poisson-like distribution from percolation theory: $sn_s \propto s^{1-\theta}e^{-(C's)^{\zeta}}$. For isotropic excitations in highly correlated ($p>p_c$) systems, the size-scaling exponents are $1-\theta=10/9$ and $\zeta=2/3$, with $C' \propto |p-p_c|^{2.2}$. Using $x=C's$, the net relaxation of a nonergodic system becomes

$$M(t)=M_0\int_0^{\infty} dx\, x^{10/9}e^{-x^{2/3}}e^{-tw_{\infty}e^{-C/x}}. \tag{2}$$

Equation (2) has only three adjustable parameters: again M_0 accommodates the magnitude of response and w_{∞} governs the time scale of relaxation, while the width and entire shape of the response is controlled by the single parameter C. For example, if $C=0$ the relaxation is size independent, yielding single relaxation rate (Debye-like) behavior, whereas if $|C|\gg 1$, the spectral width is extremely broad. Here, for response that is governed by thermal fluctuations, the correlation coefficient is given by $C=-C'/[16f''(E_e)k_BT]$.

III. EXPERIMENTAL EVIDENCE FOR THE MODEL

Measurements of magnetic response were made using a SQUID magnetometer. Features of the magnetometer include a nonconducting sample region (to minimize eddy-current effects), and a critically damped low-impedance solenoid for fields (H) of 0.05–70 Oe that can be removed within 5 μs. With a standard dc SQUID sensor coupled to a high-speed voltmeter, the magnetometer is capable of measurements from 10^{-5} to 10^4 s after removing H.

Figure 1 shows the relaxation of the primary magnetic response in a single-crystal whisker of Fe at 4.2 K after removing three different fields.[11] Best fits using the stretched exponential show significant deviations from the observed behavior, while Eq. (1) with $\tilde{x}/|C|=0.20$ gives excellent agreement. Figure 2 shows the magnetic relaxation in an 11.9% Au:Fe sample at three temperatures above the spin-glass transition $T_g=39$ K.[9] The inset shows that a simple power law gives good agreement over four or five orders of magnitude in time, but when the entire range of data are considered, Eq. (2) gives significantly better agreement. Figure 3 shows magnetic relaxation in a single crystal of EuS at three temperatures below the Curie transition $T_c=16.57$ K.[10] Linear fits to the data show that the relaxation is approximately logarithmic, but again, best fits using Eq. (2) are significantly better.

We have documented statistical, qualitative, and quantitative evidence for the validity of the mesoscopic model. Statistically, compared to previously proposed response functions, in addition to giving superior agreement with observed magnetic response from paramagnets, spin glasses, and ferromagnets, the model also provides better agreement with the observed dielectric, structural, and thermal response from dozens of liquids, glasses, polymers, and crystals.[5] Furthermore, no other previously proposed response function can fully account for the qualitative behavior of the high-frequency dielectric absorption in glass-forming liquids.[7]

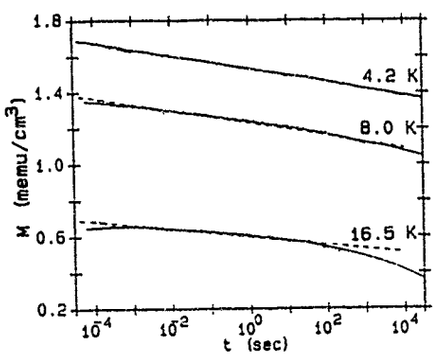

FIG. 3 Relaxation of the remanent magnetization in single-crystal EuS at three temperatures below the Curie transition $T_c=16.57$ K. Dashed lines are best logarithmic fits to the data. Solid curves are best fits to the data using Eq. (2).

Most convincing, however, is the quantitative confirmation of the size-scaling exponents.

The size distribution used in Eq. (1) [$xn_x \propto x^{1-\theta}e^{-(x^\zeta-\bar{x})^2}$] assumes thermodynamic extensivity ($1-\theta=1$) and that DCD size obeys the central-limit theorem ($\zeta=1$). For data of sufficient quality and range, it is possible to release these exponents as additional adjustable parameters, so that the only place where size scaling is fixed is in the exponent of the relaxation rate, $w_x=w_\infty e^{-Cx^\beta}$ with $\beta=-1$. For example, if response was a surface effect or if domain radius was the appropriate parameter of randomness, one would expect $1-\theta=2/3$ or $\zeta=1/3$, respectively. From magnetic relaxation in single-crystal whiskers of Fe, we find $1-\theta=0.92\pm0.12$ and $\zeta=0.99\pm0.08$, quantitatively confirming all assumptions of the model: volume response $1-\theta=1$, random DCD sizes $\zeta=1$, *and* relaxation rates vary exponentially with inverse size $\beta=-1$; otherwise $1-\theta$ and ζ would adjust to compensate. Similarly, the size distribution used in Eq. (2) ($xn_x \propto x^{1-\theta}e^{-x^\zeta}$) assumes the Poisson-like size distribution from percolation theory ($\zeta=2/3$) and thermodynamic extensivity ($1-\theta=10/9$). From magnetic relaxation in single-crystal EuS we find $1-\theta=1.10\pm0.02$ and $\zeta=0.669\pm0.004$, again quantitatively confirming all assumptions of the model. Alternatively, within experimental uncertainty, Eqs. (1) and (2) are the correct response functions for these data.

IV. APPLICATIONS OF THE MODEL

Since the model provides a physical mechanism for the primary response of condensed matter, it may be used to interpret a variety of observed behavior. For example, the model has been used to identify ergodicity in amorphous systems, and provide an explanation for observed non-Arrhenius temperature dependences of relaxation rates.[8] Here we will focus on application to magnetic materials, specifically the observed magnitude and distribution of Landau–Lifshitz damping parameters, and $1/f$ magnetic noise.

When $C>0$, the size-dependent relaxation rate ($w_x=w_\infty e^{-C/x}$) implies that larger DCDs have faster relaxation rates. $C>0$ (as is observed for the primary magnetic response of Fe) can only occur if relaxation requires activation over an intermediate barrier, where $f''(E)<0$ gives $C\propto 1/f''(E)>0$. Qualitatively, large DCDs have many degrees of freedom that facilitate traversal of a potential barrier, whereas small domains are relatively rigid, and hence require many attempts before relaxing. In the Landau–Lifshitz formalism, a fundamental attempt frequency is the Larmor precession rate $\omega=|\gamma|B$, where $|\gamma|=17.6\times10^6$ (rad/s)/G for pure electron spins.[24] If this precession is related to the asymptotic relaxation rate $w_\infty\sim|\gamma|B$, then $w_{\bar{x}}=w_\infty e^{-C/\bar{x}}$ gives a connection between the gyromagnetic precession and average relaxation rates, providing a physical explanation for the Landau–Lifshitz damping parameter $\alpha\approx w_{\bar{x}}/w_\infty=e^{-C/\bar{x}}$. Indeed, from SQUID measurements of magnetic relaxation in Fe we find $\alpha\approx e^{-1/(0.197\pm0.02)}\approx0.006$, consistent with the damping parameter found from ferromagnetic-resonance linewidths at much higher frequencies: $\delta B=32$ Oe at $f_0=9.2$ GHz and $\delta B=158$ Oe at 36.2 GHz[25] give $\alpha=(\delta B)|\gamma|/(4\pi f_0)\approx0.005$. Thus the mesoscopic model provides an explanation for both the magnitude, and distribution, of Landau–Lifshitz damping parameters in Fe. Furthermore, approximately half of the commercially available ferrite materials[26] have damping parameters consistent with $\alpha\approx e^{-1/(0.19\pm0.02)}$. However, other materials have quite different damping parameters, suggestive of alternative relaxation mechanisms. Most notably, highly polished YIG crystals have the lowest microwave loss of any material, with $\alpha\sim10^{-4}$. Such extraordinarily low loss is attributable[27] to an absence of orbital contributions, and nearly spherical charge distribution, for the ferric ions in YIG; thus the spins are decoupled from the "universal" lattice vibrations which govern the relaxation in many other materials.

Another common property that may be attributed to mesoscopic thermal fluctuations is $1/f$ noise. Electrical $1/f$ noise has been known for many years,[28] but magnetic measurements of sample noise have only been possible with recent advancements in SQUID magnetometry.[29] Within the fluctuation dissipation theorem, noise is proportional to $1/f$ times the out-of-phase (absorption) component of response, $\overline{M^2}(f)=k_BT\chi''(f)/\pi^2 f$. Thus only systems with infinitely broad absorption peaks (corresponding to logarithmic time relaxation) will exhibit purely $1/f$ noise. Of course, no physical system can have an infinitely broad absorption peak, as evidenced by deviations from logarithmic relaxation when measured over sufficient time range; similar deviations must also occur in $1/f$ noise. Indeed, magnetic noise spectra[29] from spin glasses exhibit very broad, *asymmetrical* deviations from $1/f$ behavior, consistent with relaxation rates that vary exponentially with *inverse* size, which is the key feature of our model. Furthermore, deviations from $1/f$ behavior become more conspicuous near T_g, similar to the increased deviations from logarithmic relaxation observed in EuS near T_c. Using Eq. (2), $1/f$ times the out-of-phase component of the Fourier transform of $-dM(t)/dt$ yields a specific expression for the equivalent noise spectrum:

$$\overline{M^2}(f)=\frac{2k_BT}{\pi}M_0\int_0^\infty dx\, x^{10/9}e^{-x^{2/3}}\frac{1/w_x}{1+(2\pi f/w_x)^2}, \tag{3}$$

where $w_x=w_\infty e^{-C/x}$. Although electrical measurements on small samples have shown that $1/f$ noise is often caused by a distribution of independently relaxing regions,[30] available magnetic measurements have not allowed quantitative confirmation of Eq. (3). Nevertheless, magnetic relaxation that is characterized by Eq. (1) or (2) may yield apparent $1/f$ noise. For example, Fig. 4 shows equivalent noise spectra of ferromagnetic EuS, demonstrating qualitative agreement with measured noise spectra,[29] and the difficulty in distinguishing from hypothetical $1/f$ behavior.

V. CONTRAST WITH PREVIOUS PICTURES

Domain-wall motion is an established mechanism of magnetic response. Usually, wall motion occurs on short time scales ($<10^{-5}$ s), outside the time window of our SQUID magnetometer, but by extrapolating the observed response to $t=0$, an estimate of the relative contribution of

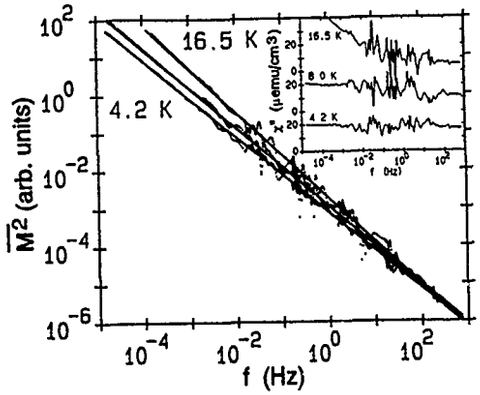

FIG. 4. Equivalent noise spectra in ferromagnetic EuS, from the imaginary part of the susceptibility (inset), as determined from the data of Fig. 3. Solid lines are the best power-law fits to the data [$\overline{M^2}(f) \propto 1/f^{\beta}$], yielding β of 1.007, 1.046, and 1.14 at temperatures of 4.2, 8.0, and 16.5 K, respectively.

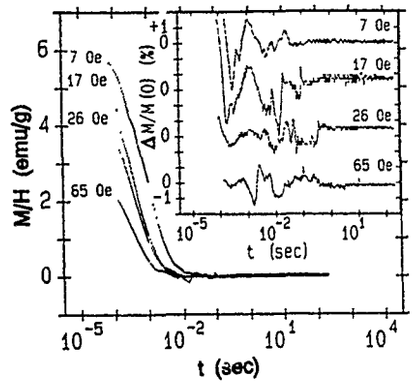

FIG. 6. Relaxation of the remanent magnetization in Fe at 4.2 K after removing four relatively large fields. Inset: deviation of the data from Eq. (1), showing small jumps and spikes (Barkhausen noise) due to domain-wall adjustments during the primary magnon relaxation.

such fast response mechanisms can be obtained. As shown in Fig. 5 for the magnetic relaxation of Fe, after removing small fields ($H<0.1$ Oe), the response accounted for by our mesoscopic model is only about 20% of the initial (infield) response; 80% of the initial response occurs before 10^{-5} s, presumably due to domain-wall motion. However, with increasing field the fraction of slow response increases, until $H>1$ Oe where essentially 100% of the initial response can be accounted for by magnon relaxation over the available time window. At still higher fields ($H>3$ Oe, Fig. 6), relatively small jumps and spikes appear, indicative of minor domain-wall adjustments (Barkhausen noise) during the otherwise smooth magnon response. Evidently, the magnetic relaxation is so slow that domain walls (which traverse the sample in $<10^{-5}$ s) cannot carry any magnetization reversal. Instead, these "proto-walls" merely break the degeneracy between regions where magnons will eventually relax the spins into distinct static alignments; magnetization evolves smoothly from saturation without any significant contribution from wall motion.

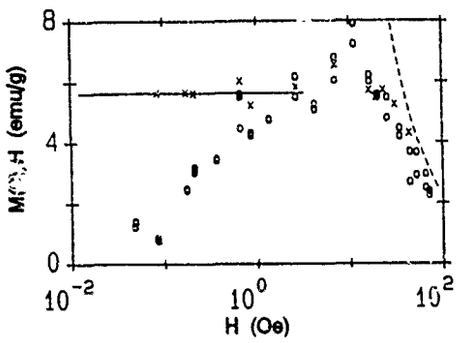

FIG. 5. Field dependence of initial (in field) susceptibility M/H (×) from before H was removed, and extrapolated initial response $M(0)/H$ (□) from Eq. (1), of an Fe whisker at 4.2 K. For $H<0.1$ Oe, only 20% of the in-field response is accounted for by Eq. (1). For $H>1$ Oe, essentially 100% of the in field response can be accounted for by magnon relaxation over the available time window.

Many investigators have considered slow relaxation due to coherent domain rotation via barrier hopping. Such coherent domains are assumed to be rigidly aligned in a common direction, with only a few degrees of freedom, similar to a rigid rod governed by classical mechanics. Generally, barrier heights are assumed to increase with increasing domain size, $\delta E_s \propto s^{\beta}$ with $\beta>0$. In contrast, we consider relaxation of low-energy internal degrees of freedom (e.g., magnons) governed by thermodynamics, for which $\beta=-1$. Our approach has some favorable features. First, even at low temperatures in highly ordered ferromagnets, where rigidly aligned spin behavior might be expected to occur, magnons are found to govern the static magnetization, hence they should also contribute to the dynamical properties. Second, it is generally assumed that slow relaxation of a rigidly aligned domain requires activation over an intermediate energy barrier. In contrast, for $C<0$, normal-mode relaxation involves simple transitions between adjacent energy levels, thus requiring only detailed balance. (Although some systems do have $C>0$, indicating relaxation over an intermediate barrier, since $\delta E_s \propto s^{\beta}$ with $\beta=-1$, large DCDs relax faster than small DCDs, as expected for systems with internal degrees of freedom.) Third, since $w_x \propto e^{-C/x}$, there is considerable asymmetry in the relation between domain size and relaxation rate, so that relatively symmetrical, and hence more physically reasonable, size distributions (e.g., Gaussian or percolation) provide good agreement with most frequently observed asymmetrical responses. Finally, within experimental uncertainty for a variety of systems, $\beta=-1$ has been confirmed quantitatively.

VI. CONCLUSIONS

A model is presented that provides a physical description for the primary response of condensed matter. The model is based on the assumption that nonexponential response is due to a heterogeneous distribution of independently relaxing regions, and that these regions obey simple thermodynamics. The model gives superior agreement with the observed response from dozens of different materials, including magnetic after-effects in paramagnets, spin glasses, and ferro-

magnets. Data of sufficient quality and range, including SQUID measurements of single-crystal EuS and whiskers of Fe over nine orders of magnitude in time, allow quantitative confirmation of all aspects of the model. The model provides a common physical basis for several previously used empirical expressions, such as the stretched exponential, power-law, and logarithmic time dependences. Furthermore, the model provides a physical explanation for other properties commonly found in the dynamical response of magnetic materials, including the magnitude and distribution of Landau–Lifshitz damping parameters, and $1/f$ noise.

The development of a number of models of slow relaxation in magnetic materials is reviewed. A phenomenological theory based on the intrinsic energy barrier is shown to explain the form of time dependence of the magnetization, including the logarithmic time dependence observed for systems with a relatively wide distribution of energy barriers. This formulation gives rise to useful analytical results which give generally good qualitative agreement with experiment. The slow relaxation is related to the irreversible magnetic behavior via a fictitious fluctuation field H_f which itself determines a quantity called the activation volume V_{act}. Both H_f and V_{act} are related to the magnetization reversal process. For granular materials V_{act} is generally smaller than the grain size. Computer simulations based on the Monte Carlo method are applied to the investigation of the behavior of thin films with perpendicular anisotropy. Detailed comparisons of the simulation with experimental data demonstrate the relationship between V_{act} and the micromagnetic magnetization reversal mode. Some recent models introducing thermal agitation into the micromagnetic formalism are discussed.

I. INTRODUCTION

In general, models of magnetization reversal proceed by determining the minimum energy state and following its evolution until at some field the minimum disappears and an irreversible transition to a new state occurs. This approach is valid for magnetization reversal at absolute zero temperature. However, at a finite temperature a different phenomenology, involving determination of the energy barriers, must be adopted. A considerable amount of work has been carried out using a simple formalism based on a distribution of energy barriers. This approach has proved extremely useful in producing analytical results which give generally good qualitative agreement with experiment, thereby illuminating the physical processes involved. Here we start by outlining the energy barrier distribution formalism and introducing the concepts of the fluctuation field and activation volume. These highlight the major deficiencies of the phenomenology, which are principally the neglect of the detailed nature of the magnetization reversal mechanisms and interaction effects. The remainder of the article is devoted to consideration of computational studies of slow relaxation.

II. ANALYTICAL MODELS FOR TIME DEPENDENCE

In magnetic materials the time-dependence effects arise due to the fact that there is a finite relaxation time τ required for the magnetization vector to rotate from one minimum to another. The origin of the energy barrier is a material property and since its magnitude depends on experimental conditions such as magnetic field, these factors govern the probability of thermally activated transitions. Almost any phenomenology shows that the probability of a transition is given by[1]

$$\tau^{-1}=f_0 \exp(-\Delta E/kT), \tag{1}$$

where f_0 is the attempt frequency which depends on the properties of the material and ΔE is the height of the energy barrier for reversal.

In general the time variation of the magnetization of any system can be characterized by a simple differential equation:

$$\frac{dM(t)}{dt}=-\frac{M(t)-M_e}{\tau}, \tag{2}$$

where $M_e=M(t=\infty)$ is the equilibrium magnetization. In principle the time variation of magnetization can be described by solving Eq. (2).

For the case of a noninteracting system which contains a distribution of energy barriers the solution of Eq. (2) gives

$$M(t)=B+A\int_0^\infty e^{-t/\tau(y)}f(y)dy, \tag{3}$$

where $B=M(\infty)$ and $A=M(t=0)-M(\infty)$ are time-independent constants. $f(y)$ is the distribution of energy barriers and $y=\Delta E/\Delta E_m$ is the reduced energy barrier relative to the average barrier ΔE_m of the system. $\tau^{-1}(y)=f_0\exp(-\alpha y)$ is the inverse of the relaxation time and $\alpha=\Delta E_m/kT$. According to Eq. (3) the time-dependent behavior is most sensitive to two parameters which characterize the relevant distribution of energy barriers for the system, i.e., the average energy barrier of the system ΔE_m and the width of the distribution.

Figure 1 shows the exact calculations of the integral in Eq. (3) at different values of α for a narrow ($\sigma=0.18$) and distribution of energy barriers. In these calculations a log normal distribution of energy barriers was used. The change in the values of α can arise from temperature changes or magnetic field changes. These calculations show that for a narrow distribution of energy barriers the decays exhibit non-

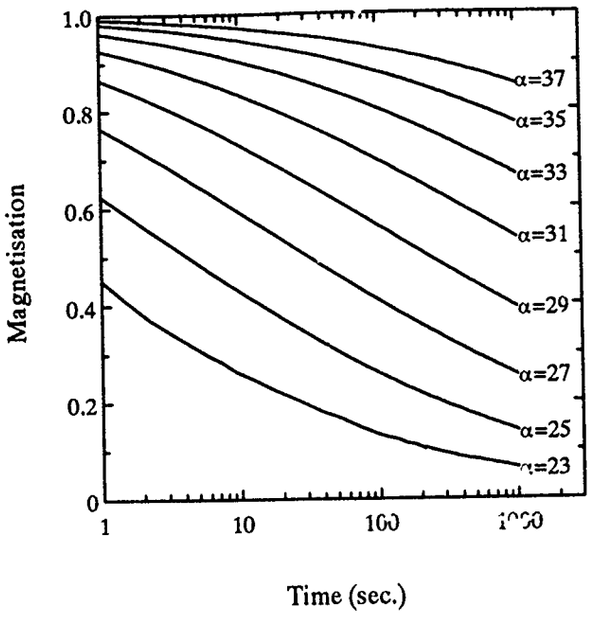

FIG. 1. The time variation of magnetization at different values of α for a narrow distribution of energy barriers (σ=0.18).

linear logarithmic time-dependent behavior. For a wide distribution of energy barriers a $\ln(t)$ law is a good approximation over the range of time examined.

In order to understand the physical interpretation of these results and examine the role of the energy barrier distribution, it is possible to simplify the integral in Eq. (3) using the critical energy barrier of activation (ΔE_c). This critical barrier can be defined in such a way that activation over barriers lower than ΔE_c happens so quickly that $e^{-t/\tau(y<y_c)} \simeq 0$. With $e^{-t/\tau} \simeq 1$ for $y > y_c$ Eq. (3) becomes

$$M(t) = B + A - A \int_0^{y_c(t)} f(y)\,dy, \tag{4}$$

where $y_c = \Delta E_c / \Delta E_m$ is the reduced critical barrier for reversal and is given using Eq. (1) by

$$y_c = \frac{1}{\alpha} \ln(t f_0). \tag{5}$$

According to Eq. (4) the rate of change of $M(t)$ with $\ln(t)$ is given by

$$\frac{dM(t)}{d\,\ln(t)} = -\frac{A}{\alpha} f(y_c). \tag{6}$$

This result explains the shapes of any $M(t)$ vs $\ln(t)$ curve where the slope of the $M(t)$ vs $\ln(t)$ curve at any instant is directly linked to the behavior of the distribution function about the critical barrier above which thermal activation is taking place.[2] Thus the data shown in Fig. 1 can be explained as being due to significant variation of $f(y_c)$ during the time-dependent process. In the case of a wide distribution of energy barriers, the variation of $M(t)$ vs $\ln(t)$ is almost linear due to the fact that $f(y_c)$ does not change appreciably about the critical barrier as in the case of a narrow distribution. An analytical expression of Eq. (4) can be derived by representing the behavior of $f(y)$ about y_c using a series expansion[3,4]

$$M(t) = M(t_0) - A \sum_{n=0} f^n(y_c) \left[\frac{\Delta\,\ln(t)}{\alpha} \right]^{n+1}, \tag{7}$$

where

$$M(t_0) = B + A - A \int_0^{y_c(t_0)} f(y)\,dy$$

and $\Delta \ln(t) = \ln(t/t_0)$ and t_0 is the initial time of measurement. $f^n(y_c)$ is the nth differential of the distribution function evaluated at y_c. Equation (7) shows that for a constant probability of activation

$$M(t) = M(t_0) - \frac{A}{\alpha} \Delta\,\ln(t), \tag{8}$$

which is the well-known logarithmic time dependence of magnetization.[5] However in general $f(y)$ is not constant and higher order terms become important as the variation of the distribution function about y_c becomes steeper. In Ref. 3 the higher order coefficients are found to be proportional to $(1/\sigma^2)^n$ and hence as the width of the distribution increases the higher order terms in the expansion will vanish.

III. THE FLUCTUATION FIELD AND ACTIVATION VOLUME

The concept of the fluctuation field was introduced by Néel[1,6] who assumed that thermal agitation could be represented by a fictitious field $H_f(t)$ which he showed to be a linear function of $\ln(t)$. As a result the magnetization can be written as

$$M = M_0 \pm \chi_{\rm irr} H_f(t). \tag{9}$$

Equation (9) directly relates the time-dependent changes to the irreversible susceptibility $\chi_{\rm irr}$ defined as $\Delta M_{\rm irr}/\Delta H$ where $\Delta M_{\rm irr}$ is the small change in the irreversible component of magnetization resulting from a small increment of field ΔH, $\chi_{\rm irr}$ is often measured as the slope of the dc-demagnetization remanence curve. Thus, as is intuitively reasonable, the time-dependent changes are related to the irreversible magnetic behavior of the system. The meaning of the fluctuation field is however, unclear from Eq. (9) and is still the matter of some debate. It would seem that the fluctuation field is intimately linked with the micromagnetics of magnetization reversal, as will be demonstrated here in the case of materials with perpendicular anisotropy. A rather different definition of the fluctuation field in terms of the time-dependence coefficient was given by Wohlfarth[7] as

$$S = \chi_{\rm irr} H_f. \tag{10}$$

Thus, in principle independent measurements of S and $\chi_{\rm irr}$ can be use to determine H_f. A considerable amount of experimental work has been carried out using this approach. This shows H_f to be a parameter dependent on a number of factors such as the volume and anisotropy field distributions[8,9] and interparticle interactions.[10]

It is also found that H_f is dependent on the magnetization reversal mechanism of the material. This is often dis-

cussed in terms of an "activation volume" V_{act} which can be defined following Wohlfarth[7] on dimensional grounds as

$$V_{act}=\frac{kT}{M_s H_f}, \tag{11}$$

where M_s is the bulk saturation magnetization of the material. V_{act} is perhaps most useful in studying the behavior of granular materials, which have a well-defined volume V for comparison with V_{act}. Generally speaking it is found that V_{act} is significantly smaller than V for elongated particles.[11,12] Flanders and Sharrock[13] have also measured particle sizes via time-dependence measurements. Although the measured volumes are in principle different from V_{act}, they are also generally found to be smaller than V for elongated particles. A similar situation is found for alumite thin films,[14] a case to be discussed in more detail later. Although the activation volume is a useful quantity in the study of granular materials it is perhaps less so in relation to domain wall processes since the equivalent physical volume is more difficult to define. In general it is perhaps more useful to concentrate on H_f, which is directly related to the material properties. Recent work[15] has shown that the form of H_f depends upon the distribution of energy barriers $f(\Delta E)$. For a single energy barrier it can be shown that

$$H_f=-kT/[\partial \Delta E/\partial H] \tag{12a}$$

while for a relatively wide distribution

$$H_f=-kT/[\partial \Delta E/\partial H]_{\Delta E=\Delta E_c}, \tag{12b}$$

where the differential is evaluated at the critical energy barrier defined earlier. Equation (12b) is the definition of H_f originally given by Gaunt,[16] and has been the starting point of a number of attempts (e.g., Ref. 17) to explain the relation between H_f and the coercive force, the so-called Barbier plot.[18] It is relatively easy to study H_f using analytical theories for simple model systems. The problem of determining H_f via micromagnetic calculations for more realistic systems is at a very early stage. Essentially the problem is that via Eq. (12) H_f is related to the energy barrier, which is not determined in the standard micromagnetic approach. This problem will be considered in detail in the final section of the article.

Finally we briefly indicate here the approach to magnetic viscosity based on a constitutive equation.[19] This phenomenological approach has proved very useful in the study of magnetic viscosity, especially via the definition of new methods of determining H_f. These methods avoid the determination of χ_{irr} [necessary for the direct determination of H_f using Eq. (10)] which itself is a quantity dependent on the measurement time. Details of this approach are given in the current issue.[20]

IV. MODELS OF TIME DEPENDENCE IN THIN FILMS WITH PERPENDICULAR ANISOTROPY

The first simulation of time-dependent magnetic behavior for an interacting many-particle system was made in 1936[21] using a Monte Carlo technique. We shall describe the model in some detail here, since it essentially forms the basis of most subsequent treatments. The first study[21] considered a three-dimensional lattice of particles interacting via a magnetostatic field. An important result of this study, which also features strongly in recent work is the fact that logarithmic time dependence can result in a system with a single intrinsic energy barrier due to a spread of interaction energies. Thus the disorder which appears necessary for logarithmic time dependence has an intrinsic contribution from the probabilistic nature of the reversal process itself.

Simulations of films with perpendicular anisotropy were prompted by the experimental work of Dahlberg *et al.*[22] on CoCr films, who observed a strong time dependence of the magnetization (driven by the demagnetizing field) which resulted in a time decay of a recorded signal. In the recording context we also note the work of Charap[23] who has used a Monte Carlo model to study the thermal stability of written information in longitudinal granular media. Because of the strong demagnetizing fields in the transition region the thermal stability is much reduced, leading to the conclusion that the ultimate lower limit of grain size in conventional recording is significantly larger than the superparamagnetic limit which is often assumed.

A. A Monte Carlo model

Central to the calculations is the determination of the energy barrier, which essentially governs the transition rate via the Arrhenius–Néel law. The film is considered to consist of a collection of grains with anisotropy easy axes oriented perpendicular to the film plane. In practice there will be a distribution of easy axis directions about the normal to the plane. However, the time dependence is most strongly dependent on the large demagnetizing fields and the spread of interaction energies and consequently the disorder due to the easy axis distribution is neglected. The grains are assumed to interact via the magnetostatic field, which can be calculated using standard techniques such as the fast Fourier transform or the Bethe–Peierls–Weiss approximation used in Ref. 21. In addition it is possible to introduce an exchange interaction which is necessary for the simulation of magneto-optical films. Assuming coherent rotation within individual grains the energy barrier is given by

$$\Delta E=KV(1-H_{tot}/H_K)^2, \tag{13}$$

where $H_{tot}=H+H_{int}$ is the sum of the applied and magnetostatic interaction field, respectively. Each individual grain has a characteristic relaxation time determined by the energy barrier and the Arrhenius–Néel law, Eq. (1). The numerical simulation is most efficiently carried out using an algorithm described by Binder.[24] The algorithm is as follows:

(1) The time is set to $t=0$.
(2) t' is sampled at random from a distribution $Nr\exp(-Nrt')$ where N is the number of particles and $r=\max\{r_\nu\}$ where r_ν is the relaxation rate of the νth particle: $r_\nu = f_0 \exp(-\Delta E_\nu/kT)$.
(3) A moment ν is selected at random, $1\leq\nu\leq N$.
(4) With probability r_ν/r we accept the reversal.
(5) Steps (2) to (4) are repeated until an equilibrium state is reached.

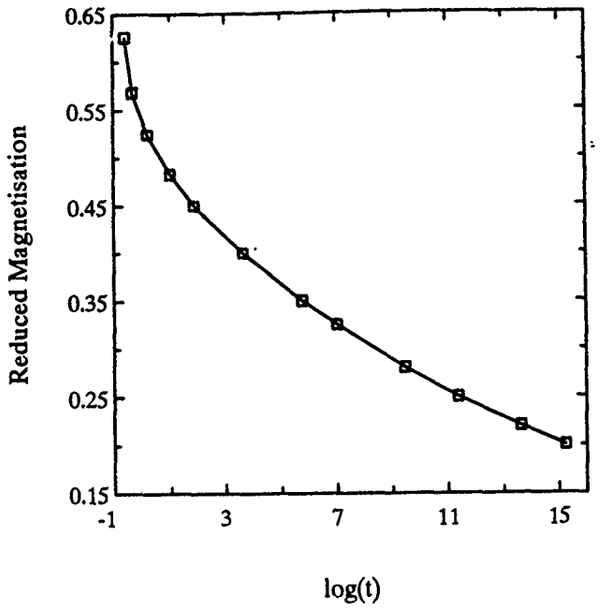

FIG. 2. Time variation of magnetization in a perpendicular thin film.

This approach has the advantage of scaling the steps along the time axis according to the transition rate at a given point in the process. Consequently it is possible to simulate the magnetic relaxation efficiently over extremely large time scales.

Simulations were first carried out in zero applied field[25] on an ensemble of particles of identical size, consisting of prolate ellipsoids with a 7:1 aspect ratio. As shown in Fig. 2 over many orders of magnitude the decay is nonlogarithmic. However, over the typical experimental time scale an approximately logarithmic slow relaxation is predicted, in agreement with experiment. Within this region it is possible to define a coefficient of magnetic viscosity S. The temperature dependence of S shows slow monotonic increase to a broad maximum followed by a rapid decrease to zero. This is broadly in agreement with experiment, indicating that the essential features of the model, in terms of interaction effects, are correct. There is however, a major discrepancy in the grain size predicted from a fit between theory and experiment which is very small in comparison with the physical size of the CoCr columns. This can be interpreted in terms of a micromagnetic model of magnetization reversal. Generally, magnetization reversal in elongated particles takes place by incoherent rotation, which can be viewed as the nucleation of a volume of reverse magnetization followed by propagation of the reversed area throughout the particle. The energy involved with the nucleation is clearly less than required to reverse the whole particle by rotation. Consequently a reduced effective volume for the model simulations is not unreasonable. The micromagnetic implications of this observation will be described in the final sections of the article.

B. Analytical models of slow relaxation in perpendicular media

In the Monte Carlo simulations there is a strong contribution to the logarithmic time dependence arising from the disorder produced by the interaction field distribution. However, materials with perpendicular magnetization have a unique feature in that logarithmic time dependence can occur as a result of the macroscopic demagnetizing field. A simple mean-field model can give very useful results in comparison with experiment. Mean-field models have been proposed by Lottis *et al.*[26] and Lyberatos *et al.*[27] Consider a material with perpendicular anisotropy and particle size V with a distribution function $f(V)$. The interactions are represented by a mean-field formalism, the total field being the sum of the applied field and demagnetizing field, i.e., $H=H-N_dM$. The variation of magnetization with time is the interval t_0 to t given by

$$M(V,t)=M(V,t_0)+[M_e(V)-M(V,t_0)] \times[1-e^{-(t-t_0)\tau^{-1}}], \tag{14}$$

where $M(t_0)$ and M_e are the reduced initial and equilibrium values of the magnetization, respectively. If the relaxation time is given by the Arrhenius–Néel law it can be shown that M_e and τ are given by

$$M_e(V)=\tanh(M_sHV/kT), \tag{15}$$

and

$$\tau^{-1}(V)=2\,f_0\exp\left[-\frac{KV}{kT}(1+h^2)\right] \times\cosh\left(\frac{M_sVH}{kT}\right) \quad \text{for } |h|<1$$

and

$$\tau^{-1}(V)=f_0 \quad \text{for } |h|\geq 1, \tag{16}$$

where $h=H/H_K$. In order to calculate the time evolution of the magnetization we approximate the decay by a series of discrete time intervals that can be made arbitrarily small thereby approximating a continuous process. Thus, taking into account the particle size distribution we have that

$$M(t_{n+1})=M(t_n)+\int [M_e(V,M)-M(V,M)] \times\{1-\exp[-(t_{n+1}-t_n)\tau^{-1}(V,M)]\}f(V)dV \tag{17}$$

the transcendental nature of Eq. (17) is stressed here by writing M_e and τ as explicit functions of M. In Ref. 27 a numerical solution of Eq. (17) was made using a log normal volume distribution. The results do not depend strongly on the form of $f(V)$ as long as this is narrow.

The analytical results agree qualitatively with the computational studies. An initial rapid demagnetization is followed by a quasilogarithmic region. The initial demagnetization arises because in the strong demagnetizing field the relaxation times are short and also $M_e=-1$. Ultimately of course as the time-dependent process proceeds the demagnetization field decreases and the system tends to a state of zero magnetization. An approximate analytical approach to the problem of relaxation in perpendicular media has been carried out by Chantrell *et al.*[28] which clarifies certain features of the experimental data and reinforces the intimate relation-

ship between slow relaxation and micromagnetics. Starting from the Eq. (2) and assuming coherent rotation, it can be shown that for large demagnetizing fields the magnetization is a solution of the equation

$$\int dM \exp[\beta(1-h^2)]/(1+M) = -tf_0, \tag{18}$$

where $\beta = KV/kT$, and in zero field $h = N_d M/H_k$. Using a steepest descent approach it can be shown that the magnetization at remanence decreases logarithmically with a normalized time-dependence coefficient $S_r = d(M/M_r)/d\ln(t)$ given by

$$S_r = \tfrac{1}{5}\beta^{-1/2}. \tag{19}$$

This approximate equation is valid for relatively short time scales. A more detailed treatment shows S_r to be a slowly decreasing function of $\ln(t)$ (in agreement with experiment) with the magnetization decay tending to an exponential as $t \to \infty$. It should be stressed that the volume in Eq. (19) is in principle the physical volume rather than the activation volume defined earlier. In Ref. 28 a comparison is made with the experimental behavior of alumite media, which consist of elongated metal particles oriented perpendicular to the plane and which are prepared by the deposition of iron into oxidized aluminum. It has been experimentally demonstrated that alumite samples reverse incoherently by a mechanism close to curling.[29] Essentially it is found that Eq. (19) is obeyed well for alumite, however the best fit to the data is obtained using an effective activation volume equal to 0.05 times the physical column volume. Given that alumite exhibits incoherent reversal of a type which might be thought of as nucleation of a reversal followed by propagation, this small activation volume seems intuitively reasonable. However, a complete understanding of this phenomenon requires a very detailed micromagnetic study, which is the subject of the final section of this article.

V. THERMAL ACTIVATION: THE MICROMAGNETIC APPROACH

Thus far all the theoretical developments have been based on the assumption of magnetization reversal by coherent rotation in single domain particles. However, the comparison with experiment leads inevitably to the conclusion that magnetization reversal involves thermally activated nucleation followed by propagation of the reverse domain. The latter process may be hindered by pinning, in which case the movement of a domain wall from a pinning site is itself a thermally activated process. It should perhaps be stressed that this presents a problem fundamentally outside the classical micromagnetic formalism. Micromagnetism is based on the determination of stationary states and their evolution with respect to changes in external parameters such as the applied magnetic field. Magnetization reversal occurs when the local energy minimum in which the system is situated disappears resulting in a transition to a new stationary state. Modern investigation using numerical techniques generally determines stationary states using the Landau–Lifschitz dynamic equation. This approach more reliably determines the stationary state after magnetization reversal. However, this approach is not valid at a finite temperature. Here we outline two rather different theories of micromagnetism at a finite temperature, the first valid for short time scales and the second applicable to slow dynamic behavior.

A. Langevin dynamics formalism

This approach takes account of collective magnetic excitations in the system, recognizing that ultimately thermal agitation occurs via spin waves. The theory is essentially an extension of Brown's model[30] of thermal activation to systems with large numbers of degrees of freedom. The dynamic behavior of a spin is governed by the Landau–Lifschitz equation

$$\frac{d\mathbf{M}}{dt} = \gamma_0 \mathbf{M}\times\mathbf{H} + \frac{\lambda}{M}\mathbf{M}\times(\mathbf{M}\times\mathbf{H}), \tag{20}$$

where γ is the gyromagnetic ratio and λ is the damping parameter. At a finite temperature the stochastic dynamics of the spin can be described by adding a fluctuating "random field" term to the deterministic field arising from interaction effects in addition to the applied field. Thus Eq. (20) becomes the Langevin equation of the problem. Using this formalism Brown[30] derived an analytical expression for the relaxation time associated with thermally activated reversal of a single particle. A model of thermal activation in a micromagnetic system of coupled spins has been proposed by Lyberatos *et al.*[31] Briefly, the technique involves linearization of the equation of motion followed by a transformation into the normal coordinates which essentially decouples the equations. The statistics of the random field can then be determined using the fluctuation dissipation theorem. This model was first used to study magnetization reversal in the simplest micromagnetic system of a pair of magnetostatically coupled particles.[32] Essentially, the set of integrated Langevin equations is solved numerically, leading to a switching behavior resembling a random walk over the energy barrier. Among the results given in Ref. 32 are detailed calculations of the pre-exponential factor f_0 in the Arrhenius–Néel law. In particular, a dependence of f_0 on the applied field and strength of coupling between the particles was demonstrated. In addition thermal agitation was shown to have a profound effect on the reversal process itself. Significant deviations from the deterministic (symmetric fanning) mode are found at a finite temperature, the magnitude of which depends on the temperature and the interparticle coupling. This has two important effects from the micromagnetic viewpoint. First, a reversal to an antiparallel state after switching becomes possible in addition to the parallel state expected at zero temperature. Second, it is found that there appears a temperature dependence of the effective energy barrier. Physically this is because of the departure from the ideal reversal mode induced by thermal perturbations as a result of which many unsuccessful reversal attempts are made in directions other than those leading to the saddle point of the transition. We note that these effects are important for reversal over low energy barriers, i.e., reversals involving very short time scales. The model described here cannot realistically be applied to rever-

sals in slow dynamic time scales. In order to study slow dynamics it is necessary to calculate energy barriers directly. This is a problem which is being given increasing attention. In the following, we outline some recent energy barrier approaches.

B. Energy barrier models

Slow relaxation in multivariate systems such as a particle in the micromagnetic formalism is best approached by direct determination of the energy barrier and the determination of the relaxation time using the Arrhenius–Néel law [Eq. (1)]. However, the determination of the minimum energy barrier on a complex energy surface is a difficult problem and one not amenable to the usual micromagnetic approach. An early model was given by Lyberatos and Chantrell.[33] This model uses a minimization approach to determine the energy barrier. The algorithm was found to give physically reasonable results for the variation of energy barrier with particle size, leading ultimately to the prediction of a peak in the variation of H_c with particle diameter, in agreement with the early experimental work of Kneller and Luborsky.[34] An interesting result, which highlights the importance of the thermal effects is the prediction of a thermally induced flower to vortex state transition in zero field. This assists nucleation via a mechanism close to curling and leads to a lower coercivity than predicted by the previous computations.[35] However, this approach, although providing useful physical results, significantly overestimates the energy barrier, and a number of other approaches have been adopted.

The study of energy barriers in the micromagnetic problem is thus of considerable importance. For the simplest case of two interacting particles analytical approaches[36,37] have given useful results and in particular[37] it was shown that the activation volume is related to the change of magnetization required to reach the saddle point of the transition, which is consistent with the definition proposed by Gaunt.[16] The superparamagnetic transition has also been studied via numerical approaches in a chain of spheres.[38] However, both these approaches rely on constrained optimization, which is known to lead to potential numerical problems in complex systems. A more recent development is a novel random search ridge method for saddle point detention on hypersurfaces. Essentially a ridge method is used, employing the linear fluctuation theory outlined earlier[31] to choose the initial direction of search for the ridge. This enhances the simulation by the introduction of the lowest eigenmodes into the thermal activation problem. A detailed study of the topology of the energy surface for three interacting particles using this technique will be published elsewhere.[39]

Time dependence of switching fields in magnetic recording media (invited)

M. P. Sharrock
Digital Media Laboratory, 3M, 236-3C-02, 3M Center, St. Paul, Minnesota 55144-1000

Coercivity and other experimental measures of switching field depend upon the time scale of interest. This time-scale dependence has practical importance in magnetic recording, because the effective time scales of writing and storage are very different. A simple model accounts for the time-scale dependence of coercivity in terms of the thermally assisted crossing of an energy barrier whose height is reduced by the applied field. Fitting this barrier-crossing model to data provides an estimate of the volume that must switch magnetization direction in overcoming the barrier. The assumption of Stoner–Wohlfarth reversal is used to obtain an initial estimate of the dependence of the barrier height on the field. With some adjustment of the resulting energy expression, the model gives good agreement between calculated switching volume and actual particle volume for advanced recording particles of three types: acicular oxide, acicular metal, and barium ferrite platelets. The model can be used to estimate minimum practical particle volumes for use in magnetic recording. Switching due to fields nearly perpendicular to the particle's preferred axis, sometimes used as a measure of the anisotropy field, also shows the effect of thermal assistance. The switching volume determined from such measurements, like that from coercivity, approximates the particle volume.

I. INTRODUCTION

Current magnetic recording media encode information, whether digital or analog, as magnetized zones in the surface of a tape or disk. The minimum dimension of these features is on the order of a micrometer (typically 0.5 μm in advanced applications). This paper will focus on media of the particulate construction,[1] as opposed to those made by thin-film deposition. A particulate medium consists of a support material upon which is coated a dispersion of magnetic particles in organic polymers, along with solvents, lubricants, and other necessary components. Usually the coating is exposed to a magnetic field before drying in order to impart a magnetic orientation to the particles. The particles have maximum dimensions, length for acicular particles and diameter for platelets, on the order of a tenth micrometer (0.05–0.2 μm, for advanced materials). They are generally assumed because of their size to be single-domain particles. The particle size is extremely important to the recording resolution, signal-to-noise properties, and magnetic stability of the medium.[2] Recent years have seen significant reduction in particle sizes of all compositions used in recording.

One of the most important magnetic properties of the particles used in a recording medium is the *remanent coercivity*, which is essentially the median switching field. For convenience, the *intrinsic coercivity* (applied field that reduces magnetization to zero after saturation in the opposite direction) is more commonly specified; it is often (and here) referred to simply as the *coercivity*. The coercivity value determines the field needed to record, and also to erase or overwrite, information on the medium. Thus it must not be excessively large. The coercivity must, however, be adequately large to prevent long-term demagnetization during the desired life of the information (typically years); this implies adequate resistance to fields from both internal and external sources.

Time-dependent magnetic phenomena have been well known for over 40 years,[3,4] and were in fact described over a century ago.[5] In particular, the coercivity value depends upon the time scale of the process used to induce magnetic reversal. That is, the value of the fixed field required to reduce magnetization to zero from saturation decreases as one increases the time that it is allowed to act. Similarly, the coercivity measured in a swept-field hysteresis loop increases with the sweep rate.[2,6,7]

These time-dependence considerations are highly relevant to magnetic recording technology, in which the time scale of the writing process may be on the order of 10^{-8} s and that of the desired storage stability on the order of 10^{+8} s. The usual laboratory methods cannot investigate behavior over this huge range, covering 16 orders of magnitude, although recent pulsed-field experiments[8] have begun to probe behavior at and below its lower end. A vibrating-sample magnetometer (VSM) typically has a time scale on the order of 1 s, and a 60-Hz magnetometer has an effective time scale of 10^{-5}–10^{-6} s.[7] The model described here and previously[2,6,7] allows the interpretation of such laboratory experiments in terms of physical quantities and also the extrapolation to the much longer and shorter time scales of interest in recording. Reducing the switching volume has the effect of increasing the amount by which the "writing coercivity" exceeds the "storage coercivity." Thus the trend toward smaller particles for benefits in signal-to-noise ratio, resolution, and surface smoothness will at some point be limited by time-dependence considerations. This potential limitation has been discussed in the past[2] and will be reevaluated in Sec. IV.

II. MEASUREMENTS AND MODEL

The essential origin of time-dependent magnetic behavior in small particles is the thermally assisted process of crossing an energy barrier that occurs in magnetic switching.[3,4,9–11] The conventional Arrhenius formulation for the rate constant r, the probability per unit time of successful crossing, is

 0021-8979/94/76(10)/6413/6/$6.00 © 1994 American Institute of Physics

$$r = A \exp(-\Delta E/kT). \quad (1)$$

The factor A is assumed to have a negligible dependence on field and temperature; k is Boltzmann's constant and T is the absolute temperature. The role of an externally applied magnetic field is to decrease the energy barrier ΔE until switching occurs on the time scale of interest. Equation (1) would suggest that in the presence of a constant opposing field, the magnetic moment $m(t)$ of a collection of particles decays exponentially with time t from an initial saturated value m_0 as

$$m(t) = m_0[2 \exp(-rt) - 1]. \quad (2)$$

This exponential behavior would in fact be observed for an ensemble of noninteracting particles having identical magnetic properties. Particles in actual recording media, however, exhibit distributions of particle size and shape (and possibly composition). This distribution of physical properties leads to a distribution of magnetic properties, which may be further complicated by the variety of interparticle magnetic interactions that can occur. The result is that observed behavior is nonexponential.[12] The decay of $m(t)$ in the presence of a constant field is often found to approximate a linear dependence on some power of the logarithm of time.[13] Such a function can be viewed as the superposition of many exponential decays, representing a distribution of magnetic properties such as switching field. Another way of measuring time dependence is the recording of hysteresis loops of differing sweep rates;[6,7,14] by combining an ac instrument (e.g., 60 Hz) with a VSM, this technique can allow a greater range of time scales than is convenient in constant-field decays. In both types of experiments, one must take the distribution of properties into account. A straightforward way of doing this is to focus attention on the center, or peak, of the switching-field distribution (SFD) and to consider the coercivity as representing the material at this peak. It will be assumed that in some approximation the peak of the SFD is associated with the peak of the distribution of other relevant parameters, such as switching volume. In other words, the coercivity characterizes the switching of the most typical, or significant, particles in the sample. (One needs to assume also that substantially the same material is represented by the peak of the SFD at all time scales of interest.) Obtaining constant-field decay curves that represent the same part of the SFD [that is, the same value of the measured moment $m(t)$] over a significant range of time values can be difficult. Over a limited time range, curves for significantly different field values may occur at very different $m(t)$ values and thus represent different parts of the SFD. The slopes of the curves will in fact reflect the height of the SFD for these fields.[15,16] The switching volumes associated with these points of the SFD may well be different. In order to concentrate on one part (the peak) of the SFD, a large range of experimental time scales may be more easily attained by using hysteresis loops, and the resulting coercivity values, for different sweep rates. The loops present their own difficulties, however. One must assign an effective time scale, t in Eq. (1), to the experimental sweep rate. This assignment can be done;[7,13,17] as expected, the t value is approximately inversely proportional to the sweep rate but also depends upon the strength of the time-dependent effects shown by the sample.

Equation (1) will be used with the above assumptions and interpretations. The factor A in Eq. (1) is an "attempt frequency" for barrier crossing. It can be estimated in a number of ways,[10] including simple precession, and appears to be on the order of 10^9 s^{-1}. A range of values around this estimate will be considered.

The energy barrier ΔE depends upon the value of a volume that is called below the "switching volume" and designated by V. This parameter is defined here as *the volume of material that must rotate magnetically in the process of overcoming the rate-limiting energy barrier*. In switching by coherent rotation, this would be expected to be the entire particle volume (assumed single-domain at the sizes of interest). In more complex reversal modes, the switching volume might be a fraction of the particle volume,[18] the portion that must rotate in order to initiate the reversal process of the whole particle. If reversal is incoherent but simultaneous, however (as in fanning[19]), V might conceivably be the entire particle volume.

The model assumes single-domain particles having uniaxial magnetic anisotropy, with anisotropy energy of the form $K \sin^2 \theta$ (angle θ between the preferred axis and the moment vector). For the case of the applied field being exactly aligned with the preferred axis and opposing the initial magnetization,[6,9]

$$\Delta E = KV(1 - H/H_o)^2, \quad (3)$$

with

$$H_o = 2K/M. \quad (4)$$

The first-order anisotropy constant is designated by K, the magnetization intensity of the particle by M, and the external field strength by H. (Note: $\Delta E = 0$ for $H = H_o$.) The switching volume V used here cannot be identified with the "activation volume" V_{act} discussed by others.[15,16,20] V_{act}, as usually defined, is explicitly field dependent. For the special case of perfect alignment of H with the preferred axis, V_{act} can be interpreted in terms of the change in magnetic moment, projected onto the preferred axis, that occurs in overcoming the barrier [Ref. 20, Eq. (26), and Ref. 16, Eq. (12)]. The V used here can best be identified with the value of the "critical volume"[16] *that applies when the field is equal to the coercivity*.

The case of perfect alignment of field and preferred axis is an improbable one in a collection of particles having even a modest distribution of orientations. Actual recording media have substantial distributions, despite efforts to orient them. [Typical ratios of remanent to saturated moment near 0.8 indicate mean deviations of roughly $\cos^{-1}(0.8)$, or 35°, from the intended direction.] Victora[21] has presented a theoretical argument that with the field not aligned with the preferred axis, the exponent in Eq. (3) is expected to be 3/2, for very general anisotropy, even including interactions. The Stoner–Wohlfarth (SW) model of reversal[22] also indicates an exponent that can differ from 2. Using the approximation of Pfeiffer,[23] one can use the SW model to write

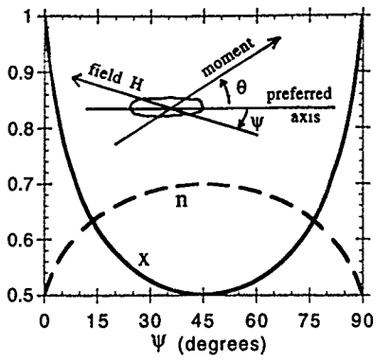

FIG. 1. Dependence of Stoner–Wohlfarth parameters, used in Eqs. (6)–(9), on the (minimum) angle ψ between the applied field and the preferred axis of a particle.

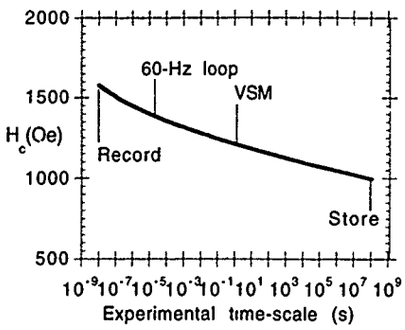

FIG. 2. Plot of Eq. (10), which models the dependence of measured coercivity on time scale t, for $H_0=1800$ Oe, $n=1/2$, $A=2\times10^9$ s^{-1}, $V=3.0\times10^{-17}$ cm^3, and $M=300$ emu/cm^3. Relevant time scales for magnetic recording and experimental measurements are shown.

$$\Delta E=KV(1-H/H_o)^m, \tag{5}$$

with

$$H_o=2xK/M, \tag{6}$$

and

$$m\approx 0.86+1.14x. \tag{7}$$

For later convenience, subsequent expressions will use the definition

$$n\equiv 1/m. \tag{8}$$

As in the case of perfect alignment, $\Delta E=0$ for $H=H_0$. The dependence of H_0 (that is, of x) on the angle ψ between the field direction and the preferred axis is the familiar SW one:

$$x=[\cos^{2/3}(\psi)+\sin^{2/3}(\psi)]^{-3/2}. \tag{9}$$

Figure 1 shows this behavior ($x=1.0$ for $\psi=0°$ or 90°; $x=0.5$ for $\psi=45°$). Using Eqs. (5)–(8) and defining coercivity $H_c(t)$ as the field that produces reversal of half of the sample in time t,

$$H_c(t)=H_o\{1-[(kT/KV)\ln(At)]^n\}. \tag{10}$$

(A relatively insignificant factor of 0.693, shown in earlier work,[2,6] has been absorbed into A for convenience.) Figure 1 shows the behavior of the exponent n in the SW model, using the Pfeiffer approximation. Figure 2 shows a plot of Eq. (10) for typical parameters, where the experimental time scale t is the duration of a constant or pulsed field and/or the equivalent values for swept-field experiments.[7] As was stated above, the coercivity is interpreted as representing the switching of material at the peak of the SFD and also the peaks of other relevant distributions. Thus Eq. (10) is taken to represent the most "typical" particles in the medium.

III. RESULTS

Equation (10) has four unknowns: H_o, A, n, and the product KV. If one is willing to assume plausible values for A and n, the other two can be determined from two measured coercivity values of sufficiently differing time scales. This has been done in the past, using a VSM and a 60-Hz instrument.[2,6] Further, if the magnetization intensity M is known, K and V can be determined separately, using Eqs. (6) and (7). These calculations allow the interpretation of the time dependence of coercivity in terms of physical parameters, and also the extrapolation to coercivity values for the experimentally difficult recording and storage time scales.[2,6] If more than two experimental time scales are available, determination of more than two parameters is possible. Figure 3 shows data and a typical fit for a tape containing cobalt-modified acicular iron oxide particles. As in all coercivity measurements reported here, the applied field direction coincides with the direction of intended magnetic orientation in the sample; the preferred axes of individual particles are distributed around this direction. The oxide particles are relatively small examples of this type of material, about 0.2 μm long, and are commonly used in advanced video and data tapes. The data are from a VSM, run at various sweep rates, and a 60-Hz instrument. Four parameters are still too many to fit meaningfully. Therefore a value of A was chosen and fitting was done on H_0, KV, and n. Equivalently good fits were achieved over a range of A values. Figure 4 shows the relationship between fitted n and assumed A. The switching volume V was computed, using Eqs. (6) and (7), with a magnetization M of 340 emu/cm^3. The value of V depends upon the assumed value of A, but not very sensitively. However, it is very interesting that the best agreement between V and the

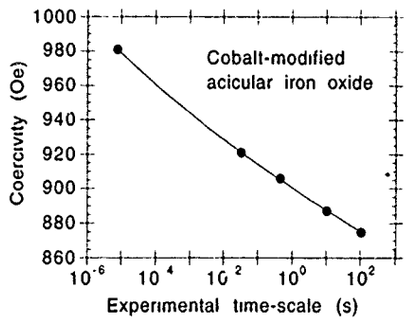

FIG. 3. Experimental data showing measure coercivity vs experimental time scale t, for tape containing acicular cobalt-modified iron oxide particles. Line is a fit of Eq. (10), for $A=3\times10^9$ s^{-1}, and is the basis for one of the points in Fig. 4. The fitting parameters are H_0, n, and the product KV.

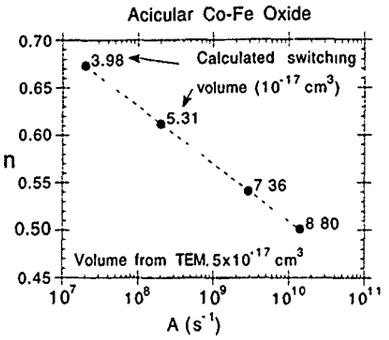

FIG. 4. Plot of values of n vs chosen values of A, obtained by fitting Eq. (10) to the data in Fig. 3. Magnetization M is 340 emu/cm^3; this is used to calculate the value of the switching volume V from the fitted values of H_0, n, and the product KV that result for each value of A. The dotted line shows a least-squares fit, yielding $n=1.115-0.0606[\log(A/s^{-1})]$.

particle volume estimated from transmission electron microscopy (TEM) occurs for n approximately 0.63, close to the 2/3 predicted by Victora[21] and for A about 10^8 s^{-1}, in reasonable agreement with results of Doyle *et al.*[8] The value of 0.63 for n is somewhat lower than would be expected in SW reversal for the sample's degree of orientation. The remanence-to-saturation ratio is 0.88, which indicates average angular deviations of nearly 30°. The SW model [Eqs. (7)–(9); Fig. 1] predicts an n value of 0.68 for this angle.

Another sample studied was a tape containing barium ferrite platelets, of a type currently of interest for advanced applications. This experimental tape had a relatively low degree of magnetic orientation (remanence-to-saturation ratio of 0.63), which tends to minimize the interaction effects. These can be very strong in barium ferrite,[24,25] especially when highly oriented.[26] Because of the low degree of orientation, n will be initially estimated as 0.7. This is the maximum allowed in SW reversal; see Fig. 1. The measured coercivities were 1460 Oe for the 60-Hz loop and 1290 Oe for the VSM run at 13 Oe/s sweep rate. The effective t values for these measurements can be estimated[7] as 1.5×10^{-5} s and 0.8 s, respectively. The hysteresis loops were recorded to limits of ±3240 Oe (the maximum possible) with the 60-Hz instrument, and ±2940 Oe with the VSM. These limits provide that the ratio of maximum applied field to measured coercivity is approximately the same in the two instruments, in order to avoid the possibility that one produces more complete saturation of the sample than the other. (This precaution is necessary only because of the relatively low 60-Hz field capability relative to this sample.) The results of fitting, using 0.7 for n, 10^9 s^{-1} for A, and 300 emu/cm^3 for M, are given in Table I.

In addition, remanence coercivities were measured in the following way: A fixed reverse field, opposite the direction of initial magnetization by a field of 11 kOe, was applied. Periodically, the reverse field was shut off and the remanence measured. The total accumulated field exposure time required to reduce remanence to zero was taken to be the t value for remanence coercivity H_r equal to this reverse field. The results were t values of 10 and 290 s for H_r values of 1350 and 1300 Oe, respectively. The results of fitting these values, using the same values for n, A, and M, are also shown in Table I.

The agreement between the two coercivity methods with regard to V is good. The average is given in Table I, with a measure of the uncertainty resulting from their spread. The 9% increase in H_0 from the first to the second line is typical of a remanence coercivity relative to the coercivity from a scanned loop. These results are not very sensitive to the value chosen for A; variation over the range 2×10^8–3×10^9 s^{-1} produces an insignificant difference (3%–5%) in H_0 and V.

TEM pictures indicate that most of the particles have volumes of $2–3\times10^{-17}$ cm^3. The factor-of-2 discrepancy between the model calculation of V and the apparent particle size may not be significant, in view of various assumptions made in the model and the difficulty of estimating representative TEM volumes. (Particle size is quite nonuniform.) The discrepancy is largely removed (calculated $V\approx2\times10^{-17}$ cm^3) if $n\approx0.6$, close to the value found for the acicular oxide. This n value would in SW reversal [Eqs. (7) and (9); Fig. 1] be appropriate for a very well oriented sample, which is not the case.

It seems worthwhile to investigate the possibility that the switching volume V is less than the total particle volume because of an incoherent mode of switching. This would be plausible in view of recent theoretical work.[27] The method of Flanders and Shtrikman,[28] applied previously to barium ferrite anisotropy studies,[25,29] allows measurement of switching by only those particles whose preferred axes lie nearly perpendicular to the applied field, as in Fig. 5. Even if switching at lower ψ values in the usual coercivity measurement is incoherent, the nearly perpendicular field very likely produces parallel rotation of the moment throughout the particle, and thus coherent switching. In SW reversal, by Eqs. (7)–(9) (Fig. 1), the value of n is expected to be close to 0.5 and that of x to 1.0. In this study, switching was measured for particles having ψ in the range 85°–90°. The field needed to produce this switching was measured as a function of the duration of application. The results, shown in Fig. 6, have a large amount of scatter, possibly as a result of deviations from isolated-particle behavior due to interactions. The fit of Eq. (10), using 0.5 for n, yields the values shown in the last line of Table I, for $M\approx300$ emu/cm^3.

Both the "remanence coercivity" and the "perpendicular switching" methods use the measurement of remanent moment after the application and removal of a field. Therefore their H_0 values can be directly compared (Table I). The ratio of these two values, 4800/1850=2.6, exceeds the maximum ratio, 2.00, that the SW model (Fig. 1) can explain between switching fields for different angles. (Recall that because of the low degree of orientation the coercivity measurement represents particles near the center of the curves in Fig. 1.) Therefore it is likely that some form of incoherent switching occurs in the coercivity measurement. The agreement of the values for V shown in the last two lines of Table I is perhaps remarkable in view of the fact that different reversal modes may be involved.

A third material chosen for this study was a tape con-

TABLE I. Ba ferrite.

Method	Initial magnetizing field (kOe)	H_0 (Oe)	V (10^{-17} cm^3)
Coercivity	3	1700	1.28
Remanence coercivity	11	1850	1.10
Average of above two	...	...	1.2±0.1
Perpendicular switching	11	4800±300	1.3±0.4

taining metal particles (MP). As with the barium ferrite, the coercivity values were measured from loops where the ratio of maximum field to coercivity was the same for the 60-Hz magnetometer and the VSM. These instruments gave, respectively, 1735 Oe from a loop of ±3170 Oe and 1650 Oe for ± 3000 Oe. The resulting fit to Eq. (10) yields (with values of 2/3 for n, 10^9 s^{-1} for A, and 1800 emu/cm^3 for M)

$$H_0=1860 \text{ Oe}, \quad \text{and}, \quad V=0.73\times10^{-17} \text{ cm}^3.$$

This value of V represents only the metallic core of the particle; this core is surrounded by the oxide shell produced by the passivation process. Chemical analysis, magnetic moment, and particle mass density, together with TEM pictures, indicate that the core is only about 35% of the particle volume and that the shell is only weakly magnetic. The TEM pictures also show that particle volume is about $3–4\times10^{-17}$ cm^3. Thus the actual particle core volume appears to be about 1.2×10^{-17} cm^3, nearly twice the calculated value of V. As in the case of the barium ferrite particles in this study, the discrepancy is removed if n is set to approximately 0.6. Again, for SW reversal, this is not consistent with the degree of orientation in actual media. Equations (7)–(9) require a value of less than 10° for ψ to give an n value of 0.6; this would imply a remanence-to-saturation ratio of 0.99. The MP tape studied had a ratio of 0.85.

IV. DISCUSSION AND CONCLUSIONS

The results presented here represent magnetic switching behavior for particulate recording media representing the current state of the art in three materials: acicular oxide, barium ferrite, and metallic particles. All show significant

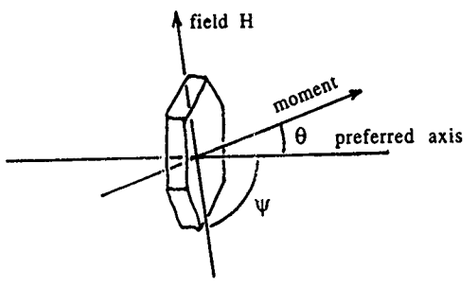

FIG. 5. Diagram of particle in the presence of field nearly perpendicular to preferred axis; ψ is less than, but close to, 90°. Remanence will switch from right to left if moment rotates past the energy barrier.

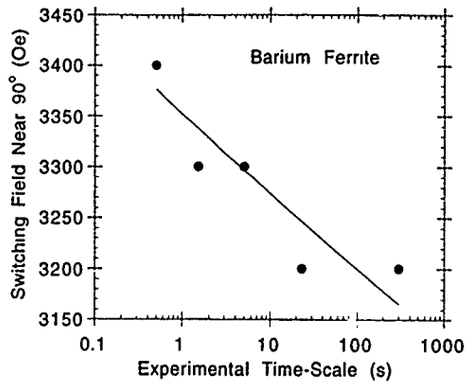

FIG. 6. Plot of measured value of near-perpendicular switching field vs field application time t. Angle ψ was in the range 85°–90° in the experiment. The fit was done for $A=10^9$ s^{-1} and $n=1/2$. The fitting parameters are H_0, n, and the product KV.

time-scale dependence in typical laboratory experiments. The thermally assisted barrier-crossing model discussed here is successful in analyzing this time-scale dependence. Using SW reversal,[22,23] the model determines switching volumes that are within a factor of 2 of particle volumes estimated from TEM pictures. With the assignment of the exponent n to a value of 0.6, rather than 0.7 as determined from SW reversal for typical particulate orientation, the agreement is essentially perfect (within the precision of determining TEM volumes). The good agreement between calculated V and particle volume for n values of 0.6, rather than 0.7, may indicate that the dependence of ΔE on applied field is not accurately given by SW reversal. Regardless of the reversal model used, however, the barrier-crossing model described here can be expected to be useful in extrapolating from coercivities measured in the laboratory to the much shorter and longer times relevant to magnetic recording and storage of information.

By using Eq. (10) to estimate coercivities that would be relevant to writing and storage time scales, one can obtain an estimate of the smallest particle volumes practical for magnetic recording. If the highly arbitrary criterion is adopted that the coercivity relevant to 3-year storage (10^{+8} s) be no less than one half of the value relevant to 10-MHz writing (10^{-8} s),[2] then for $A=10^9$ s^{-1} and $n=0.6$,

$$(KV)_{\text{minimum}}=4.3\times10^{-12} \text{ ergs}. \tag{11}$$

This is 106× the room-temperature value of kT; Lu and Charap found significant decay of simulated high-density recorded transitions for a KV value of $60kT$.[30]

Using Eqs. (6) and (7), Eq. (11) can be rewritten as

$$V_{\text{minimum}}=6.1\times10^{-12} \text{ ergs}/H_0M, \tag{12}$$

where V_{minimum} will be expressed in cm^3 if H_0 is in Oe and M in emu/cm^3. The difference between Eq. (12) and similar expressions discussed earlier[2] is the use of Eqs. (5)–(7) in place of Eqs. (3) and (4). Equation (12), however, does not take account of the differing need for long-term coercivity in materials of very different magnetization intensity. A simple way of estimating this need is through the familiar expres-

sion of Williams and Comstock[31] for the magnetic transition length that results from self-demagnetization:

$$a = B_r d / 2\pi H_c . \tag{13}$$

In Eq. (13), B_r is the remanent induction for the medium (in G), d the recording depth, and H_c the coercivity (in Oe). This expression essentially says that a medium having a higher B_r value needs a higher H_c value in order to resist transition broadening. If the transitions occur at spacing b, then a reasonable degree of transition sharpness requires

$$a \leqslant b/4 \approx d/2. \tag{14}$$

Equations (13) and (14) together give

$$H_c \geqslant B_r/\pi. \tag{15}$$

With Eq. (15) as a lower limit for H_c (10^8 s), and 2200 Oe as an assumed practical upper limit for the writing coercivity H_c (10^{-8} s), Eq. (10) can again be used to estimate the minimum practical particle volume. With $A=10^9\ s^{-1}$ and $n=0.6$, $V_{\text{minimum}}=4\times10^{-18}$ cm^3 for barium ferrite and 1.1×10^{-18} cm^3 for the metallic core of MP. Assuming a passivation shell thickness comparable to that of current MP, the latter value implies a volume of $3\text{–}4\times10^{-18}$ cm^3 for the entire MP particle (M=300 and 1800 emu/cm^3, B_r=1400 and 3000 G for barium ferrite and MP, respectively).

The estimated minimum practical particle volumes given above for MP and barium ferrite are nearly identical; the lower self-demagnetization and absence of a passivation shell in barium ferrite media compensate for the higher value of M that would otherwise appear to give an advantage to MP [Eq. (12)]. These calculated values of V_{minimum} are substantially smaller than the volumes of the smallest currently available particles ($2\text{–}4\times10^{-17}$ cm^3). Thus the model discussed here argues that particulate media technology can advance significantly further toward smaller particles and the resulting higher signal-to-noise ratios.

The barrier-crossing model discussed here will become invalid at time scales on the order of $1/A$ or less. The values of A used here would imply that this limitation occurs at a time scale of about 1 ns (10^{-9} s), at least for barium ferrite and MP. In fact, the observations of Doyle *et al.*[8] made with extremely short field pulses have shown a pronounced increase of the required switching field with decreasing pulse duration at just this order of magnitude. The point at which this increase is considered to be significant is somewhat arbitrary. Equation (10), with parameters typical of advanced media, gives a 1%–2% increase of switching field with each halving of the field exposure time t, for times approaching the $At \approx 1$ condition. If one defines the onset of the regime where the model is no longer adequate as the pulse width where the switching field rises about 10% (an order of magnitude more rapidly) per octave, then this appears to occur at about 0.6 ns for MP and about 1.5 ns for barium ferrite [Figs. 3(a) and 4(a) of Ref. 8]. In data-recording terms, the required switching field begins to deviate significantly from that predicted by Eq. (10) somewhere around 1 Gbit/s for both materials. Since the data rates in anticipated recording systems are generally on the order of 10–100 Mbit/s per channel, recording processes will probably stay within the regime of the model discussed here during the foreseeable future, for both MP and barium ferrite.

Magnetic and structural instabilities of ultrathin Fe(100) wedges (invited)

S. D. Bader, Dongqi Li, and Z. Q. Qiu[a)]
Materials Science Division, Argonne National Laboratory, Argonne, Illinois 60439

An overview is provided of recent efforts to explore magnetic and related structural issues for ultrathin Fe films grown epitaxially as wedge structures onto Ag(100) and Cu(100). Experiments were carried out utilizing the surface magneto-optic Kerr effect. Ordinary bcc Fe is lattice matched to the primitive unit cell of the Ag(100) surface. Fe wedges on Ag(100) can be fabricated whose thick end has in-plane magnetic easy axes due to the shape anisotropy, and whose thin end has perpendicular easy axes due to the surface magnetic anisotropy. A spin-reorientation transition can thus be studied in the center of the wedge where the competing anisotropies cancel. The goal is to test the Mermin–Wagner theorem which states that long-range order is lost at finite temperatures in an isotropic two-dimensional Heisenberg system. Fe wedges on Cu(100) can be studied in like manner, but the lattice matching permits fcc and tetragonally distorted fcc phases to provide structural complexity in addition to the interplay of competing magnetic anisotropies. The results of these studies are new phase identifications that help both to put previous work into perspective and to define issues to pursue in the future.

I. INTRODUCTION

It is of interest to explore magnetic instabilities associated with competing anisotropies in ultrathin epitaxial films. A simple approximation is to equate the two dominant contributions to the anisotropy energy density

$$\frac{2K_s}{t}=2\pi M^2.$$

This provides the condition for which the "shape" anisotropy ($-2\pi M^2$) balances out the surface anisotropy ($2K_s/t$), where K_s is the surface anisotropy constant, t is the thickness of the magnetic film, and M is the magnetization. The underlying assumptions are that any other anisotropy terms can be ignored, *and* that the magnetization orientation within the film is uniform (i.e., all spins point in the same direction). The critical thickness for spin reorientation is

$$t_R=\frac{K_s}{\pi M^2}.$$

For $t<t_R$ the easy axis of magnetization is perpendicular to the film plane (i.e., vertical), while for $t>t_R$ the easy axis is in plane. The question is what happens in the vicinity of $t=t_R$?

Recent theoretical treatments and ideas can be summarized. First, in an isotropic two-dimensional (2D) Heisenberg system there is no long-range order at finite temperature. This is known as the Mermin–Wagner theorem.[1] Hence, spin melting might be expected to occur in the vicinity of t_R. Pescia and Pocrovsky[2] used a renormalization group approach to consider thermal fluctuations, and concluded that the spin reorientation occurs as a phase transition at a temperature T_R which can be less than the Curie temperature T_C. They used the idea of Jensen and Bennemann[3] of a transition driven by the entropy of disorder on going from a uniaxial to a planar spin configuration as temperature increases. Morr, Jensen, and Bennemann[4] recently used a Greens function approach within the random phase approximation to phenomenologically describe the loss of long-range order in the vicinity of the spin-reorientation phase transition. However, it is known that even arbitrarily small anisotropies can restore long-range order.[5] Therefore, it also may be necessary to explore the additional anisotropies, such as arise from the bulk or from finite-size effects, or from higher-order terms in the expansions of the anisotropies than the dominant terms that vary as the square of the magnetization. The higher-order terms can manifest themselves in the vicinity of t_R where the dominant anisotropy terms vanish. Experimentally, ultrathin magnetic films are always grown on a substrate for which lattice constants and thermal expansion coefficients tend to be mismatched to some degree. Thus, epitaxial strain also can influence the magnetic surface or interface anisotropy. This has been treated recently for a test case, for example, by Victora and MacLaren[6] who used electronic structure calculations.

Alternatively, it also becomes important to explore nonuniform magnetization configurations. For example, Yafet and Gyorgy[7] considered the conditions necessary to stabilize ferromagnetic stripe domains in an atomic monolayer that possesses strong surface magnetic anisotropy. They found that while the short-range part of the dipolar interaction gives rise to the familiar $-2\pi M^2$ shape anisotropy term, the long-range part, which can be represented as a domain wall-wall interaction, can result in a lower energetic state than the uniformly magnetized case. The wall-wall interaction, however, has to be evaluated explicitly for the domain configuration under consideration. The domain size will reach an experimentally observable magnitude in the vicinity of the spin-

reorientation transition. Thieville and Fert[8] treated twisted spin configurations using a micromagnetic approach. Alternatively, Erickson and Mills[9] reached similar conclusions for canted spin structures by considering spin wave excitations in 2D films. They found that the excitation energy becomes imaginary in a gap region near the spin-reorientation transition, implying that there exists a static spin-density wave in real space in this region (i.e., the stripe domain structure). A striped domain structure in a 2D film can be viewed as a one-dimensional (1D) ordered system. It is well known that 1D ordered states are unstable against thermal fluctuations. Indeed, Kashuba and Pokrovsky[10] examined 2D striped domains by means of renormalization group methods and found that while thermal fluctuations destroy the regular *spatial* distribution of the stripe domains predicted by Yafet and Gyorgy[7] for the $T=0$ case, the *orientation* of the domain walls remains stable in the presence of thermal fluctuations. Therefore, they reached the conclusion that the 2D stripe domains can be mapped onto the smectic liquid-crystal case.

It is of interest to discuss in more detail the issue of a film of fixed thickness that undergoes a temperature-dependent spin-reorientation transition from perpendicular at low $T(T<T_R)$ to in plane at high $T(T>T_R)$. The question arises as to the existence of a temperature gap ΔT for which either long-range order disappears or for which a uniform magnetization configuration is unstable with respect to canting, twisting, or domain formation. Erickson and Mills roughly estimate a value of $\Delta T/T_R \sim 0.5\%$ for an ultrathin Fe film. A gap due to domain formation can be appreciably larger in magnitude than this estimate. This is because the gap would signal the T range over which the scale of the domain structure shrinks to dimensions that are less than the sample size or probing length.

Much has been said about 2D spin-reorientation phenomena so far, but perhaps the most fascinating aspect to appreciate is that it is predicated on the existence of perpendicular surface anisotropy that is strong enough to compete with the shape anisotropy of the film. For Fe the shape anisotropy gives rise to an ~20 kG demagnetizing field. Thus, the surface anisotropy must be quite substantial in magnitude. Néel[11] was the first to recognize that unusually strong surface anisotropies relative to bulk anisotropies can exist. The bulk magnetocrystalline anisotropy was first attributed to the spin-orbit interaction by Van Vleck.[12] Néel recognized that strong spin-orbit interactions could arise from the broken symmetry at the surface. Much more recently Gay and Richter[13] performed the first computational study to confirm that strong surface anisotropies can be anticipated in particular systems. Wang, Wu, and Freeman[14] have contributed the most recent state-of-the-art advances to this demanding approach.

Gradmann[15] was the first to experimentally identify perpendicular easy axes attributed to strong surface anisotropy He recently reviewed his work that dates back to the 1960s on a variety of films, in an outstanding book chapter. Jonker *et al.*[16] reawakened interest in the surface anisotropy issue in 1986. They attributed the nonobservation of spin polarization in photoemission experiments on Fe/Ag(100) films as being due to the existence of vertical easy axes, and to the technical constraint that the spin detectors employed in their experiments were only sensitive to *in-plane* magnetization components. Recent work on surface magnetic anisotropy in ultrathin films have been reviewed in a variety of publications.[17]

Another experimental manifestation of strong surface anisotropies can be observed in enhanced coercivity (H_c) values displayed in the ultrathin regime. The earliest studies of this type are due to Hirsch[18] who observed a factor of ~5 enhancement in H_c for ultrathin Fe interleaved with Cu. Bader[19] documented a number of systems for which H_c peaks in the monolayer region. Engel *et al.*[20] have observed H_c peaks in monolayer-range films that occur as a function of the thickness of a nonmagnetic overcoating layer. This can be due to electronic effects or morphological (i.e., wetting) changes in the magnetic layer. Gradmann has documented similar examples of coercivity and anisotropy changes due to nonmagnetic overcoats.[15]

The first experimental identifications of temperature-dependent 2D spin-reorientation transitions in transition-metal films are due to Pappas, Kämper, and Hopster.[21] They studied both Fe/Ag(100) and Fe/Cu(100). A ΔT range of ~20–30 K was identified that had vanishingly small remanence. Allenspach and Bischof[22] subsequently imaged the magnetic domains of Fe/Cu(100) and observed striped domains with smectic liquid-crystal-like orientational order, as described by Kashuba and Pokrovsky.[10] However, the question is still not answered as to whether the spontaneous magnetization, as opposed to the average magnetization, is at all reduced or not in the immediate vicinity of the spin-reorientation transition.

In the present work we describe recent surface magneto-optic Kerr effect (SMOKE) contributions to this fundamental problem in 2D magnetism. We first examine Fe/Ag(100) for which magnetic instabilities can be studied without concern for structural instabilities, since Fe is well lattice matched to the Ag(100) square net. Then we progress to the more complex case of Fe/Cu(100) which can exhibit similar spin-reorientation behavior to Fe/Ag(100), but also possesses structural instabilities.

fcc Fe(100) is lattice matched to Cu(100). In the ultrathin limit a tetragonally distorted fcc structure is stable. This fct structure relaxes to an undistorted fcc structure upon increasing the Fe thickness.[23] The fct phase is itself unusual for an element. Only elemental Sn has a naturally occurring fct phase. In the case of Fe/Cu(100) the fct structure is stabilized epitaxially. (This is one of the attributes of modern thin-film-magnetism research—the ability to artificially stabilize new phases.) Eventually, thicker Fe films grown on Cu(100) transform to the equilibrium bcc structure. bcc(110) epitaxial relationships to fcc(100) have been described elsewhere.[24] Metastable phases, therefore, abound in Fe/Cu(100) as a function of growth temperature and Fe thickness. The fct spin-reorientation transition, for example, is only found for low-T growth ($T \leq 200$ K). At higher temperatures the fct structure relaxes to fcc and the magnetic properties change dramatically, as studied recently by Thomasen *et al.*[25] and Li *et al.*[28] Thus, Fe/Cu(100) provides a system rich in magnetic and structural instabilities. The interplay of these instabilities has intrigued, challenged, and stymied a whole generation of

modern researchers. An enormous collective effort has been devoted to this system. It is the prototype chosen by many who seek a rite of passage into the realm of surface magnetism.

II. EXPERIMENTAL DETAILS

Background information on the sample preparation, characterization, and magneto-optic-measurement techniques appear elsewhere.[26–28] For the sake of completeness we briefly mention that the Fe samples were prepared by ultrahigh vacuum evaporation, also known as molecular beam epitaxy. The Fe wedges are formed by linear translation of the substrate behind a mask during growth. Evaporation rates are in the range of 1 monolayer (ML) every ~2–3 min. The wedges have a slope of ~0.2 ML/mm for Fe/Ag and ~1.5 ML/mm for Fe/Cu. The slopes are substantially larger for the Fe/Cu wedges in order to scan the broader region of interest that includes a range of the fct, fcc, and bcc phases. The crystals were ~1 cm in length, and the laser beam for the SMOKE studies was focused to ~0.2 mm. Thus ~50 discrete positions could be sampled along a wedge. The substrates were prepared utilizing standard surface-science techniques involving sputter-anneal cycles. Low- and high-energy electron diffraction (LEED and RHEED) were used to characterize the substrates and films. RHEED oscillations during Fe growth are published in Refs. 27 and 28.

Magneto-optic Kerr-effect measurements were made at the He-Ne laser line using p-polarized light. The films were magnetized using a split-coil superconducting solenoid that provides a homogeneous field with low trapped flux at zero current (<10 Oe). Hysteresis loops were generated with no attempt to convert to ellipticity units. Ellipticities are reported elsewhere for related film structures.[29] The important point for the present studies is that the signal is proportional to the magnetization. The remanent magnetization M_R was used to track the phase transitions in order to avoid possible field-induced transitions. The hysteresis loops are used to identify the easy axis of magnetization. Square polar loops identify vertical easy axes, while square longitudinal loops identify in-plane easy axes. To obtain polar or longitudinal signals the sample was positioned appropriately within the solenoid to face one of two orthogonal laser stations used to generate the data. Thus, it was necessary to rotate the sample by 90° between full scans of a wedge to obtain data for both configurations. This introduced an absolute uncertainty in the positioning of the beam along the wedge, but it presented no obvious problem for our purposes. The hysteresis loops permitted the H_c values to be obtained. They were used to identify the structural transitions for Fe/Cu and to augment the spin-reorientation studies for both systems.

III. RESULTS

A. Fe/Ag(100)

The spin-reorientation transition for Fe/Ag(100) is shown in Figs. 1(a) and 2. Figure 1(a) displays the transition as a function of temperature for a fixed Fe thickness. This is the manner in which the transition was studied originally by Pappas *et al.*[21] who used polarized electron scattering to identify a region ΔT with vanishing magnetization. The high signal-to-noise ratio and data density in Fig. 1(a) enables one to discern an asymmetric ramp structure within the pseudogap encompassed by ΔT. Thus, if the remanence vanishes, it does so over a very limited T range (a few kelvin at most), as estimated by Erickson and Mills. Note that M_R in Figs. 1(a) and 2 are normalized to the film thickness, and the longitudinal and polar M_R values at saturation are normalized to each other for clarity. (The polar signal is ~25 times as intense as the longitudinal signal, as expected.) The question that Fig. 1(a) raises is what is the root cause of the remanence decrease within ΔT? Is long-range ferromagnetic order lost anywhere within this region, as might be anticipated from the Mermin–Wagner theorem? How do domains or other nonuniform spin configurations manifest themselves within ΔT? If long-range order does not vanish, do enhanced thermal fluctuations in 2D suppress the magnetization even

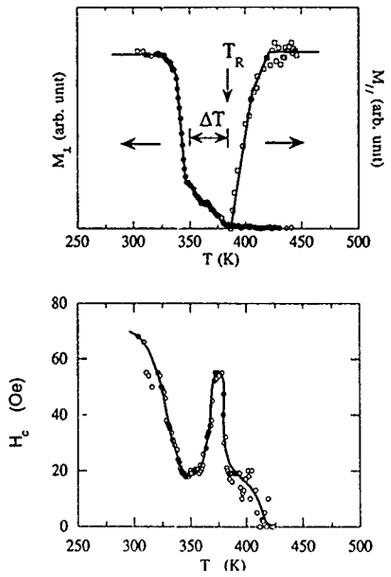

FIG. 1. The perpendicular and parallel components of the remanent magnetization for a 6.0 ML Fe film grown on Ag(100) vs temperature are shown in (a) and the corresponding coercivities from polar SMOKE measurements are shown in (b). The noise in the longitudinal Kerr data (parallel magnetization component) is greater than that in the polar data because of the inherent weakness on the longitudinal signal, as mentioned in the text

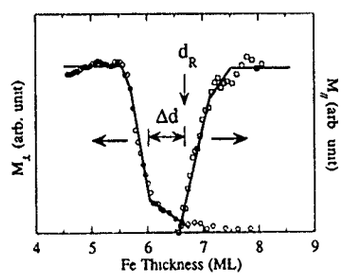

FIG. 2. Perpendicular and parallel components of the remanent magnetization at room temperature along an Fe/Ag(100) wedge.

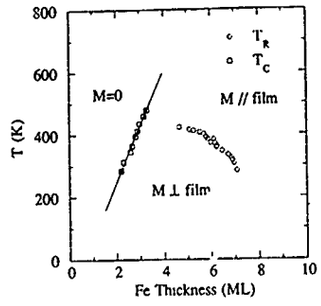

FIG. 3. Magnetic phase diagram of Fe/Ag(100).

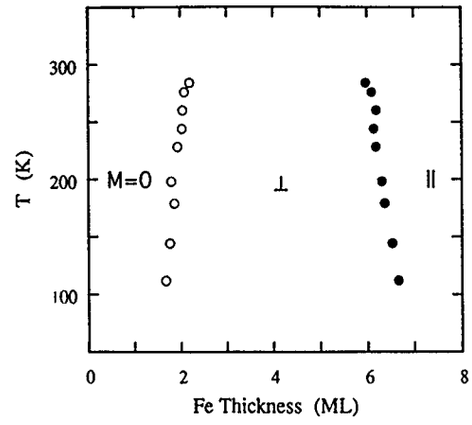

FIG. 4. Boundaries of the uniform ferromagnetic phase with vertical easy axis for an fct Fe/Cu(100) wedge as a function of measurement temperature and Fe thickness. The left-hand boundary delineates the onset of detection of a ferromagnetic signal, while the right-hand boundary terminates in a transition to the spin-in-plane fct phase.

partially due to the system becoming more isotropic in the vicinity of T_R? These questions should motivate future progress in the field.

Figure 2 provides similar data to Fig. 1(a) but as a function of Fe thickness along a wedge. The region Δd and the point d_R are defined operationally in an analogous manner to ΔT and T_R in Fig. 1(a). The asymmetric ramp structure within Δd is very similar in appearance to that observed in Fig. 1(a) within ΔT. The same questions apply as outlined above. It is interesting to note that Kashuba and Pokrovsky[10] have found that their calculations linearize to first-order expansion in both T and d in the vicinity of T_R and d_R, as observed experimentally in Figs. 1(a) and 2.

To augment Fig. 1(a) further, we show the corresponding H_c data in Fig. 1(b). The transition at T_R is defined by a peak in H_c which is almost 3 times as large as its value at $(T_R-\Delta T)$. For $T>T_R$ the value of H_c drops precipitously because the vertical axis becomes a hard direction for the magnetization. For $T<(T_R-\Delta T)$, H_c decreases substantially as T increases. Thus, the hysteresis loops are shrinking in area in this interval as T increases. This can be due to enhanced thermal fluctuations as T_R is approached, or to the fluidity of the domain structure. The peak in H_c at T_R, in any case, represents a striking observation and a challenge to interpret.

Figure 3 summarizes results for the spin-reorientation phase-boundary determinations for Fe/Ag(100). The data represent measurements taken along wedges at different temperatures. The pseudogap regions are not indicated in Fig. 3, but Curie temperatures T_C are shown for some initial Fe thicknesses. The Curie transitions are found to be 2D-Ising-like, as described in Ref. 27. The Curie transitions can be examined to provide an estimate of the intrinsic width that might apply also to the spin-reorientation transitions. The 3%–5% tails reported at T_C imply that the correlation length is limited by finite-size effects to ~100 Å, which corresponds to a typical terrace width in a metallic single crystal.[27] Thus, with inclusion of the Curie transitions, Fig. 3 delineates the $M=0$, $M_{\parallel}$, and $M_{\perp}$ phase regions.

B. Fe/Cu(100)

The region of stability of vertical easy axes for Fe/Cu(100) was first explored systematically by Liu *et al.*[30] They constructed a phase diagram to represent the metastability of the system by plotting growth temperature versus Fe thickness for a large number of films. Vertical easy axes were observed in a region bounded by a thickness of ~6 ML Fe and growth temperatures that do not extend very much above room temperature. The onset of ferromagnetic signals for the thinnest films occurred between ~1 and 3 ML. Figure 4 shows a somewhat different mapping than that of Liu *et al.*[31] for one of our wedged samples grown at low temperature. Figure 4 is analogous to the plot of the Fe/Ag(100) data in Fig. 3. The left-hand boundary in Fig. 4 represents the onset of detection of ferromagnetic signals with vertical easy axis (i.e., T_C), while the right-hand boundary represents the termination of the vertical ferromagnetic phase (i.e., T_R). The left-hand boundary is believed to be influenced by the non-ideal morphology of the films (i.e., intermixing) as well as by decreased T_C values for decreasing film thickness.

Subsequent to the work of Liu *et al.*[31] interest focused on the region beyond the right-hand boundary of Fig. 4. It became clear that two phases exist in this region depending on growth temperature. For low temperature (~100 K) growth the spin-reorientation transition ensues, as for Fe/Ag(100). This occurs even if the samples are annealed to the

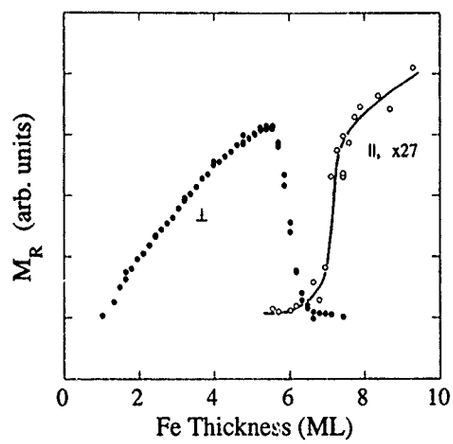

FIG. 5. Spin-reorientation transition for Fe/Cu(100).

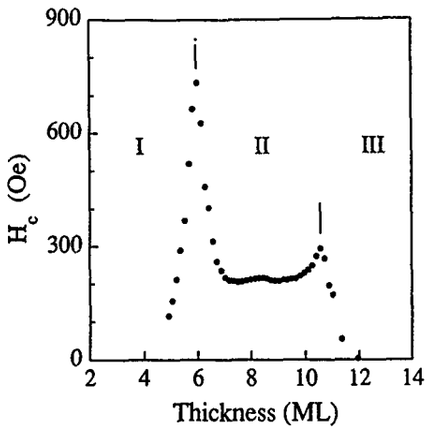

FIG. 6. Coercivities along a wedge of Fe/Cu(100) illustrating peaks at the phase transitions. The left-hand transition is from the fct (I) to the fcc phase (II), while the right-hand transition is to the bcc structure (III).

vicinity of room temperature after growth, as in the work of Ref. 21. For example, the spin reorientation is shown in Fig. 5 for a wedge grown at 190 K, annealed at room temperature, and measured at 110 K. However, different results are obtained for room-temperature growth. Xhonneux and Courtens[31] found evidence for a nonmagnetic phase beyond the 6–7 ML Fe phase boundary. Thomasen *et al.*[25] further clarified the new phase identification as having a surface ferromagnetic "live" layer with vertical easy axis. Li *et al.*[28] more recently confirmed the work of Thomasen *et al.*[25] and, further, found evidence that the ferromagnetic surface is the termination of an antiferromagnetic (AFM) phase. Antiferromagnetism does not manifest itself directly in SMOKE measurements, so further explanation is necessary. While Ref. 25 observed a constant magnetization in the region of interest, Li *et al.*[28] found that upon cooling the constant signal developed peaks of monolayer-type amplitude. For an AFM structure built up of alternating ferromagnetic (100) sheets, a peak would arise due to an uncompensated ferromagnetic sheet whenever there is an odd number of total layers in the structure.

Structural studies indicate that the AFM phase corresponds to the relatively undistorted fcc structure. The $M_\perp$ ferromagnetic phase that precedes it in Fe thickness corresponds to the unrelaxed fct structure. The spin-reorientation transition takes place within the fct structure, and the transition to fcc is suppressed at low-temperature growth. The fct structure is probably strain stabilized under these conditions due to the morphology of the interface and/or to magnetostriction effects. In this latter regard, Hembree *et al.*[32] recently documented for Fe/Cu(100) striking field-induced metastable states attributed to magnetoelastic effects. It is also of interest to speculate on the relationship of the AFM fcc phase identified by Li *et al.*[28] to that observed in γ-Fe coherent precipitates in Cu host alloys. For the bulk alloys the Néel temperature T_N is low as is the magnetic moment ($<1\mu_B$).[33] For the films the magnetic ordering temperature is much higher (200–250 K) suggestive that the moments may also be larger. However, it remains to be determined to what extent the surface ferromagnetic layer boosts the properties (T_N and μ) of the underlying AFM film.

Finally, with increasing Fe thickness the bcc phase is reached at ~10–12 ML Fe. The bcc films are ferromagnetic with in-plane easy axis dictated by the shape anisotropy. The coercivity exhibits striking peaks at the phase transitions, as shown in Fig. 6 for a wedge than spans the fct-fcc transition as well as the bcc transition. The coercivity provides a convenient way to track phase boundaries between fct-fcc, fcc-bcc, and fct-bcc, as well as for the spin-reorientation transition. The most recent magnetic phase diagram for the growth of Fe/Cu(100) is presented in Ref. 28.

IV. SUMMARY

Recent SMOKE studies for Fe/Ag(100) and Fe/Cu(100) were highlighted. The documentation of the spin-reorientation transition for Fe/Ag(100) provides detailed corollary measurements to those of Refs. 21 and 22. A suppressed but nonvanishing remanent magnetization was found within most of the pseudogap region in temperature and Fe thickness that characterizes the phase transition. The coercivity also exhibits a pronounced peak. The role of thermal fluctuations in a nearly isotropic 2D Heisenberg system is quite dramatic and can suppress long-range order and/or give rise to domain structures with unusual characteristics.

For fct Fe/Cu(100) the spin-reorientation transition occurs for low-temperature ($\lesssim$200 K) growth. However, for room-temperature growth the ferromagnetic fct phase with vertical easy axis transforms to an AFM fcc phase with a surface ferromagnetic live layer. Fe films of ~10–12 ML transform to the equilibrium bcc ferromagnetic structure with in-plane easy axis of magnetization. The Fe/Cu(100) system offers complexity associated with the interplay of magnetic and structural transitions. However, coercivity peaks can be used to track a variety of its phase transitions. The underlying mechanisms for achieving phase stability and that control coercive behavior remain a challenge to pursue in the future.

Magnetic and structural instabilities of ferromagnetic and antiferromagnetic Fe/Cu(100)

Dongqi Li, M. Freitag,[a] J. Pearson, Z. Q. Qiu,[b] and S. D. Bader
Materials Science Division, Argonne National Laboratory, Argonne, Illinois 60439

Fe wedges epitaxially grown on Cu(100) have been employed to investigate the interplay between magnetic and structural instabilities. 2–4 monolayer (ML) clean Fe films grown at room temperature are ferromagnetic with perpendicular easy axes. bcc Fe films>11 ML thick are ferromagnetic with in-plane easy axes. Most importantly, 6–11 ML fcc Fe films are antiferromagnetic and have a ferromagnetic surface. Films grown below 200 K and annealed to room temperature do not exhibit the antiferromagnetic phase, but remain ferromagnetic and undergo a spin-reorientation transition from perpendicular to in plane at ~6 ML. A new phase diagram for Fe/Cu(100) is proposed as a function of thickness and growth temperature. In addition, an impurity-stabilized layer-by-layer growth that persists to 30–40 ML Fe is also reported.

Iron, especially fcc Fe, is intrinsically unstable magnetically in the sense that its nearest-neighbor exchange interaction can be either positive (ferromagnetic) or negative (antiferromagnetic), depending on structural details.[1,2] Fe films grown onto Cu(100), in particular, form various structural and magnetic phases to illustrate the tendency toward instability.[3–9] In the current work, we focus on these instabilities and their interplay to achieve a better understanding of the relation between structure and magnetism. Most important, we observe an antiferromagnetic phase with a ferromagnetic surface for 6-11 monolayer (ML) films of Fe grown on Cu(100) at ambient temperature. The different magnetic phases are displayed in a new magnetic phase diagram. In addition, an impurity-induced layer-by-layer growth of Fe on Cu(100) is observed that persists into the 30–40 ML regime.

Sample preparation proceeded first via mechanical and electrochemical polishing of the Cu(100) substrate, and then via sputtering and annealing (600 °C) cycles in the ultrahigh vacuum chamber. Fe was evaporated from an alumina crucible with a typical evaporation rate of 0.7 Å/min. The base pressure of the chamber was 1×10^{-10} Torr, and the pressure during deposition was $2\text{–}5\times10^{-10}$ Torr. The ordering and cleanness of the crystal and the films were confirmed with reflection high-energy electron diffraction (RHEED), low-energy electron diffraction (LEED), and Auger spectroscopy. The Fe wedges were grown while moving the substrate behind a mask during evaporation to define a slope of ~1.5 ML/mm. The substrate temperature during growth is denoted as T_s. The magnetic properties were studied *in situ* by means of the surface magneto-optic Kerr effect (SMOKE). A He-Ne laser beam focused to 0.2 mm was used to scan along the wedge to obtain hysteresis loops for different Fe thicknesses. The height of the Kerr loop in remanence is denoted as M_R, due to its relation to the remanent magnetization. First the results of "dirty" growth will be presented. The remainder of the article will then be devoted to the properties of clean films.

Quite striking behavior is observed for dirty growth. In that case persistent layer-by-layer growth can be obtained (see Fig. 1) as judged by relatively undamped RHEED oscillations up to 32 ML Fe. The oscillations resume after restarting the stopped deposition (not shown in Fig. 1) and persist to 40 ML, where the experiment was terminated. This is surprisingly thick for a metastable phase. The LEED patterns before and after deposition were both $c(2\times2)$, which is a common pattern for contaminated fcc(100) surfaces. Auger measurements indicate an oxygen level of 10–20 at. % for both the substrate and the film. The chamber pressure during this dirty deposition was 2×10^{-9} Torr, which is significantly higher than that for the clean films to be reported herein. It is apparent that the layer-by-layer growth of the metastable fcc Fe shown in Fig. 1 is extrinsically stabilized by impurities, as can be qualitatively understood. There are two factors that mitigate against persistent layer-by-layer epitaxial growth. One involves the thermodynamic argument that opposes the wetting of a high-surface-free-energy species (Fe) on a low-surface-free-energy substrate (Cu). Three-dimensional growth would be anticipated in such a case. The other factor is that the slight lattice mismatch between fcc Fe (3.59 Å) and Cu (3.61 Å) should cause strain in the film and lead to a critical thickness for epitaxial growth. The impurities appear to act as surfactants to lower the surface free energy of Fe so

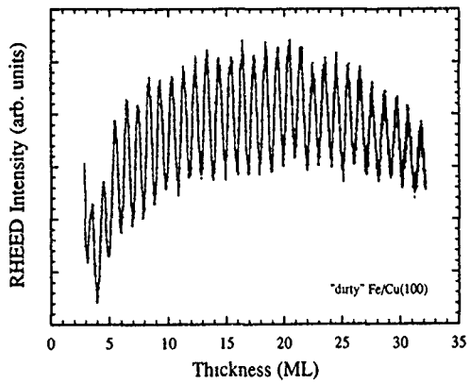

FIG. 1. RHEED intensity oscillations for a dirty deposition of Fe on Cu(100). The persistent oscillation, indicative of layer-by-layer growth, are impurity induced, as discussed in the text. The deposition rate was 0.64 Å/min T_s=315 K.

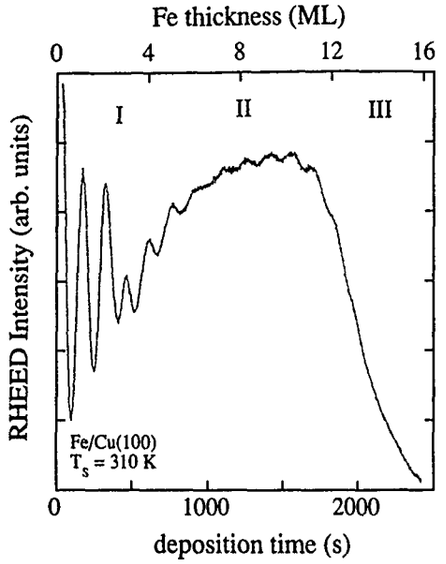

FIG. 2. RHEED intensity oscillations for Fe grown on Cu(100) at 310 K. Regions I–III are labeled as in Ref. 3.

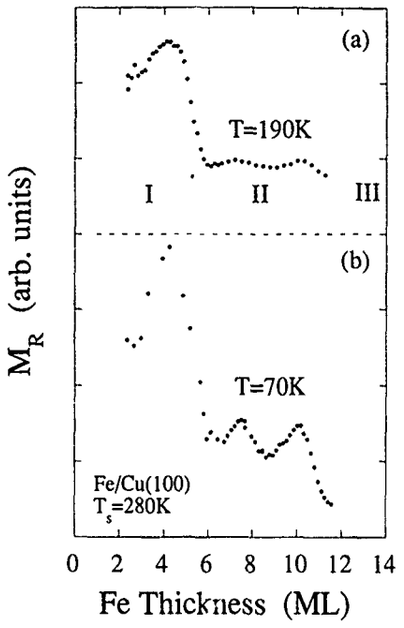

FIG. 3. Perpendicular remanent magnetization from polar SMOKE vs thickness across an Fe wedge grown at T_s=280 K and measured at 190 K (a) and 70 K (b). Region II has a enhanced surface ferromagnetic layer and antiferromagnetic underlayers as discussed in the text.

that it can wet the Cu(100) surface. Such an effect was discussed by Egelhoff *et al.*,[10] who point out that various atoms can serve as surfactants for 1 ML Fe/Cu(100) and related systems, and that some impurity atoms can float to the surface during growth to continue to activate layer-by-layer growth. The impurities may also serve as defect centers to help release film strain and to thwart the transition into the equilibrium bcc phase. Thus, impurity surfactant agents can provide a promising way to extend the study of epitaxial growth of metastable phases.

The growth characteristics of clean Fe films on Cu(100), as documented in Fig. 2, are more complex than the behavior shown in Fig. 1. Three growth regions are delineated in Fig. 2 for films grown above 250 K on the (1×1) Cu(100) substrate with no detectable C or O Auger signals, in agreement with previous studies.[3] No in-plane lattice-constant differences are observed by RHEED or LEED between the first two thickness regions as Fe grows into pseudomorphic face-centered structures. Region I has been attributed to a face-centered tetragonal (fct) phase and region II to the fcc phase.[11] Region II exhibits regular oscillations characteristic of a tendency toward layer-by-layer growth. The sharp decay of the RHEED intensity on going from region II to III at ~11 ML has been attributed to the onset of three-dimensional growth of bcc Fe.[3,7,8]

Different magnetic properties accompany the structural phases of regions I–III. For films grown above 250 K, the magnetic easy axis changes from perpendicular to in plane at ~11 ML. The magnetic anisotropy is dominated by the shape anisotropy in region III. In region I the surface anisotropy yields a perpendicular easy axis. Most strikingly, there is a dramatic change in the magnetic properties between regions I and II from the ferromagnetic phase to an antiferromagnetic phase with a ferromagnetic surface. This is shown in Fig. 3. The remanent magnetization obtained from our magneto-optic measurements increases initially in region I with Fe thickness as expected for a ferromagnetic film. At ~5 ML Fe, however, the magnetic signal drops to ~30%–40% of its maximum value. In addition, in region II the remanent magnetization forms a two-peaked structure between 6 and 11 ML which is most apparent at low temperature. These observations suggest that the bulk of the Fe film is antiferromagnetic with alternating layers of spins pointing out of or into the surface. There is a relatively constant magnetic signal in region II at relatively high temperature (right below T_C). And the signals at the valleys do not go to zero in the temperature range we performed our experiments. These facts suggest that the surface layer is ferromagnetic, as reported in Ref. 9, and has an enhanced magnetic order. The antiferromagnetic order is more significantly reduced by thermal fluctuations than is the ferromagnetic surface order. This unique magnetic phase was observed only when the substrate was clean and the pressure during deposition was $<5\times10^{-10}$ Torr. A recent theoretical calculation[12] suggests that the for 4–11 ML of fcc Fe on Cu(100), the surface and one subsurface layer are ferromagnetically aligned while the underlayers are antiferromagnetically aligned, in general agreement with our experimental observations. It is noted that the peak separation in our experiments is ~2.6 ML instead of 2 ML. Such an incommensurate magnetic structure is not indicated by the calculation of Kraft *et al.* It could relate to the quantization of the electronic states and the corresponding spin density wave in a finite thickness film.

The richness of magnetic phases of Fe/Cu(100) is demonstrated in the new magnetic phase diagram shown in Fig. 4. Region I contains the ferromagnetic phase with perpendicular magnetic anisotropy. A nonmagnetic region <2 ML, not delineated in Fig. 4, is presumably due to a reduced

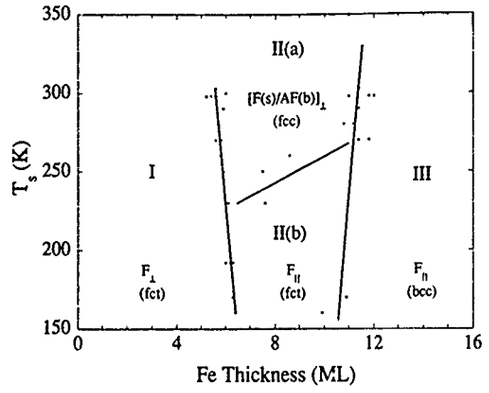

FIG. 4. Magnetic phase diagram with respect to growth temperature and Fe thickness. In region I, the films are ferromagnetic with perpendicular easy axes (fct). In region II(a) the films are AF and the surface is ferromagnetic (fcc). In region II(b), the films are ferromagnetic with in-plane easy axes (fct). In region III, the films are ferromagnetic with in-plane easy axes (bcc). (Measurements were performed in the range of 110–190 K.)

Curie temperature. Thick films (>10–11 ML) are bcc and possess in-plane ferromagnetic magnetization. At the intermediate thicknesses of region II different phases can be formed depending on the substrate temperature. For low-temperature deposition, where the fct-to-fcc phase transition is suppressed, a spin-reorientation transition occurs into region II(b) wherein the easy axis changes from perpendicular to in plane.[9] For growth temperatures higher than ~250 K, the newly identified antiferromagnetic phase with the live ferromagnetic surface layer appears in region II(a), as discussed above.

The difference in structure between regions I and II for ambient-temperature-grown films is believed to be the difference in interlayer spacing.[11] The initial phase is a fct structure with interlayer spacing different from the in-plane lattice constant. Such a distortion appears to stabilize ferromagnetic ordering. The second phase is the more isotropic fcc phase[11] which is antiferromagnetic and has a ferromagnetic surface. Because of the magnetic instability of fcc Fe, a small lattice distortion can drive the system into either antiferromagnetic or ferromagnetic states with different anisotropies. Recent work reported that fcc Fe grown on diamond (capped with Cu) is also ferromagnetic, but with in-plane anisotropy.[13] This might be consistent with the expected in-plane compression of Fe on diamond (lattice constant of 3.51 Å) as opposed to the expected in-plane expansion of Fe on Cu(100).

In conclusion, we investigated the ferromagnetic and antiferromagnetic phases of Fe/Cu(100) which correlate with its structural phases. We observe a new antiferromagnetic phase with a live ferromagnetic surface. We propose a new magnetic phase diagram for the growth of Fe on Cu(100). We also observe impurity-induced layer-by-layer growth of Fe on Cu(100) that persists to at least ~40 ML.

A new spectrum component is observed in Mössbauer spectra of thin body centered cubic Co layers doped with ^{57}Co which have previously been shown to be in this metastable state with nuclear magnetic resonance. It is characterized with a large magnetic hyperfine field (31.2 T) and an isomer shift nearly equal to that of α-Fe. The decrease of the isomer shift in bcc Co with respect to hcp Co is consistent with a smaller $s-d$ charge transfer in bcc Co as compared to hcp Co. The influence of structure on the hyperfine field in a Co crystal is reflected in the decrease of the magnetic hyperfine field of Fe in bcc Co as compared to hcp Co and is similar to the volume dependence of the magnetic hyperfine fields in a Co crystal.

Over the last years magnetic films and superlattices grown with molecular beam epitaxy have attracted considerable attention in the search for new materials with unusual magnetic and structural properties. Recently it has been shown that a metastable body centered cubic Co phase can be grown on GaAs, Fe, and in Co/Fe superlattices.[1–4] One of the properties which is expected to be strongly dependent on the structure of a Co crystal is the magnetic hyperfine field. The characterization of the bcc phase was therefore established with NMR spectroscopy which showed a NMR frequency at 199 MHz for bcc Co, a value which is about 10% lower than the known NMR frequencies in fcc and hcp Co. The purpose of the present study is to use radioactive ^{57}Co as a probe material for the magnetic hyperfine fields in these layers. A ^{57}Fe source experiment in which the Mössbauer isotope is the daughter isotope of ^{57}Co is one of the few methods to measure the hyperfine interaction at Fe in a thin metastable bcc Co crystal. ^{57}Fe-NMR measurements or absorber Mössbauer measurements would require a much larger concentration of Fe into Co. The introduction of ^{57}Co as a radioactive probe in the Co phase under investigation offers at least five orders of magnitude of sensitivity as compared to absorber experiments.[5] There are two more distinct advantages in the use of Mössbauer spectroscopy to study ^{57}Co in bcc Co: first, one can be completely confident that the Fe atoms will occupy Co sites, as ^{57}Co is expected to take a regular substitutional lattice site in bcc Co and second, ^{57}Fe is the best Mössbauer probe with a high recoil-less fraction and a good sensitivity of the isomer shift (δ) to pressure.[6] In such source experiments it is generally believed that the atomic configuration surrounding the probe atom is not modified during the extremely short lifetime of the excited Mössbauer state, i.e., the ^{57}Fe directly probes the bcc Co atomic configuration.

It is intriguing to notice that the hyperfine field at ^{59}Co in a Co crystal determined with NMR is quasilinearly decreasing with the atomic volume of the specific Co phase studied (hcp, fcc, or bcc Co). A similar behavior is observed in the pressure dependence of the magnetic hyperfine field in a Co crystal, i.e., the magnitude of the hyperfine field is decreasing with the volume.[7] The pressure effect on the hyperfine field is however an order of magnitude smaller than the observed decrease of the hyperfine field of bcc Co with respect to hcp Co. In recent years several studies, both theoretical and experimental, have been performed to explain systematic trends and the pressure dependence of the magnetic hyperfine fields of impurity atoms into ferromagnetic host metals such as Co, Fe, and Ni.[7,8] The experimental determination of the magnetic hyperfine field in a metastable magnetic phase such as bcc Co might shed some light on the dependence of the magnetic hyperfine field of impurity atoms on the structure of the crystal phase under investigation. Co is, just like Fe, a unique material which can take the form of three crystallographically different magnetic phases. In the present study the hyperfine field of Fe in bcc Co is determined with Mössbauer spectroscopy and compared with the known hyperfine field of Fe and its volume dependence in hcp Co. In addition Mössbauer spectroscopy is sensitive to the atomic volume via the isomer shift. We will demonstrate that the decrease of the hyperfine field of Fe in bcc Co with respect to hcp Co is certainly not a volume effect but more likely is due to a coordination effect.

Samples were prepared by implanting 80 keV radioactive ^{57}Co with a dose of 10^{14} atoms/cm^2 into Co/Fe superlattices grown with molecular beam epitaxy. The metastable bcc Co epitaxy on Fe (001) is possible because of the small lattice mismatch of 1.6% between the predicted bcc Co phase ($a=2.82$ Å) and an (1×1) construction on Fe ($a=2.87$ Å). $[Fe_xCo_y]_{20}$ superlattices with various Co layer thickness ($x=25$ Å, 6 Å$<y<$24 Å) were prepared on MgO (001) substrates. Details of the preparation conditions can be found elsewhere.[9] The Mössbauer spectra were recorded at 300 K using a sodiumferrocyanide absorber (SFC). The δ values are expressed as absorber isomer shift with respect to SFC.

NMR measurements on these samples revealed a metastable state for Co characterized with a frequency of 199 MHz, a value which is lower than the Co frequency in fcc (217 MHz) and hcp Co (220–228 MHz). The metastable state is attributed to Co in a bcc phase and relaxes for this growth direction to the regular hcp phase only for Co layer thickness above 24 Å.[10] Co/Fe superlattices with Co thickness smaller than 24 Å are expected to contain the following atomic configurations for the implanted ^{57}Co probe atoms: α-Fe, bcc Co, Co/Fe interface region, and a possible surface

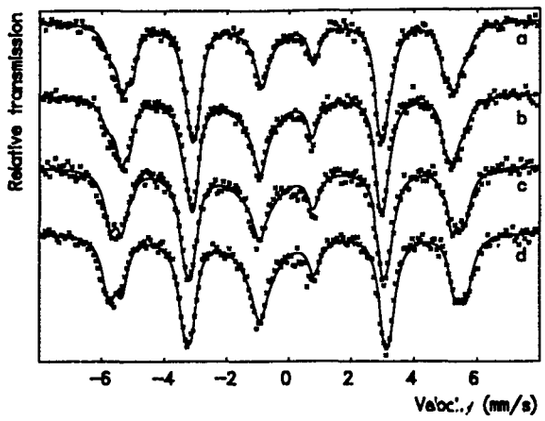

FIG. 1. Mössbauer spectra of bcc Co/Fe superlattices with various Co layer thickness [24 Å (a), 18 Å (b), 12 Å (c), and 6 Å (d)] implanted with 10^{14} ^{57}Co measured at 300 K with respect to a sodiumferrocyanide absorber.

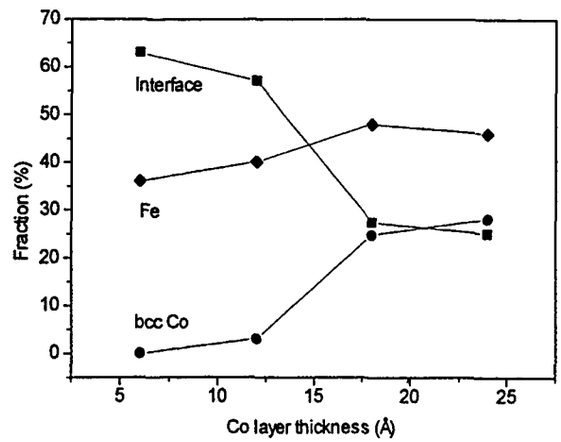

FIG. 2. Relative contribution of the magnetic spectrum components of Mössbauer spectra of bcc Co/Fe superlattices for various Co layer thickness [(♦) α-Fe, (●) bcc Co, (■) CoFe interface].

oxide layer. Figure 1 shows the ^{57}Fe Mössbauer spectra of Co/Fe superlattices with different Co-layer thickness. For the layer with 6 Å Co only two magnetic spectrum components are present. The hyperfine field of the first spectrum component and its isomer shift are within error limits equal to that of α-Fe [B=33.1 T]. The second component has a hyperfine field of 35.4 T and an isomer shift δ=0.10 mm/s. It is reasonable to attribute this component to Fe in the Co/Fe interface region since it is almost equal to the hyperfine field of Fe in an equiatomic Co/Fe alloy. With increasing Co layer thickness in addition to the above-mentioned magnetically split components a third spectrum component is observed with a slightly lower hyperfine field [B=31.0 T (12 Å Co), B=31.4 T (18 Å Co), and B=31.2 T (24 Å Co)]. The assumption that this new component is due to Fe in bcc Co is justified by two observations: first, the increase of the relative contribution of this component with Co layer thickness is accompanied by a decrease of the interface component (see Fig. 2) and is similar to the increase of the NMR component at 199 MHz, and second, this hyperfine field component is clearly lower than the known hyperfine fields of Fe in hcp Co and in Co/Fe alloys. Therefore we attribute it to Fe in bcc Co and estimate the hyperfine field of Fe in bcc Co to be 31.2(2) T. Finally, a nonmagnetic single line component with δ=0.90 mm/s is observed in all the Mössbauer spectra and is probably due to the presence of an oxide layer. The contribution of this spectrum component is decreasing with increasing Co layer thickness which reflects the higher resistance of Co to oxidation as compared to Fe.

The bcc Co spectrum component is characterized by an isomer shift which is only slightly smaller than the isomer shift of the α-Fe component and consequently is also smaller than the isomer shift in hcp Co. The isomer shift is well know to be proportional to the electron density at the nucleus and thus depends on the atomic volume. The behavior in bcc Co is opposite to what can be expected from the volume dependence of the Fe isomer shift in hcp Co. The isomer shift of Fe in hcp Co decreases with pressure[6] and one might expect an increase of the isomer shift for bcc Co since it has a larger volume then hcp Co. The decrease of the isomer shift in bcc Co can however be explained by a smaller $s-d$ charge transfer in bcc Co with respect to hcp Co. It is therefore supporting without really proving such a charge transfer effect which has been proposed a long time ago to explain the stronger volume dependence of the isomer shift in the bcc metals then in the close packed fcc and hcp metals.[6]

Recently the hyperfine interaction of Cd in bcc Co/Fe superlattices was studied with the angular correlation technique.[11] Also in these measurements a new value for the hyperfine field of Cd is observed which is substantially lower than the known hyperfine fields of Cd in fcc and hcp Co. It is remarkable that the hyperfine fields for Co, Fe, and Cd in the three Co phases are increasing almost linearly with the atomic density of the specific Co phase (see Fig. 3) and that the slope of this behavior reflects the difference of the experimental volume dependence of the hyperfine field of Co, Fe, and Cd in hcp Co. In pressure measurements one observed $d\ln B/dp=0.3\times10^{-3}$ kbar^{-1} for Fe,[12] $d\ln B/dp=0.615\times10^{-3}$ kbar^{-1} for Co,[7] and $d\ln B/dp=1.04\times10^{-3}$ kbar^{-1} for Cd[7] in hcp Co. The mag-

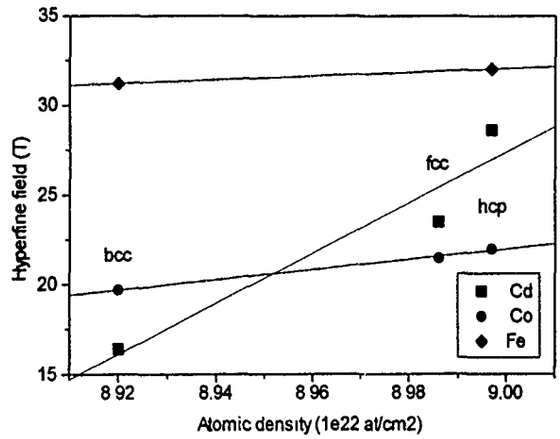

FIG. 3. Hyperfine fields of Co (●), Fe (♦), and Cd (■) in hcp, fcc, and bcc Co vs the atomic density of the specific Co phase.

nitude of the hyperfine field of Cd is decreasing much more rapidly with the atomic volume than that of Co and Fe, respectively. It is therefore tempting to associate the decrease of the hyperfine field in bcc Co with respect to hcp Co to a volume effect. However if one estimates the hyperfine field changes for bcc Co from the experimental volume dependence one gets a value which is much lower than the experimentally observed changes of the hyperfine fields of bcc Co. The corresponding microscopic change when going from a fcc to a bcc crystal is however predominantly governed by a change in the specific coordination. In the analysis of the transferred hyperfine field it is common to use a formalism proposed a long time ago by Stearns.[8] This model proposes that the transferred hyperfine field due to $4s$ neighbor conduction electron polarization (B_Σ) can be obtained by a summation over the neighboring atoms with a specific contribution ΔBi for each neighbor shell.: $B_\Sigma = \Sigma_1 n_i \Delta B_i$. Experimentally the different contributions have been determined up to the fifth-neighbor shell in fcc Co.[13] If one scales the fcc values to a bcc structure under the assumption that ΔBi has a Ruderman–Kittel–Kasuya–Yosida behavior and that the contributions in a specific shell for fcc Co have the same sign as in bcc Co one obtains a transferred hyperfine field for bcc Co which is a few tesla smaller than in fcc Co. This result is merely supporting the fact that the decrease of the hyperfine field in bcc Co is due to a structure effect. Finally it is noteworthy that recent theoretical calculations[14] based on a spin-polarized Korringa–Kohn–Rostoker (SP-KKR) formalism performed for bcc Co/Fe alloys show that the hyperfine field for pure bcc Co is about 20 T a value which is almost in perfect agreement with the NMR value we obtain for bcc Co in Co/Fe superlattices.

Ferromagnetism and growth of Ru monolayers on C(0001) substrates

G. Steierl, R. Pfandzelter, and C. Rau
Department of Physics and Rice Quantum Institute, Rice University, Houston, Texas 77251

The magnetic and growth properties of Ru monolayers on C(0001) are studied using spin-polarized secondary electron emission and Auger electron spectroscopy (AES). Using AES, we find that the initial growth of Ru on C(0001) occurs *laterally* until the first monolayer is completed. One monolayer-thin Ru film shows ferromagnetic order below a surface Curie temperature of approximately 250 K. The in-plane magnetization saturates in small applied fields of a few tenths of an Oe. This is the first observation of spontaneous, long-ranged, two-dimensional ferromagnetic order in an ultrathin film composed of a 4*d* transition metal.

Recent advances, both experimentally and theoretically, enable us to explore the possibility of inducing spontaneous, two-dimensional, long-ranged ferromagnetic order in elements that are paramagnetic in their bulk form. Interesting candidates are the paramagnetic 3*d*, 4*d*, and 5*d* transition metals.[1–6]

One way to address this interesting issue is to grow such a metal epitaxially on an adequate nonmagnetic substrate. Ferromagnetic order in such ultrathin films may be induced by the reduced coordination number and hence reduced interatomic hybridization, band structure effects due to the restriction to two dimensions and, compared to the bulk paramagnetic solid, an increased lattice constant imposed by pseudomorphic film growth.

As to ultrathin films of the 4*d*-transition metals, recent studies[2–10] have focused on Ru and Rh monolayers (ML) deposited on Ag(100) and Au(100) substrates. Theoretical works indicate that these systems should possess a ferromagnetic ground state.[2–6] Recent experiments for Rh on Ag(100) and on Au(100), however, failed to find any evidence for spontaneous, long-ranged ferromagnetic order,[13,14] or were inconclusive.[15] There is experimental evidence that an explanation for the discrepancies between theory and experiment can be found in the structural properties of the films deposited on these substrates: Schmitz *et al.*[16] propose that the equilibrium structure of Rh on Ag(001) is actually that of a sandwich with an Ag monolayer atop. Mulhollan *et al.*[14] find evidence for diffusion of Rh into the Ag matrix. Other authors do not rule out islanding.[13,14] These effects are indeed likely to prevent spontaneous, long-ranged ferromagnetic order.

Therefore we decided upon a different substrate and selected graphite C(0001) for the following reasons: similar to the noble metals, there is hardly a band overlap with the 4*d*-transition metals due to the low density of states near the Fermi level, which should prevent strong hybridization with the 4*d* bands. Moreover, the graphite (0001)-surface is known to be very flat, possessing only few steps and nearly no defects. This should considerably suppress interdiffusion. As film material we selected Ru, which has a hexagonal bulk lattice structure with an in-plane nearest neighbor distance which is almost twice that of graphite. Despite the difference in the surface free energy, epitaxial or pseudomorphic growth of metastable Ru with a lattice slightly stretched (5%) compared to the bulk should be favored.[11,12]

To study the growth and magnetic properties, we used Auger electron spectroscopy (AES) and spin polarized secondary electron emission (SPSEE). For many metal-on-metal systems, it was already shown, that AES is a very suitable technique to distinguish between various types of initial growth modes (lateral growth, islanding, intermixing).[19] We recorded the Auger intensity of the substrate and that of the adsorbate line as function of coverage or deposition time. The lateral growth and the completion of a ML is evident from the *linear* increase in the signal and the abrupt change in slope in both plots.

In SPSEE, an unpolarized electron beam of energy of a few keV is used to induce the emission of secondary electrons from the sample. The electron spin polarization (ESP) of the emitted secondary electrons is a direct measure of the surface magnetization. For SPSEE, we use an einzellens system with a 90° cylindrical energy analyzer connected to a 20 keV Mott polarimeter.

As substrate, we use highly oriented, pyrolytic graphite (HOPG) ($8\times15\times1$ mm^3) with a standard distribution of the *c* axes $\sigma=0.2°$ and randomly oriented *a* axes. The HOPG sample is cleaved in air. No further *in situ* treatment is necessary, because the extremely low gas adsorption efficiency guarantees a clean surface for ample time. The sample is mounted on a manipulator between the pole caps of an electromagnet and can be cooled to liquid nitrogen temperatures. The temperature is monitored using a copper-constantan thermocouple. Ru (purity 99.95%) is evaporated using electron beam evaporation (evaporation rate: 0.03 ML/min). The film thickness is monitored by using a quartz microbalance. AES is performed using a cylindrical mirror analyzer (CMA). During the magnetic measurements, the residual gas pressure amounted to $\approx3\times10^{-10}$ mbar; during the evaporation, it increased to $\approx8\times10^{-10}$ mbar.

The growth of Ru on C(0001) was studied by measuring peak-to-peak heights of differentiated Auger lines versus deposition time. In Fig. 1, dN/dE vs E Auger spectra of the clean and the Ru covered graphite surface are given. The graphite spectrum shows one peak at 272 eV. The Ru spectrum is more complicated with nearly symmetric peaks at

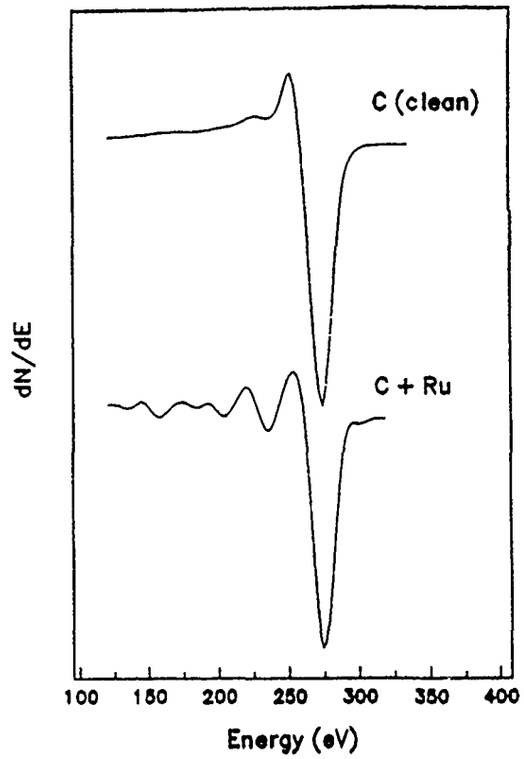

FIG. 1. Differentiated Auger spectra for the clean and Ru covered C(0001) surface.

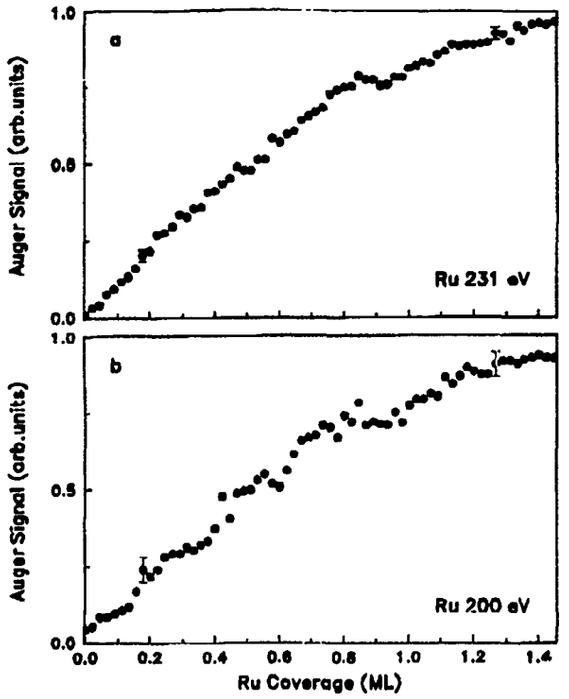

FIG. 2. Auger peak-to-peak height vs Ru coverage on C(0001) of the (a) Ru 231 eV and (b) Ru 200 eV line. The coverage is referred to the atomic density of the bulk Ru(0001) plane.

273, 231, 200, and 160 eV.[20] The most prominent Ru peak at 273 eV overlaps with the graphite peak, therefore, we used the smaller Ru peaks as adsorbate Auger signal. A quantitative analysis of the substrate Auger signal was already the subject of several studies.[21]

In Fig. 2(a), the peak-to-peak heights of the Ru 231 eV Auger line is shown. The x-axis scale is converted from deposition time to coverage, using the quartz reading, calibrated by a geometrical factor. We refer the coverage to the atomic density of the (0001) plane in bulk Ru and assume the sticking coefficient to be one. The Auger signal increases linearly up to a coverage of nearly 1 ML, where a breakpoint occurs. For higher coverages, the Auger signal increases further and reveals a smaller slope. These results are confirmed by the Ru 200 eV Auger signal [Fig. 2(b)], although the data points show a little more scattering due to the smaller signal.

The linear increase of the Auger signal shows that Ru grows laterally until the graphite surface is homogeneously covered, and the first Ru ML completed. From our data, it is unlikely that Ru continues to grow in a layer-by-layer mode (Frank–van der Merwe). Our findings point to a Stranski–Krastanov growth mode (three-dimensional islands on top of a ML) for the following reasons: The (average) slope ratio between the data beyond and below the breakpoint is 0.42, which is smaller than the value 0.70 calculated for layer-by-layer growth using an inelastic mean free path $\lambda=0.82$ nm for 231 eV electrons and a thickness $d=0.214$ nm for one Ru layer.

In Fig. 3(a), we show the peak-to-peak heights of the composite C 272 eV+Ru 273 eV Auger signal. The signal decreases linearly until a sharp breakpoint occurs at nearly 1 ML. These findings are even clearer, when we take only the graphite contribution of the composite Auger line [Fig. 3(b)]. The substrate signal then shows the qualitative behavior as expected for lateral growth and confirms the findings from the adsorbate signal.

To summarize, we find that Ru grows laterally on the graphite surface until the first ML is completed. Beyond the first ML, the data indicate that Ru begins to form three-dimensional islands, i.e . Ru seems to grow on C(0001) in a Stranski–Krastanov mode. These findings are corroborated by our scanning tunneling microscopy measurements, showing in the range of submonolayer coverage lateral growth of Ru.[17]

Next, we report on the magnetic properties of Ru ML films. Initially, we measured the ESP as function of small applied fields up two 2 Oe which were reversed in order to calibrate for instrumental asymmetries. From the magnetization curves, we find that saturation is reached at field strengths of a few tenths of an Oe.

For more refined checks on the effect of instrumental asymmetries on the measured ESP, we used the nonmagnetic surface of the graphite crystal and performed the same procedure as for the Ru films. We find that the small applied fields have no effect on the measured ESP.

The results of the SPSEE experiment are shown in Fig.

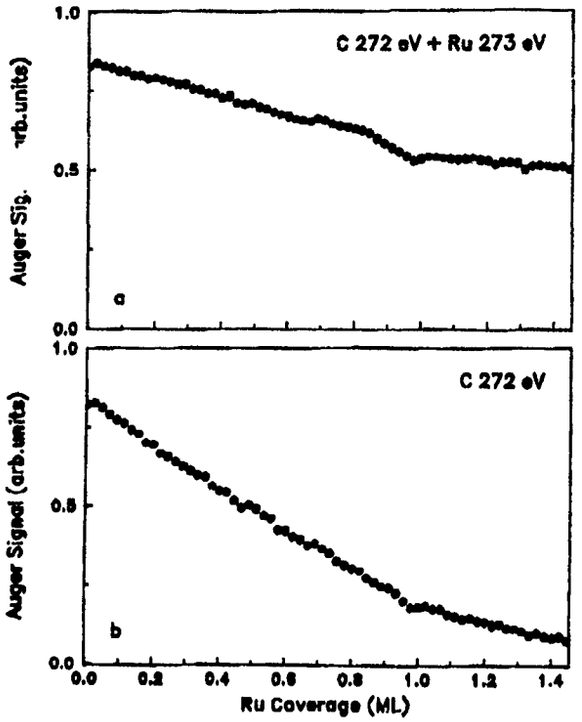

FIG. 3. Auger peak-to-peak height vs Ru coverage on C(0001) of (a) the composite C 272 eV+Ru 273 eV line, and (b) the C 272 eV line only. (b) is obtained from the composite signal in (a) by subtracting the Ru 231 eV Auger intensity multiplied by a factor of 2.35.[13] The coverage is referred to the atomic density of the bulk Ru(0001) plane. Statistical errors are contained withint the symbol size.
